- The overall incidence of endocarditis decreased with the advent of antibiotics. However, a recent increase in frequency has been associated with improved survival of patients with congenital heart disease and the more widespread and often prolonged use of central vascular catheters, especially in premature infants.

RISK FACTORS

- Preexisting heart disease (congenital or acquired)
- Prior history of endocarditis
- Cardiac surgery
- Intracardiac pacemakers and implantable cardioverter-defibrillators
- Prosthetic valves or conduits
- Indwelling catheters/IV drug use

GENERAL PREVENTION

- Dental hygiene
- Minimal use of central lines
- Correction of the cardiovascular anomaly by surgery or interventional catheterization techniques
- Subacute bacterial endocarditis (SBE) prophylaxis regimes as per the 2007 American Heart Association (AHA) recommendations. Give as a single dose 30–60 minutes prior to procedure:

- Oral: amoxicillin (50 mg/kg, max 2.0 g)
- IV or IM: ampicillin (50 mg/kg, max 2.0 g) or ceftriaxone/cefazolin (50 mg/kg, max 1.0 g)
- Oral for penicillin-allergic patients: cephalexin, if no history of urticaria, angioedema, or anaphylaxis (50 mg/kg, max 2.0 g); clindamycin (20 mg/kg PO/IV, max 600 mg); or azithromycin/clarithromycin (15 mg/kg PO, max 500 mg)
- IV or IM for penicillin-allergic patients: cefazolin, ceftriaxone, or clindamycin (doses as above)
- SBE prophylaxis is recommended by the AHA only for the following cardiac conditions:
 - Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
 - Prior history of IE
 - Unrepaired cyanotic congenital heart disease, including palliative shunts and conduits
 - Congenital heart defect repaired with prosthetic material or device for the first 6 months after the procedure
 - Repaired congenital heart disease with residual defect near the site of prosthetic patch or device
 - Cardiac transplantation recipients with cardiac valvulopathy
- SBE prophylaxis is recommended only for the following procedures:
 - Dental procedures involving manipulation of the gingival or periapical region of teeth or perforation of the oral mucosa
 - Invasive respiratory tract procedures involving incision or biopsy, such as tonsillectomy/adenoidectomy or abscess drainage
 - Surgery involving prosthetic intravascular or intracardiac material, including heart valves
- Procedures that do not require SBE prophylaxis:
 - Placement of removable prosthodontic or orthodontic appliances
 - Bleeding from trauma to the lips or oral mucosa or shedding of deciduous teeth
 - Routine anesthetic injections through noninfected oral mucosa tissues
 - Bronchoscopy without a biopsy

- Gastrointestinal (GI) or genitourinary procedures: Prophylaxis solely to prevent IE is not recommended.

PATHOPHYSIOLOGY

- IE is primarily seen in patients with preexisting heart disease (congenital or acquired) who develop bacteremia with organisms that are likely to cause infection.
- IV drug abusers and patients with indwelling central venous catheters may develop endocarditis even in the absence of prior heart disease.
- Local turbulence secondary to the cardiovascular abnormality is thought to result in damage of the endocardial surface. The development of a fibrin and platelet network occurs in which bacteria may then become entrapped, causing infection.
- Bacteremia may be a complication of focal infection (e.g., pneumonia, cellulitis, or urinary tract infection) or may be associated with various dental and surgical procedures. Bacteremia, however, also occurs spontaneously with usual activities, such as chewing, flossing, and brushing teeth.
- Peripheral manifestations in chronic endocarditis are mediated by immune complex reactions.

ETIOLOGY

- Gram-positive cocci account for 90% of culture-positive endocarditis. There has been a recent shift in the microbial etiology, corresponding with a more acute presentation:
 - *Streptococcus viridans* and *Staphylococcus aureus* are the most common agents.
 - Other organisms that can cause endocarditis are coagulase-negative staphylococci, β -hemolytic streptococci, enterococci, the HACEK group (*Haemophilus aphrophilus*, *Haemophilus paraphrophilus*, *Haemophilus parainfluenzae*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella* species), *Candida* species, *Aspergillus* species, *Pseudomonas* species, pneumococci, and *Neisseria* species.
- <20% of endocarditis cases are reported as culture negative.

DIAGNOSIS

- The Modified Duke criteria define diagnostic categories (definite endocarditis, possible endocarditis, and rejected cases) based on combinations of major and minor criteria.
- Criteria:
 - Major: organism specific for IE demonstrated by positive blood culture or histologic specimen and definitive echocardiographic data
 - Minor: predisposing heart disease, fever, vascular/immunologic phenomena, or microbiologic evidence not within major criteria
- Definitive endocarditis requires 2 major, or 1 major plus 3 minor, or 5 minor criteria.
- Several studies have confirmed the high sensitivity and specificity of these criteria.

HISTORY

- Fever
- Malaise
- Anorexia
- Weight loss
- Heart failure symptoms
- Arthralgia/myalgia
- Neurologic symptoms
- GI symptoms
- Chest pain
- Occasionally, a recent infection, dental visit, or surgical procedure can be identified.
- Acute endocarditis is associated with a more rapidly progressive, fulminant course.

PHYSICAL EXAM

- General
 - Fever (usually low grade with α -hemolytic streptococci and high grade with *S. aureus*)
 - Petechiae (occurring in 1/3 of cases)
- Embolic or immunologic phenomena

- Renal: glomerulonephritis, infarct
- Splinter hemorrhages
- Retinal hemorrhages (Roth spots)
- Osler nodes (painful)
- Janeway lesions (painless)
- Splenomegaly (occurring in about 50% of cases)
- Arthralgia/arthritis
- Neurologic: cerebral infarction, embolism, or hemorrhage. Mycotic aneurysms may also occur.
- Cardiac/valvulitis
 - New or change in heart murmur
 - Signs of congestive heart failure (CHF)
- Newborns with IE may present with feeding difficulty, respiratory distress, tachycardia, hypotension, seizures, apnea, and septic emboli.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Blood cultures
 - Most important diagnostic test for endocarditis
 - Positive in 85–90% of reported cases
 - Obtain 3–5 sets from different sites during the first 24 hours of suspected endocarditis.
 - Collect the largest volume that is clinically reasonable.
 - The bacteremia of endocarditis is continuous; therefore, it is not necessary to wait to obtain the blood cultures during a fever spike.
- Nonspecific data
 - Elevated erythrocyte sedimentation rate (ESR) (80%) and C-reactive protein
 - Anemia (44%)
 - Positive rheumatoid factor (38%)
 - Hematuria (35%) and red cell casts
 - Leukocytosis
 - Decreased complement

Imaging

- Echocardiography, transthoracic

- Valuable noninvasive technique in the identification of vegetations
- Specificity is 98%, but sensitivity is <60%, so a negative echocardiogram does not rule out endocarditis.
- Also invaluable for follow-up, including evaluation for potential cardiac complications
- Echocardiography, transesophageal
 - Especially in older or obese patients, provides better visualization of smaller vegetations, with sensitivity of 76–100%
 - Recommended in patients with an inconclusive transthoracic study but a high index of suspicion for endocarditis

ALERT

- The absence of vegetation(s) by echocardiography does not rule out endocarditis.
- In patients with a prosthetic valve, echocardiography is not always helpful as there is frequently artifact from the prosthetic valve. Abnormal movements of the valve leaflets may suggest a vegetation.
- The ESR may remain elevated for some time, even after cessation of bacteremia.

Diagnostic Procedures/Other

Electrocardiogram: New-onset abnormalities such as atrioventricular block (even 1st-degree) may represent conduction system and myocardial involvement from invasive disease.

DIFFERENTIAL DIAGNOSIS

- Other infections
- Acute rheumatic fever
- Malignancy
- Connective tissue disorders

TREATMENT

MEDICATION

Antibiotics

- Prolonged IV therapy (at least 4 weeks) is needed.

- Choice of antibiotic(s) and duration of treatment depend on the infecting organism, sensitivity pattern, and patient risk factors.
- For staphylococcal or fungal endocarditis, IV therapy is given for at least 6–8 weeks.

SURGERY/OTHER PROCEDURES

- Severe/worsening CHF
- Valvular disease with unstable hemodynamics
- Failing medical therapy
- Large (>10 mm), mobile vegetations
- ≥ 2 major embolic events
- Fungal endocarditis
- Abscess formation/periannular extension
- Prosthetic valve endocarditis

INPATIENT CONSIDERATIONS

Initial Stabilization

- Rest
- Antipyretics
- Optimal nutrition and hydration
- Careful dental hygiene

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Obtain repeat blood cultures after a few days of antibiotic or antifungal therapy to ensure the eradication of bacteria.
- Obtain blood cultures again 2 months after completion of a full course of antibiotic therapy.

PROGNOSIS

If diagnosed in a timely fashion and appropriate therapy is instituted, prognosis is relatively good for bacterial endocarditis. *S. aureus* and fungal endocarditis are associated with higher morbidity and mortality.

COMPLICATIONS

Despite improvements in diagnosis and treatment, IE continues to be a disease with significant morbidity and mortality (~10–20%):

- Cardiac: valve destruction and perforation leading to incompetence, abscess and fistula formation, heart failure, or conduction abnormalities
- Embolic events (22–50%) may occur to multiple organ systems (central nervous system, bowel, coronary arteries, kidneys, spleen, skin, lungs).

- I33.0 Acute and subacute infective endocarditis

FAQ

- Q: I forgot to give my child antibiotics prior to the procedure. Should I give him a dose afterward?
- A: The dosage may be administered up to 2 hours after the procedure.
- Q: SBE prophylaxis is recommended for my child, but she already is on long-term antibiotic therapy with that recommended antibiotic. Should she use an additional antibiotic or increase her current dose for the procedure?

- A: An antibiotic from a different class should be selected.
- Q: My child has a congenital heart defect. Does he/she require SBE prophylaxis?
- A: The answer depends on the type of the congenital heart defect and the status of any needed intervention. The child's physician should be contacted regarding the need for prophylaxis.

ENURESIS

Eugene R. Hershorin • Marissa Janel DeFreitas

BASICS

DESCRIPTION

- Involuntary, urinary incontinence after age of expected bladder control; term generally reserved for children ≥ 5 years of age. May be
 - Primary: has never been dry for 6 months (80%)
 - Secondary: patient previously dry for 6 months or longer
- Classified as
 - Monosymptomatic nocturnal enuresis (MNE)
 - Nonmonosymptomatic nocturnal enuresis (NMNE) if there is evidence of lower urinary tract malfunction (e.g., delayed voiding, frequency, urgency, holding maneuvers)

EPIDEMIOLOGY

- Male > female (3:1)
- Prevalence of 10–15% in children at age 5 years, 7–15% at 7 years, 5% at 10 years, and 0.5–1% in teenagers and adults.

Genetics

- 60–70% have a positive family history of enuresis.
- Risk of severe enuresis is greater with maternal enuresis history compared with paternal history (odds ratio 3.6 vs. 1.8).
- Risk is twice as high in monozygotic compared with dizygotic twins.
- Autosomal dominant pattern seen in 50%, whereas 30% of cases are sporadic.
- Several loci on chromosomes 13q, 12q, and 22q associated with a nocturnal enuresis phenotype, but no candidate genes have been identified.

RISK FACTORS

- Constipation
- Lower urinary tract dysfunction
- Sleep disorders

- Neuropsychiatric disorders

ETIOLOGY

- Primary nocturnal enuresis: the interplay of one or more of the following:
 - Nocturnal polyuria
 - Decreased functional bladder volume
 - Increased arousal threshold when asleep
- Daytime incontinence and enuresis, day and night
 - As above. More concerning for underlying urologic and neurologic disorder
 - Urinary reflux into vagina with seepage after conclusion of voiding
 - Insertion of ureter into urethra or vagina
 - Stress incontinence with increased abdominal pressure (laughing, coughing, increased intravesicular pressure)
- Secondary enuresis
 - Any condition causing polyuria
 - Urinary tract infection (UTI)
 - Encopresis
 - Emotional stress or trauma including physical and sexual abuse, parental divorce, depression, new sibling, household moving, new school

COMMONLY ASSOCIATED CONDITIONS

Neuropsychiatric comorbidities: ADHD, anxiety, and oppositional behavior are more commonly associated with secondary nocturnal enuresis.

DIAGNOSIS

HISTORY

- Onset
 - Nocturnal versus diurnal
 - Dry period (even if only weeks)
 - Concomitant recent onset of polydipsia (sometimes accompanied by candidal infection) suggests new-onset diabetes.

- Frequency
 - A frequency–volume chart provides information on daily fluid intake and volumes and timing of voids; identifies subtle lower urinary tract symptoms and can aid in treatment approach
- Pattern of urination
 - Constantly wet pants (dribbling)
 - Frequent small amounts of urine
 - Presence of weak urinary stream
 - Dysuria
 - Frequency
 - Hesitancy
 - Urine holding maneuvers (e.g., pressing the heel into perineum)
 - Nocturia
- Past medical history
 - Obstipation/constipation/fecal incontinence (encopresis)
 - History of UTI
 - Behavioral/developmental history
 - Toilet training history
 - Medications
 - Neurologic symptoms
 - Other medical problems
- Family history
 - 1 parent or both parents
- Social history
 - For whom does this pose problem—parent or child?
 - Effect on child
 - Ability to sleep away from home without embarrassment
 - Teasing at school
 - Emotional effects
- Social changes
 - Divorce
 - New significant other for parent
 - New sibling
 - Household move
 - New school

PHYSICAL EXAM

- Vital signs
- Growth parameters and pattern
- Neurologic exam
 - Gait, tone, sensory, motor, deep tendon reflexes, cremasteric reflex
- Funduscopy: to rule out raised intracranial pressure
- Abdominal exam: to rule out masses, especially renal mass, fecal impaction, bladder distention
- Genitalia: rule out adhesions, vulvovaginitis, balanitis, stenosis, foreign bodies
- Urinary stream
- Rectal exam: tone, perianal sensation, anal wink
- Spine: bony defects, cutaneous signs of underlying spinal defects

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Urinalysis
 - Specific gravity (first morning void)
 - Glucose
 - Protein
 - Blood
- Urine culture: usually not necessary if no symptoms are present

Imaging

- Rarely necessary in primary enuresis
- Perform if suggestion of anatomic or functional abnormality of genitourinary tract
- Ultrasound least invasive modality
- Renal/bladder ultrasound with pre/post void bladder images to assess residual urine volume and look at bladder contour
- Noninvasive uroflow with pelvic floor electromyography—done by pediatric urologists

ALERT

Laboratory evaluation rarely yields a specific diagnosis. Balance risks and costs with unlikelihood of yield. Evaluation should generally not involve more than urinalysis.

DIFFERENTIAL DIAGNOSIS

- UTI/urethritis
- Obstipation/constipation
- Water intoxication
- Type 1 or type 2 diabetes
- Diabetes insipidus
- Sickle cell disease or trait
- Nephritis/nephrosis
- Anatomic abnormalities of the urinary tract
- Sleep disorders
- Depression
- Anxiety
- Behavioral disorders
- Medications (sedatives, soporifics, antihistamines, diuretics, caffeine, methylxanthines)
- Spinal cord disease
 - Cognitive disorders
 - Seizure disorders
- Legitimate safety issues in going to bathroom alone
- Substandard living conditions (cold bathrooms, poor facilities)

TREATMENT

GENERAL MEASURES

- If the problem is affecting only the parents and child is not affected, the treatment should be education and support for the parents.
- Avoid all negative interventions.
- Minimize fluid intake during evening.
 - Success rate: low
- Encourage child to void regularly during the day and immediately prior to retiring to bed.
- Alarm therapy
 - Most effective in motivated patient and family
 - Improves arousal and nocturnal bladder function as a reservoir through conditioning

- Use nightly for at least 2–3 months until 14 consecutive dry nights are achieved.
- “Overlearning” (after dryness is achieved, have child drink modest amount of water 1 hour before bedtime) reduces risk of relapse if dryness is maintained for 1 month on this regimen.
- High relapse rate; 2nd remission very frequent with reintroduction of alarm system; 2nd relapse rare

MEDICATION

- Avoid medication use before age 6–8 years.
- Desmopressin (DDAVP)
 - Dose not based on age or weight.
 - Standard dose 0.2–0.4 mg PO given 1 hour before bedtime
 - Use oral formulation only (nasal formulation is associated with increased risk of hyponatremia and seizures).
 - Caution against excessive fluid intake
 - Can be used intermittently or continuously
 - Drug holidays are advised to assess for resolution of symptoms.
- Anticholinergics (e.g., oxybutynin)
 - Often used in combination with DDAVP
 - Usual dose: 5 mg given at bedtime
 - Exclude postvoid residual bladder volume.
 - Adverse effects: constipation, decreases saliva (hence, stress proper dental hygiene), hallucinations/agitation
- Imipramine
 - Tricyclic antidepressant
 - 80% effective
 - No longer 1st- or 2nd-line choice for benign condition because of risk of QTc prolongation and controversial risk of sudden cardiac death and risk of ingestion by siblings.

ADDITIONAL TREATMENT

- Urotherapy: aims towards normalizing bladder emptying and storage by teaching relaxed voiding techniques (e.g., biofeedback programs)
- Cognitive behavioral interventions
 - Formal programs developed and used by pediatric psychologists:

high rate of success; involve “overcorrection techniques”—frequent practice and rewards for voiding procedures along with enuresis alarm

- Positive reinforcement for dry nights
- Use of praise, stickers, token economies
- Hypnotism
 - Appears to work by increasing subconscious awareness of bladder pressure during sleep, allowing increased awareness during sleep of intravesicular pressure

INPATIENT CONSIDERATIONS

Initial Stabilization

- Specific therapy to address specific anatomic, infectious, or functional genitourinary problems
- Address constipation and lower urinary tract dysfunction, as both may lead to treatment failure, whereas addressing these problems may result in spontaneous enuresis resolution.

ALERT

Decision to treat is a balance of the effect on the child of nontreatment (social, emotional) with the potential side effects of medication.

ONGOING CARE

PROGNOSIS

- 99% of cases resolve without treatment.
- Spontaneous resolution is ~15% per year after age 5 years.

COMPLICATIONS

- Physical
 - Vulvovaginitis
 - Diaper dermatitis
- Emotional
 - Embarrassment
 - Poor self-esteem
 - Reluctance to sleep out with peers or nonimmediate family

CODES

ICD10

- R32 Unspecified urinary incontinence
- N39.44 Nocturnal enuresis

FAQ

- Q: Do the medications cure the enuresis?
- A: None of the medications cure the problem. DDAVP increases reabsorption of water in the kidney, resulting in decreased bladder volumes. Tricyclic antidepressants cause urinary retention by the noradrenergic effects on bladder contraction and detrusor relaxation. Oxybutynin decreases detrusor irritability, resulting in larger bladder capacity before emptying. The medications result in nonemptying of the bladder during sleep but do not affect the underlying cause. Any

resolution that occurs after cessation of medication treatment is probably from the natural resolution of the problem with age.

- Q: Isn't it important to treat the enuresis when the parents bring it up as a problem?
- A: Developmental resolution of nocturnal enuresis occurs at a range of ages, and in almost all cases, the enuresis resolves spontaneously. It is important to elicit for whom the enuresis is a problem. If the child is not affected by the enuresis, and it is only the parents who desire a cure, the important intervention is to educate them on the natural history of the problem and to let them know about the available interventions and their success rates for when the child desires a cure.
- Q: Are there any other interventions available for use only on sleep-out nights?
- A: One helpful tip is to allow the child to take a sleeping bag with him or her on sleep-outs. Place a pull-up inside the sleeping bag. When the child gets into the sleeping bag, he or she can change into the pull-up without anyone knowing. In the morning, the child puts his or her underwear back on, leaving the damp pull-up in the sleeping bag; the parent can take it out when the child gets home.

EOSINOPHILIC ESOPHAGITIS

Elizabeth H. Yen • Hemant P. Sharma

BASICS

DESCRIPTION

- Eosinophilic esophagitis (EoE) is a chronic immune-mediated esophageal disease characterized clinically by variable symptoms of esophageal dysfunction and pathologically by localized eosinophilic inflammation.
- The diagnosis is established in symptomatic patients who have the following:
 - At least 15 eosinophils/HPF isolated to the esophagus on endoscopic biopsies
 - Persistent eosinophilic infiltrate in esophageal biopsies after a trial of proton pump inhibitor (PPI) therapy

EPIDEMIOLOGY

- Incidence rates range from 0.7 to 10 per 100,000 person-years, and prevalence from 0.2 to 43 per 100,000.
- 3:1 male-to-female ratio
- Peaks of onset in childhood and 3rd–4th decade

PATHOPHYSIOLOGY

- The exact pathophysiology of EoE is unknown but likely involves an immune response to environmental antigens in genetically predisposed individuals.
- Environmental factors (food and possibly aeroallergens) trigger inflammatory response mediated by type 2 T-helper (Th2) cells.
- Genetic polymorphisms which predispose to EoE include eotaxin-3, thymic stromal lymphopoietin, and filaggrin.

DIAGNOSIS

ALERT

Any patient who presents with esophageal food impaction should be evaluated for EoE. More than half of patients with food impaction are ultimately diagnosed with EoE.

HISTORY

Symptoms of EoE vary with age:

- In younger children, symptoms may include feeding difficulty or refusal (median age 2 years), vomiting (median age 8 years), and abdominal pain (median age 12 years).
 - Assess for:
 - Failure to thrive (poor weight gain, weight loss)
 - Feeding difficulties (not advancing past liquids, refusal of previously tolerated solids)
 - Gastroesophageal reflux (arching, irritability/fussiness)
 - Vomiting
- In adolescents and adults, symptoms include dysphagia, food impaction, refractory heartburn, epigastric abdominal pain, chest pain.
- Questions to assess dysphagia:
 - Sensation of difficulty swallowing or food getting stuck?
 - Is the child a slow eater? Does the child overchew or overcut food? Does the child avoid specific foods?
 - Personal history of esophageal food impaction?
- EoE is often associated with atopic disease (asthma, allergic rhinitis, atopic dermatitis, food allergy). Ask about the following:
 - Personal or family history of atopic disease?
 - Family history of EoE, dysphagia, refractory GERD, esophageal food impactions or dilations?
- No relief of symptoms after acid-blocking medication (minimum 8 weeks)

PHYSICAL EXAM

- Typically normal
- Growth failure (rare but may occur if feeding dysfunction or significantly decreased appetite)
- Signs of comorbid atopic disease: allergic shiners, wheezing,

eczematous skin lesions

DIAGNOSTIC TESTS & INTERPRETATION

Labs

- Blood tests:
 - No diagnostic serum markers for EoE
 - Peripheral eosinophilia observed in <50% of patients
 - Elevated serum IgE present in 50–60%.
- Food allergy testing
 - Performed after biopsies confirm EoE
 - In vitro–specific IgE testing: serum testing for food-specific IgE antibodies; no studies of predictive value, limited or no role
 - Skin prick testing (SPT): assesses for IgE-mediated reactions; good specificity (>82%) for identifying EoE triggers, but poor sensitivity
 - Atopy patch testing (APT): assesses for non–IgE-mediated reactions; application of fresh or rehydrated food in occlusive chambers for 48 hours on back; similar specificity as SPT but better sensitivity
 - Combination of SPT and APT identified causative food antigens in 70% of patients at one center. More studies, especially prospective randomized controlled studies, are needed.
- Aeroallergen testing
 - SPT may identify aeroallergen triggers of EoE and inform timing of follow-up endoscopies relative to pollen seasons.

Imaging

- Upper GI series fluoroscopy
 - Provides complementary information to an upper endoscopy
 - Evaluates esophageal anatomy for strictures, hiatal hernia, Schatzki ring (lower esophageal ring), and achalasia
 - Is not sufficient to make a diagnosis of EoE
- Use upper GI series to evaluate worsening dysphagia for development of stricture that may require dilation.

Diagnostic Procedures/Other

- Esophagogastroduodenoscopy (EGD)
 - Required for diagnosis of EoE

- Used to evaluate appearance of esophagus and obtain biopsies for pathology
- As some forms of EoE are responsive to high doses of PPI, the diagnostic endoscopy is usually performed after an 8-week trial of a twice daily PPI.
- 4–6 esophageal biopsies are obtained by cold forceps. The distal and proximal esophagus should be sampled separately. A pathologist experienced with the diagnosis of EoE should examine the biopsies for the presence of ≥ 15 eosinophils/HPF. Corroborating features include surface layering of eosinophils, eosinophilic microabscesses, extracellular eosinophilic granules, basal zone hyperplasia, dilated intercellular spaces, and lamina propria fibrosis.
- Gastric and duodenal biopsies should also be obtained to rule out other causes of esophageal eosinophilia. In EoE, there is no associated gastric or duodenal eosinophilic infiltrate.
- pH/impedance probe
 - Use in diagnosis and management of EoE is unclear.
 - Some patients clearly suffer from both pathologic reflux and EoE. pH/impedance monitoring may clarify who should be treated with PPI.
- Endoscopic ultrasound
 - Findings include thickened mucosal and muscular layer.

DIFFERENTIAL DIAGNOSIS

- GERD
- Crohn disease
- Eosinophilic gastroenteritis
- Parasitic infection
- Connective tissue disease
- Drug allergy
- Hypereosinophilic syndrome
- Autoimmune enteropathy
- Candida esophagitis
- Viral esophagitis (HSV, CMV)
- Achalasia
- Peptic stricture

TREATMENT

MEDICATION

- Proton pump inhibitors (PPIs)
 - Part of the diagnostic criteria for EoE is that the esophageal eosinophilia persists after treatment with high-dose PPI (e.g., omeprazole, pantoprazole, esomeprazole, lansoprazole, dexlansoprazole, or rabeprazole). If the eosinophilia persists after an 8-week course of PPI, then the diagnosis of EoE is applied.
 - Useful as adjunctive therapy to treat associated reflux symptoms
 - Insufficient to treat EoE
- Non-systematic corticosteroids
 - Description
 - Swallowed topical steroids (fluticasone propionate and budesonide) are an alternative to dietary therapy.
 - Discontinuation is associated with recurrence of disease. They are safe for short-term administration.
 - Local fungal infections are known complications.
 - Data on long-term safety are lacking.
 - Fluticasone propionate
 - Use metered-dose inhaler.
 - Dose is sprayed into mouth and swallowed.
 - Initial doses:
 - Adults: 440–880 mcg twice daily
 - Children: 88–440 mcg 2–4 times daily
 - Avoid eating or drinking for 30 minutes after each dose.
 - Budesonide (viscous suspension)
 - Liquid budesonide inhaled solution ampules are mixed with sucralose/maltodextrin (e.g., Splenda, 5 packets per ampule) or other sweetener to form thick slurry that coats the esophagus when ingested (see [Liacouras CA, Furuta GT, Hirano I, et al, 2011](#) in “Additional Reading”).
 - Initial doses:
 - Adults: 2 mg daily
 - Children (<10 years): 1 mg daily

- Avoid eating or drinking for a minimum of 30 minutes after dose.
 - Bedtime dosing is optimal.
- Systemic corticosteroids
 - Are effective but should only be used in cases of severe dysphagia and weight loss affecting growth
 - Long-term use should be avoided.
 - Prednisone or methylprednisolone: 1–2 mg/kg/24 h (max 60 mg daily)

Dietary Therapy

- Elemental diet
 - Use amino acid–based formula for 100% of caloric requirements.
 - Highest efficacy for clearing eosinophilic inflammation
 - Reintroduction of foods into diet should be stepwise and guided by allergist.
- Six food elimination diet (SFED)
 - Avoid most common food allergens: (1) milk, (2) soy, (3) wheat, (4) egg, (5) peanuts and tree nuts, (6) fish and shellfish.
 - Efficacy not as high as with elemental diet but comparable to topical swallowed steroids
- Targeted elimination diet
 - Use results from multimodal allergy testing to guide food eliminations from diet.
 - Efficacy comparable to SFED

When reintroducing foods into the diet following one of the above dietary therapies, caution should be taken to do so stepwise with reevaluation of esophageal biopsies after each food reintroduction to determine the actual dietary trigger that should continue to be avoided.

ONGOING CARE

COMPLICATIONS

- Failure to thrive
- Esophageal strictures
- Small-caliber esophagus

- Esophageal perforation
- Esophageal fungal or viral superinfection

ENDOSCOPIC THERAPY

- Dilation of esophageal strictures
 - Useful in alleviating dysphagia
 - Does not address underlying problem
 - A trial of medical or dietary therapy is advisable prior to dilation unless a high-grade stricture is present.
 - Complications include chest pain (5%) and esophageal rupture (<1–5%).
- Removal of esophageal food impaction
 - Should be performed within 24 hours of food impaction to decrease risk of esophageal rupture

K20.0 Eosinophilic esophagitis

FAQ

- Q: What are the goals of EoE treatment?
- A: There is no agreed upon definition of EoE remission. Treatment goals include symptom reduction, decrease in esophageal eosinophilia to <15 eosinophils/HPF, and improvement in histologic and visual endoscopic changes. However, several studies show discordance between symptoms and histologic findings.
- Q: Do patients who have symptom response but persistent esophageal eosinophilia require further treatment?
- A: There is insufficient natural history data to answer this question. The concern is that untreated esophageal eosinophilia may progress to dysphagia, strictures, and esophageal fibrosis, but predictors of this progression are not well-defined.
- Q: Why might the SFED and targeted elimination diet have similar efficacy?
- A: The targeted elimination diet is guided by allergy testing (SPT and APT) results, but data on their diagnostic use are poorly reproducible. For certain foods (milk, wheat), they have poor reliability. Also, the APT process is not standardized and interpretation may be subjective and variable. More prospective controlled trials are needed to evaluate the diagnostic use of these tests.
- Q: What is the best 1st-line therapy for EoE?
- A: The approach to each patient is individualized, as there is no agreement on the single best 1st-line therapy for EoE. Younger children may be more amenable to dietary restrictions. Children with failure to thrive benefit from elemental formula either as monotherapy, or as a nutritional supplement in conjunction with either an elimination diet or topical corticosteroids. Dietary compliance in teenagers makes topical corticosteroids a popular option.

EPIDIDYMITIS

Melissa T. Sanford • Hillary L. Copp

BASICS

DESCRIPTION

Epididymitis is an acute inflammation of the epididymis that can cause severe scrotal pain. It is important to differentiate epididymitis from testicular torsion or testicular appendage torsion.

EPIDEMIOLOGY

- Epididymitis is the most common cause of acute scrotum, approximately 37–65% of cases. The incidence ranges between 0.8 and 1.2 cases/1,000 persons per year.
- There is a bimodal distribution with a peak in incidence in infants younger than 1 year of age and peripubertal boys.

RISK FACTORS

Urologic manipulation (cystoscopy, intermittent self-catheterization, surgery of the urethra)

PATHOPHYSIOLOGY

- The majority of epididymitis is idiopathic (73%).
- Viral epididymitis: 2nd most common cause
 - Urinalysis and culture are negative.
 - Often elevated titers of enterovirus, *Mycoplasma pneumoniae*, and adenoviruses
 - New research shows that some epididymitis might be due to postinfectious inflammation, as 50% of patients had respiratory symptoms within 1 month of presentation and presentations appear to peak in concert with rotavirus and enterovirus.
- Bacterial epididymitis: 2–6% of cases and is related to age
 - Due to ascending infection from the urethra or bladder, reflux of infected urine into the vas deferens, or hematogenous dissemination
 - Infants <1 year of age

- Typically due to genitourinary anomalies (73% vs. 21% in children >1 year of age)
- Abnormalities include meatal stenosis, neurogenic voiding dysfunction, urethral stenosis, posterior urethral valves, ectopic ureter.
- Typical bacteria include *Escherichia coli*, *Klebsiella*, and *Enterococcus*.
- Postpubertal sexually active boys may have infection with sexually transmitted diseases such as gonorrhea or chlamydia.
- Chemical epididymitis: due to reflux of sterile urine into the vas deferens or drugs (amiodarone)
- Posttraumatic

COMMONLY ASSOCIATED CONDITIONS

- Systemic serositis (familial Mediterranean fever, sarcoidosis, Kawasaki disease)
- Systemic vasculitis (Henoch-Schönlein purpura, polyarteritis nodosa)

DIAGNOSIS

HISTORY

- It is not always possible to distinguish between testicular torsion, testicular appendage torsion, and epididymitis based on history and physical exam.
- Duration of symptoms is longer than in testicular torsion, typically >12 hours.
- The majority of patients complain of scrotal pain (91–98%), scrotal swelling (83%), and scrotal erythema (74%).
- Patients who have bacterial epididymitis are more likely to have prior urologic history than patients without bacterial epididymitis (73% vs. 0%).
- 16–33% of patients have a fever, almost always in bacterial epididymitis

PHYSICAL EXAM

Inflamed, swollen scrotum with localized epididymal pain early in the

course that can spread to generalized testicular inflammation late in the course.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Urinalysis and urine culture are only positive in a minority of presentations (7% and 1–6% respectively), but they should be sent for all patients to help guide therapy if they are positive for bacterial epididymitis.
- WBC, CRP, and ESR are most elevated in systemic serositis or vasculitis.
- Any sexually active boy or boy with an unclear sexual history should have gonorrhea and chlamydial testing performed.

Imaging

ALERT

For acute scrotum, perform scrotal ultrasound with Doppler to differentiate between testicular torsion, testicular appendicular torsion, or epididymitis.

- Epididymitis typically appears as an enlarged epididymis with hypervascular flow and mixed echogenicity with reactive fluid.

DIFFERENTIAL DIAGNOSIS

- Testicular torsion
- Testicular appendage torsion
- Incarcerated inguinal hernia
- Hydrocele
- Systemic vasculitis
- Recent urologic surgery
- Idiopathic scrotal edema
- Testicular tumor
- Appendicitis
- Mumps orchitis

TREATMENT

GENERAL MEASURES

Given that the majority of acute epididymitis is nonbacterial, initial treatment should be supportive with analgesics, nonsteroidal anti-inflammatory drugs, bed rest, scrotal ice packs, and scrotal elevation.

MEDICATION

- Any children younger than 1 year of age or with pyuria should be empirically begun on antibiotics based on a local antibiogram.
- If a child has culture-proven bacterial epididymitis, they should be started on culture-sensitive antibiotics for a 2-week course.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Schedule for follow-up appointment in 2–4 weeks to ensure resolution of epididymitis.
- Recommend referral to pediatric urology.
- Children <1 year of age and any child with a positive urine culture should be evaluated with a renal bladder ultrasound to rule out genitourinary anomalies.

CODES

ICD10

- N45.1 Epididymitis
- N45.3 Epididymo-orchitis
- N45.4 Abscess of epididymis or testis

FAQ

- Q: What is the best empiric antibiotic?
- A: Empiric antibiotic choice should be based on local antibiogram. Typically reasonable choices include cephalexin, sulfamethoxazole and trimethoprim (Bactrim, Septra), or fluoroquinolone.
- Q: What should be done if the epididymitis has not resolved after 2 weeks?
- A: The child should have repeat urinalysis and urine culture to ensure he or she has not developed a resistant bacterial infection and repeat scrotal ultrasound to ensure he or she has not developed an abscess.
- Q: What is a Prehn sign?
- A: A Prehn sign (named after Douglas T. Prehn, MD) is a historical diagnostic maneuver that was previously used to help diagnose epididymitis. This maneuver is inferior to Doppler ultrasound. To conduct the Phren maneuver, elevate the testicles from below. The elevation of the testes should decrease pain if it is due to epididymitis; however, it does not theoretically relieve pain due to testicular torsion.

EPIGLOTTITIS

Laura H. Brower • Erin E. Shaughnessy

BASICS

DESCRIPTION

Acute life-threatening bacterial infection consisting of cellulitis and edema of the epiglottis, aryepiglottic folds, arytenoids, and hypopharynx, resulting in narrowing of the glottic opening and airway obstruction; also known as supraglottitis

EPIDEMIOLOGY

- Disease due to *Haemophilus influenzae* type B occurs most often between the ages of 1 and 7 years (overall range: infancy to adulthood).
- Epiglottitis and other invasive disease secondary to *H. influenzae* have been reduced by 99% since the introduction of the conjugate vaccines in 1987 (approved for use at 15 months) and 1990 (approved for use at 2, 4, and 6 months).
- Nontypeable *H. influenzae* now appears to be a more common cause of invasive disease than type B.
- Year-round occurrence
- All geographic areas
- Can have secondary cases in households or child care centers
- May be more frequent in children with sickle cell anemia, asplenia, immunoglobulin defects, or hematologic malignancies (e.g., leukemia)
- Increasing ratio of adult to pediatric cases

Incidence

- Incidence of pediatric epiglottitis due to any organism has declined in the postvaccine era (0.3–0.7/100,000 per year from 3.47 to 6.0/100,000 per year).
- Incidence in adults has remained steady (1–4/100,000 per year).

GENERAL PREVENTION

- Universal immunization with *H. influenzae* type B capsular

polysaccharide conjugate vaccines at 2 and 4 months (potential dose at 6 months, depending on the vaccine), with booster at 12–15 months.

- Isolation of hospitalized patient: Droplet precautions should be continued for at least 24 hours from the initiation of effective antimicrobial therapy.
- Control measures: prophylaxis for *H. influenzae* type B index case and susceptible children in household and child care setting and intimate contacts with the assistance of infection control
 - Rifampin: 20 mg/kg/day in single dose for 4 days

PATHOPHYSIOLOGY

Edema of the supraglottic structures (uvula, aryepiglottic folds, arytenoids, epiglottis, and vocal cords) that reduces the airway aperture. Respiratory arrest can be caused by airway obstruction, aspiration of oropharyngeal secretions, or mucous plugging.

ETIOLOGY

- *H. influenzae*, nontypeable and type B (type B accounted for up to 90% of cases prior to the introduction of Hib vaccine)
- *Streptococcus pneumoniae*
- *Streptococcus pyogenes* (group A β -hemolytic *Streptococcus*)
- *Staphylococcus aureus*
- Groups C and G β -hemolytic *Streptococcus*
- *Candida albicans* may be an etiologic agent in immunocompromised patients and those receiving prolonged corticosteroid treatment.
- *Pasteurella multocida* has been implicated in a few cases after exposure to nasopharyngeal secretions from a cat.
- Other rare isolates: *Moraxella catarrhalis*, *Klebsiella pneumoniae*, *Neisseria meningitidis*, *Pseudomonas* species
- Bacterial superinfection of viral infections including herpes simplex, parainfluenza, varicella, Epstein-Barr
- Varicella can cause primary infection or lead to a secondary infection, often with *S. pyogenes*.
- Noninfectious etiologies include thermal injuries, trauma, and caustic ingestions.

DIAGNOSIS

HISTORY

- Abrupt onset of high fever (39–40°C), sore throat, and dysphagia
- Drooling or difficulty handling secretions
- Very limited or no prodrome of mild upper respiratory tract infection (URI)
- “Hot potato” voice (muffled)
- Rapid onset of toxicity and respiratory distress
- Cough and hoarseness are late symptoms, if they occur at all.
- Time from onset of symptoms to presentation with progressive respiratory distress is generally <12 hours.
- Immunization against *H. influenzae* type B
- Child’s preferred position or way of sitting (i.e., sitting upright, leaning forward with chin hyperextended)

PHYSICAL EXAM

- Extremely anxious appearance
- Child prefers to remain sitting up.
- Child often leaning forward with chin hyperextended to maintain airway in a “tripod” position
- Slow and labored respiratory effort
- Drooling is seen as a manifestation of dysphagia.
- Inspiratory stridor, retractions, and late cyanosis
- Diagnosis can be suspected on history and observation of child’s appearance alone.
- Do not attempt to examine the throat if epiglottitis is a serious consideration.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Complete blood count: increased white blood cell count with left shift
- Cultures of blood and epiglottis (performed only in the operating room)

Imaging

Lateral neck radiography (should not be performed until airway team is in

place): characteristic “thumb sign” of edematous epiglottitis, with narrowing of the posterior airway and ballooning of the hypopharynx

Diagnostic Procedures/Other

Definitive diagnosis requires direct visualization of erythematous and edematous epiglottitis.

ALERT

- Ensure appropriate airway management prior to any other interventions, including intrusive examination components, radiographs, and blood collection.
- A radiograph is indicated only when the diagnosis is in doubt and should not delay airway management.

DIFFERENTIAL DIAGNOSIS

- Viral laryngotracheobronchitis (croup) with or without secondary bacterial tracheitis
- Severe parainfluenza or influenza infection
- Uvulitis
- Peritonsillar, retropharyngeal, or lingual abscess
- Foreign body aspiration in a child with URI
- URI, including croup, in a child with a congenital or acquired airway problem (e.g., premature infant with subglottic stenosis, laryngeal web, vascular ring, tracheal stenosis)
- Hereditary angioedema (deficiency of complement C1 esterase inhibitor) can present with edema of the airway including the epiglottis.
- Diphtheria: rare in the United States
- Laryngeal infections

TREATMENT

MEDICATION

First Line

- Empiric parenteral antibiotic coverage to include gram-positive cocci and *H. influenzae* (type B and nontypeable)

- Cephalosporins
 - Cefotaxime: 200–225 mg/kg/24 h (max 12 g/24 h) divided q4–6h
 - Ceftriaxone: 100 mg/kg/24 h (max 2 g/24 h) divided q12–24h
 - Cefuroxime: 100–200 mg/kg/24 h (max 9 g/24 h) divided q6–8h
- Ampicillin/sulbactam: ampicillin 200 mg/kg/24 h (max 8 g/24 h) IV divided q6h
- Serious penicillin/cephalosporin allergies
 - Levofloxacin (IV or PO): <5 years: 10 mg/kg/dose twice daily; >5 years: 10 mg/kg/dose once daily; max dose: 750 mg/24 h
- Duration of therapy: 7–10 days for all but staphylococcal disease (14–21 days).
- Switch may be made to oral medication after extubation and resumption of oral intake.
- Steroids are used commonly but without convincing evidence for their efficacy.

Second Line

- Discuss with infectious disease consultant.
- Chloramphenicol: 50–75 mg/kg/24 h (max 4 g/24 h) IV divided q6h; monitor levels
- Ampicillin: 200–400 mg/kg/24 h (max 12 g/24 h) IV divided q6h
- Penicillin: 200,000–300,000 U/kg/24 h (max 24 million U/24 h) IV divided q6h for streptococcal disease
- Oxacillin: 150–200 mg/kg/24 h (max 4 g/24 h) IV divided q4–6h for susceptible staphylococcal disease

ISSUES FOR REFERRAL

Airway should be secured by clinician skilled in airway management (e.g., otolaryngologist, anesthesiologist) prior to any attempt to transport a child with suspected epiglottitis.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Airway management: Maintain child upright, never supine. Personnel experienced in airway management should accompany the child at all times, including during transport and in radiology.
- Rapid assembly of a team, which should include an anesthesiologist, an

otolaryngologist, and a pediatrician, if possible

- Allow the child to assume his or her most comfortable position (usually in the parent's arms/lap).
- Oxygen by mask or blown by face
- Transport to operating room as soon as possible for anesthesia.
- Secure airway via direct laryngoscopy and bronchoscopy with intubation.
- Institute intravenous catheterization and blood collection and culturing of epiglottis only after the airway is secured.
- Perform emergent cricothyrotomy if obstruction occurs prior to controlled airway management.
- Use fluid resuscitation in cases of septic shock.

Admission Criteria

Admit all children with suspicion of epiglottitis for airway management.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Extubation is usually possible within 24–48 hours. Criteria include decreased erythema and edema of the epiglottis on direct inspection and development of an air leak around the endotracheal tube.
- Defervescence is usually prompt after initiation of appropriate antimicrobial therapy.

PROGNOSIS

Mortality is estimated to be 5–10%.

COMPLICATIONS

- Without prompt medical intervention: complete airway obstruction leading to respiratory arrest, hypoxia, and death
- Necrotizing cervical fasciitis (rarely)
- Therapeutic complications
 - Aspiration
 - Endotracheal tube dislodgment and extubation

- Tracheal erosion or irritation
- Pneumomediastinum
- Pneumothorax
- Pulmonary edema
- Complications of *H. influenzae* type B bacteremia:
 - Septic shock
 - Pneumonia
 - Cervical lymphadenopathy
 - Rarely, arthritis, meningitis, and pericarditis

CODES

ICD10

- J05.10 Acute epiglottitis without obstruction
- J05.11 Acute epiglottitis with obstruction

FAQ

- Q: What is the incidence of epiglottitis since the introduction of conjugate vaccines against H. influenzae type B?
- A: Because H. influenzae type B caused 90% of epiglottitis and the incidence of all invasive disease due to H. influenzae type B has decreased by 99% in children <5 years of age, it is estimated that the incidence of epiglottitis has been reduced by more than 90%.
- Q: Have there been reports of epiglottitis caused by H. influenzae type B after complete vaccination?
- A: Yes. Several cases due to H. influenzae type B have been reported in the United States and abroad after partial and complete vaccination. Therefore, even a history of having received a full vaccination series does not eliminate the possibility of Hib-associated epiglottitis. In one case series from 2004, 5/6 patients with Hib epiglottitis had completed the Hib vaccination series.
- Q: Should a fully vaccinated child who develops invasive disease due to H. influenzae type B be tested for an underlying immunodeficiency?
- A: Probably. In one study, about 1/3 of children diagnosed with invasive disease due to H. influenzae type B were found to have a previously undiagnosed immunoglobulin deficiency.
- Q: Can epiglottitis recur?
- A: Yes, but rarely.
- Q: Are corticosteroids of any value in the management of epiglottitis?
- A: They are used commonly, but there is no evidence to support their benefit.

EPSTEIN-BARR VIRUS (INFECTIOUS MONONUCLEOSIS)

Jessica Newman • Jason Newland

BASICS

DESCRIPTION

A double-stranded DNA virus implicated as a causative agent for infectious mononucleosis by an infected laboratory worker in 1968

GENERAL PREVENTION

- No vaccine is clinically available.
- Standard precautions should be used in the hospitalized patient.
- Restriction of intimate contact with immunosuppressed individuals may be advisable.
- Patients with recent Epstein-Barr virus (EBV) infection, either proven or suspected, should not donate blood or solid organs.

EPIDEMIOLOGY

- Worldwide distribution
- Humans are the only known reservoir.
- Transmission occurs through saliva and, occasionally, via blood transfusions and solid organ transplant (SOT).
- Incubation period is 4–7 weeks.
- Antibodies to EBV are almost universally present in adult populations.
- Areas with a high population density or low socioeconomic status usually become primarily infected within the first 3 years of life.

Incidence

In developed countries, acquisition of EBV is biphasic.

- Initial peak in incidence occurs before the age of 5 years.
- Second peak occurs during adolescence, coinciding with an increased frequency of intimate oral contacts.

Prevalence

90–95% of adults have demonstrable EBV titers.

PATHOPHYSIOLOGY

- Replicates initially in the oropharyngeal epithelium
- Selective infection of B lymphocytes occurs.
- The clinical syndrome of infectious mononucleosis results from proliferation of cells in the tonsils, lymph nodes, and spleen.
- Nonspecific humoral immune responses include the formation of heterophile antibodies and autoantibodies.
- Specific antibodies to EBV antigens are produced.
- Despite humoral responses, cellular immunity is responsible for controlling EBV infection.
- Latent, lifelong infection of B lymphocytes occurs.
- Latent virus may be reactivated during periods of immunosuppression.

COMMONLY ASSOCIATED CONDITIONS

- Subclinical infection
 - Most EBV infections in children, and even in adolescents, are clinically inapparent.
 - Mild, nonspecific symptoms may include coryza, diarrhea, and/or fever.
 - Immunologic seroconversion does occur.
- Infectious mononucleosis (“glandular fever”): most commonly observed with late primary acquisition of EBV. The classically defined illness is characterized by the following:
 - Fatigue
 - Malaise
 - Fever
 - Tonsillopharyngitis (often exudative)
 - Lymphadenopathy
 - Splenomegaly
 - Usually associated with increased atypical lymphocytes in the peripheral blood
- Rare illnesses of the nervous system have been reported, including the following:
 - Guillain-Barré syndrome
 - Bell palsy
 - Aseptic meningitis

- Meningoencephalitis
- Peripheral and/or optic neuritis
- Hematologic complications have been reported in association with EBV.
 - Aplastic anemia
 - Hemolytic anemia
 - Agranulocytosis
 - Hemophagocytic syndrome
- Other illnesses associated with EBV in case reports include the following:
 - Hemolytic uremic syndrome
 - Hepatitis
 - Pancreatitis
 - Myocarditis
 - Mesenteric adenitis
 - Orchitis
 - Genital ulcerative disease
- Lymphoproliferative disorders
 - Burkitt lymphoma
 - Nasopharyngeal carcinoma
 - Lymphoma and non-Hodgkin lymphoma (in immunocompromised children)
 - Lymphomatoid granulomatosis
 - Posttransplant lymphoproliferative disorders (PTLD)
 - X-linked lymphoproliferative disease (Duncan disease)

DIAGNOSIS

HISTORY

- A prodrome may occur.
 - Most often, lasts 3–5 days
 - Malaise, fatigue, with or without fever
- In the acute phase, the following features are common:
 - Fever: begins abruptly, lasts 1–2 weeks
 - Fatigue

- Malaise
- Anorexia
- Sore throat
- “Swollen glands”
- Rash; more common with ampicillin administration
- Young children are more likely to have rash or abdominal pain.

PHYSICAL EXAM

- Tonsillopharyngitis
 - May be exudative and mimic streptococcal pharyngitis
 - Often accompanied by palatal petechiae
- Lymphadenopathy
 - Occurs in 90%
 - Most prominent in cervical chains
 - May be diffuse
 - Usually nontender, nonerythematous, and discrete
- Hepatosplenomegaly
 - Splenomegaly occurs in more than half the cases.
 - Even if not palpable, splenomegaly may be demonstrated on ultrasound.
 - Most prominent in 2nd–4th week of illness
 - Hepatomegaly is less common.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Complete blood count with differential
 - Leukocyte count up to 20,000/mm³
 - Lymphocytosis
 - Atypical lymphocytes often constitute >10% of total leukocyte count.
 - Thrombocytopenia may occur.
 - False positives: Atypical lymphocyte counts >10% of the total leukocyte count also occur with cytomegalovirus and toxoplasmosis infections.
- Liver enzymes
 - Mild hepatitis is often found.

- Jaundice is rare.
- “Monospot” (mononucleosis rapid slide agglutination test for heterophile antibodies)
 - Detects heterophile antibodies (nonspecific IgM antibodies to unrelated antigens)
 - Appears in first 2 weeks of illness, usually slow decline over 6 months
 - Detects 85% of cases in adolescents/adults
 - False positives: infrequent; heterophile antibodies are also produced in serum sickness and neoplastic processes; heterophile antibodies may persist for months after acute infection and be indicative of past illness.
- EBV serology
 - Usually reserved for heterophile-negative patients or children <4 years of age when strong clinical suspicion persists
 - Antibodies are detected by indirect immunofluorescence or enzyme-linked immunosorbent assay techniques.
 - Acute or past infection can usually be detected and differentiated.
 - EBV IgM is consistent with acute infection, whereas EBV nuclear antibody (EBNA) is indicative of past infection.
- Other technology
 - Tissue culture of EBV is difficult and, therefore, not clinically useful.
 - Polymerase chain reaction (PCR) may detect EBV genetic material.
 - Real-time PCR may quantify the amount of EBV genome present, which is useful in patients with PTLD.

ALERT

- Heterophile antibodies may not appear early in the illness.
- Up to 10% of patients with acute EBV infection may have no heterophile response 3 weeks into the illness.
- The heterophile response is less common in infants and children and should not be used in children <4 years of age.

DIFFERENTIAL DIAGNOSIS

- Infectious

- Group A Streptococcus
- Adenovirus
- Cytomegalovirus
- Toxoplasma gondii
- Human herpesvirus-6
- Mycoplasma pneumoniae
- Human immunodeficiency virus
- Rubella
- Diphtheria
- Viral hepatitis (A, B, C)
- Noninfectious
 - Leukemia/lymphoma

TREATMENT

MEDICATION

- Acetaminophen or ibuprofen reduces fever and provides analgesia.
- Corticosteroids (prednisone 1 mg/kg/24 h PO, maximum of 20 mg/24 h) may reduce swelling of lymphoid tissues (see “[FAQ](#)”)
 - Indicated for patients with impending airway obstruction
 - May be considered for patients with severe tonsillopharyngitis requiring IV hydration
 - May be considered for patients with rare, life-threatening manifestations of EBV infection, such as hepatitis, aplastic anemia, and central nervous system dysfunction
 - 7-day treatment followed by tapering
- Acyclovir has not been shown to provide clinical benefit; sometimes, used in cases of active replicating EBV in posttransplant situations
- Patients with PTLN should have immunosuppression reduced.
- Advise avoidance of contact sports until resolution of symptoms and no further splenomegaly.

INPATIENT CONSIDERATIONS

Admission Criteria

- Respiratory distress secondary to airway obstruction

- Dehydration secondary to severe pharyngitis and poor oral intake

Discharge Criteria

- Resolved airway obstruction
- Good oral intake

ISSUES FOR REFERRAL

- PTLT
- EBV in immunocompromised host
- EBV-associated lymphoproliferative disorders
- Considering steroid use as treatment

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Immunocompetent individuals usually recover uneventfully in 1–4 weeks.
- Recovery is often biphasic, with a worsening of symptoms after a period of improvement.
- Splenomegaly may persist for weeks after primary infection (see [“FAQ”](#)).
- Fatigue may persist months after recovery.

PROGNOSIS

- Most patients with primary EBV infection will recover uneventfully in 1–4 weeks.
- Long-lasting immunity generally ensues.
- Prognosis of patients with unusual manifestations of EBV infection depends on the severity of the illness and the organ system involved.
- Patients with inherited or acquired immunodeficiency are at higher risk of complications and neoplasms.

COMPLICATIONS

- Dehydration
 - Severe pharyngitis often limits fluid intake.
 - Most common problem requiring hospitalization

- Antibiotic-induced rash
 - Morbilliform in appearance
 - Most common after administration of ampicillin or amoxicillin
 - Rare association with penicillin
 - Usually benign; resolves with discontinuation of the aminopenicillin
- Splenic rupture
 - Incidence of ~1 in 1,000 patients
 - More common in males
 - 50% of the cases of splenic rupture are spontaneous; 50% follow blunt trauma.
- Airway obstruction: may result from massive lymphoid hyperplasia and mucosal edema

CODES

ICD10

- B27.90 Infectious mononucleosis, unspecified without complication
- B27.99 Infectious mononucleosis, unsp with other complication
- B27.91 Infectious mononucleosis, unspecified with polyneuropathy

FAQ

- Q: Should all patients with infectious mononucleosis be given corticosteroids?
- A: No. Symptomatic EBV infection is most often self-limited. EBV has been linked to certain lymphoproliferative disorders, and theoretic risks to modulating the host immune response with corticosteroids have been proposed.
- Q: How long after infectious mononucleosis may a patient return to athletic activity?
- A: More than half of patients with “mono” will have a boggy, enlarged spleen, which is prone to rupture even if it is not palpable. Athletic activity should be restricted until no evidence exists for a clinically enlarged spleen. Return to contact sports is not advised until 4–6 weeks after resolution of illness. Some experts recommend ultrasound of the spleen before a return to heavy contact sports such as rugby, football, lacrosse, and hockey.

ERYTHEMA MULTIFORME

Minnelly Luu • Kelly M. Cordoro

BASICS

DESCRIPTION

- Erythema multiforme (EM) is an acute, self-limited mucocutaneous eruption characterized by distinct targetoid lesions on the skin.
- Although classically defined by the presence of target lesions, at various stages of evolution, EM may appear as erythematous macules, papules, vesicles, or bullae.
- EM is considered an immune-mediated reaction, usually to infectious triggers; numerous additional triggers have been reported in the literature.
- Ranges from relatively mild cutaneous disease (EM minor) to severe forms with significant mucosal involvement (EM major)
- Historically viewed as a spectrum of diseases, most authors now regard EM to be a separate entity from Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN). SJS and TEN are distinguished from EM by differing patterns of cutaneous involvement, precipitating factors, and prognosis.

EPIDEMIOLOGY

- Predominantly affects healthy young adults but can also affect younger children
- Possible seasonal variation with increased frequency in spring and summer. The more severe form (EM major) has been reported to occur more frequently in winter.
- Recurrences are common.

ETIOLOGY

- ~90% of cases are caused by an infectious agent, most commonly herpes simplex virus (HSV) or *Mycoplasma pneumoniae*.
- <10% of cases are secondary to drug exposure. Common culprits include NSAIDs, sulfonamides, antiepileptics, and antibiotics.

- Reported causes are numerous. Rare precipitants include the following:
 - Chemical and physical exposures
 - Immunizations
 - Autoimmune disease
- Often, the causative factor is not identified.
- HSV is the major cause of recurrent EM.
- *M. pneumoniae* is associated with more severe bullous skin disease and significant mucosal involvement.

DIAGNOSIS

HISTORY

- Prodrome of fever and malaise may precede skin eruption. The prodrome is generally uncommon except in cases of EM major, where symptoms are usually indistinguishable from those of the underlying illness.
- Onset is abrupt with rapid evolution of lesions over the course of 3–5 days.
- Although usually appearing at the same time, mucosal lesions occasionally precede or follow cutaneous lesions by a few days.
- Lesions may be associated with pruritus or burning.
- Elicit careful drug (prescription and OTC) and exposure history, including personal and family history of herpetic lesions.
- Symptoms of HSV, mycoplasma, or other infections may be present.
- Assess for symptoms of mucosal involvement, including dysphagia, dysuria, and ocular symptoms.

PHYSICAL EXAM

- Early lesions are usually round, well-defined erythematous, edematous papules.
- Classically, some of these will evolve to the characteristic target lesion defined by three zones of concentric color change:
 - Dark, dusky center
 - Pale, edematous middle zone
 - Well-defined erythematous outer border

- The center of well-formed lesions will have signs of necrosis: duskiness, blistering, or erosion.
- Atypical target lesions may also be present, defined by only two zones of color change and/or a poorly defined border.
- Lesions may have multiple morphologies including macules, papules, and vesicles/bullae.
- Distribution is typically symmetric and favors acral sites.
- Oral mucosal involvement (labial and buccal mucosa, vermillion lip) is most common, although any mucosal site may be affected.
- Mucosal involvement usually starts with erythema and edema and progresses to painful erosions with crusting.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Laboratory tests do not establish diagnosis, although they may provide supporting evidence and reveal the underlying cause.
- Eosinophilia may suggest drug as etiology.
- Any lesions suspicious for herpes should be evaluated with culture, direct fluorescent antibody testing (DFA), or polymerase chain reaction (PCR).
- Consider evaluation for Mycoplasma with chest radiograph and cold agglutinins, serology, or PCR.
- Erythrocyte sedimentation rate, white blood cell count, and liver function tests may be elevated in severe EM.

Diagnostic Procedures/Other

Diagnosis of EM can usually be made on clinical grounds. Biopsy is often not required, although it can help confirm diagnosis and exclude other possibilities. Of importance, pathology does not reliably distinguish EM from SJS/TEN and thus differentiation between these entities requires clinical correlation.

Pathologic Findings

- Necrotic keratinocytes
- Vacuolar basal layer degeneration (liquefactive or hydropic degeneration)
- Subepidermal blistering may be seen in cases of extensive basal layer

degeneration.

- Perivascular inflammation in the upper and mid dermis composed mainly of mononuclear cells
- Spongiosis, papillary dermal edema, and exocytosis of lymphocytes may also be seen.

DIFFERENTIAL DIAGNOSIS

- SJS/TEN should be considered when a drug is suspected or morphology consists of predominantly macular atypical targets or dusky, ill-defined macules/patches with or without epidermal detachment.
- Urticaria
- Urticaria multiforme
- Vasculitis/urticarial vasculitis
- Fixed drug eruption
- Atypical hand foot and mouth disease
- Pemphigus vulgaris
- Paraneoplastic pemphigus
- Bullous pemphigoid
- Polymorphous light eruption
- Serum sickness reaction
- Systemic lupus erythematosus (Rowell syndrome)
- Sweet syndrome
- Kawasaki disease
- Varicella (chickenpox)

TREATMENT

GENERAL MEASURES

- Treat the underlying cause (e.g., acyclovir for HSV-related cases) or withdraw the offending agent.
- EM minor
 - Care is supportive and symptom-based.
 - White petrolatum +/- topical corticosteroids
 - Oral antihistamines for pruritus

- EM major
 - Skin-directed therapy as above
 - White petrolatum and nonstick dressings for bullous lesions
 - Pain control
 - “Swish and spit” oral preparations composed of diphenhydramine or viscous lidocaine for painful oral lesions.
 - Ophthalmology consultation; consider ENT and urology based on signs and symptoms.
 - Avoid aggressive debridement of crust, which can lead to further scarring.
 - Monitoring of fluid and electrolyte balance and observation for secondary infection
 - The role of systemic steroids is controversial and randomized controlled trials are lacking. Generally thought to be most beneficial when given early in the course of disease. The risks and benefits of corticosteroid therapy must be weighed carefully in the setting of potential infection.

INPATIENT CONSIDERATIONS

Admission Criteria

- Severe mucositis with inability to adequately hydrate
- Atypical progression with suspicion for SJS/TEN or other potentially life-threatening process

ONGOING CARE

PROGNOSIS

- The course of EM is self-limited. Lesions resolve in 2–4 weeks with postinflammatory pigment alteration. Severe cases of EM may take longer to heal.
- Recurrences may occur and are often associated with HSV. Prophylactic therapy with acyclovir may be considered with frequent episodes.

COMPLICATIONS

- Complications of the triggering/underlying infection may occur in

individual cases.

- EM minor generally heals without significant sequelae.
- In EM major, mucosal involvement may lead to sequelae at individual sites: stricture formation of the oral cavity, trachea, esophagus, and urethra. Ophthalmologic consequences include conjunctivitis, corneal erosions, scarring, and rarely, blindness.
- Skin scarring in severe, ulcerated, or secondarily infected sites

- L51.0 Nonbullous erythema multiforme

ERYTHEMA NODOSUM

Vikash S. Oza • Erin Mathes

BASICS

DESCRIPTION

Delayed, cell-mediated hypersensitivity panniculitis characterized by red, tender, nodular lesions most often seen on the pretibial surface of the legs

EPIDEMIOLOGY

- Girls are affected more often than boys.
- Incidence peaks in adolescence and is rare under 2 years of age.

Incidence

Greatest seasonal incidence in spring and fall

PATHOPHYSIOLOGY

- Most likely a host hypersensitivity immune response to circulating immune complexes secondary to infectious and/or inflammatory stimuli
- The response results in chronic injury to the blood vessels of the reticular dermis and subcutaneous fat.

ETIOLOGY

- Most cases are idiopathic (~50% of cases).
- Infectious associations
 - Bacterial: β -hemolytic streptococcal infection is the most common cause in children.
 - Other bacteria: Mycoplasma, Yersinia, Shigella, Brucella, Neisseria meningococcus and gonococcus, chlamydia, cat-scratch disease, rickettsial diseases including syphilis
 - Viral: Epstein-Barr virus (EBV), HIV, hepatitis B virus (HBV)
 - Mycobacterial: tuberculosis and atypical mycobacteria, leprosy
 - Fungal: histoplasmosis, coccidioidomycosis
- Systemic associations
 - Sarcoidosis

- Inflammatory bowel disease
- Behçet disease
- Malignancy (lymphoma, leukemia)
- Pregnancy
- Medications
 - Oral contraceptives
 - Sulfonamides
 - Phenytoin
 - Halides

DIAGNOSIS

HISTORY

- Arthralgia is commonly noted 2–8 weeks prior.
- Prodromal symptoms of fatigue/malaise or upper respiratory infection often occur by 1–3 weeks.
- Pain and tenderness of the extremities is common, sometimes causing difficulty in ambulation.
- Important questions to ask:
 - Recent streptococcal infection
 - Medication history (oral contraceptives, sulfonamides, iodides/bromides)
 - Last menses (erythema nodosum is seen in pregnancy)
 - History of diarrhea (inflammatory bowel disease or infectious diarrhea)
 - Tuberculosis exposure

PHYSICAL EXAM

- Red, often tender nodules on anterior lower legs, 2–6 cm in diameter
- Lesions can also be present in other areas with subcutaneous fat such as the thighs, arms, trunk, and face.
- Overlying skin is normal except for erythema.
- Initially, lesions are slightly elevated, bright to deep red nodules with palpable warmth.
- Later, lesions develop a brownish red or violaceous, bruise-like

appearance.

- Exam pearls
 - Symmetric distribution
 - Erythema nodosum never ulcerates or suppurates.
 - Usually, there are no more than 6 lesions at a time.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Throat culture
- Antistreptolysin-O titer
- Tuberculin skin test
- CBC
- Erythrocyte sedimentation rate (ESR)
- Stool culture, if history of diarrhea
- Serologic testing, if yersiniosis, rickettsial disease, histoplasmosis, or coccidioidomycosis suspected

Imaging

Chest radiograph can help screen for possible underlying tuberculosis or sarcoidosis.

Diagnostic Procedures/Other

- Erythema nodosum is a clinical diagnosis.
- Biopsy for histopathology and culture (bacterial, fungal, mycobacterial) is used if diagnosis is in doubt.

Pathologic Findings

- Septal panniculitis: lymphocytic perivascular infiltrate in the dermis; lymphocytes and neutrophils in the fibrous septa in the subcutaneous fat
- Older lesions: Histiocytes, giant cells, and occasionally plasma cells can be seen.
- No fat cell destruction or vasculitis is present.

DIFFERENTIAL DIAGNOSIS

- Infection
 - Erysipelas/cellulitis
 - Erythema induratum (nodular vasculitis)

- Deep fungal infection or Majocchi granuloma
- Superficial or deep thrombophlebitis
- Trauma: accidental or from child abuse
- Palmoplantar hidradenitis
- Metabolic
 - Panniculitis secondary to pancreatic disease
 - Pretibial myxedema
- Major insect bite reaction
- Psychosocial (self-injection with foreign material)
- Cutaneous sarcoidosis
- Polyarteritis nodosa
- Granuloma annulare

TREATMENT

FIRST LINE

- Bed rest
- Leg elevation
- Salicylates or other NSAIDs, such as ibuprofen, naproxen, or indomethacin

ADDITIONAL THERAPIES

- Potassium iodide 300 mg PO t.i.d. for 3–4 weeks, especially for cases diagnosed early in course
- Colchicine
- Corticosteroids (rarely used) for severe cases; courses generally last 2–4 weeks

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Can expect improvement within 1 week
- If lesions recur after cessation of treatment, an underlying infection/inflammatory trigger may still be present.

- If atypical locations or exuberant or suppurative nodules are present, a biopsy is warranted to rule out a disseminated infection.

PROGNOSIS

- Most individual lesions will completely resolve in 10–14 days.
- In general, erythema nodosum resolves in 3–6 weeks with or without treatment unless the underlying cause is a chronic infection or systemic disorder.
- Aching of legs and swelling of ankles may persist for weeks; rarely, symptoms may persist for up to 2 years.
- In children, the recurrence rate is 4–10% and is often associated with repeated streptococcal infection.

CODES

ICD10CM

- L52 Erythema nodosum

- A18.4 Tuberculosis of skin and subcutaneous tissue

FAQ

- Q: Will the lesions leave a scar?
- A: In the vast majority of cases, erythema nodosum heals without scarring.

EWING SARCOMA

Erin E. Karski • Steven G. DuBois

BASICS

DESCRIPTION

- Family of cancers with common biology and treatment:
 - Ewing sarcoma of bone
 - Extraskkeletal Ewing sarcoma (arises in soft tissue adjacent to bone)
 - Peripheral neuroectodermal tumor (PNET) of bone or soft tissue
 - Askin tumor (Ewing sarcoma of the chest wall)
- Most common primary tumor sites are as follows:
 - Pelvic bones (26%)
 - Femur (20%)
 - Chest wall (16%)

EPIDEMIOLOGY

- 2nd most common primary bone cancer of children and young adults after osteosarcoma
- Median age of diagnosis is 15 years, although can occur in any age group
- Slight male predominance

Incidence

- ~200–250 new cases are diagnosed in the United States each year.
- Annual incidence in the United States of 2.7 cases per million children younger than 15 years of age
- Most (~65%) occur in the 2nd decade of life.
- Strikingly lower incidence in sub-Saharan Africa and in African American population

RISK FACTORS

- Most cases occur sporadically.
- Not associated with familial cancer syndromes
- Only rarely reported as a second malignancy
- One genome-wide association study identified several single nucleotide

polymorphisms (SNPs) associated with higher risk.

- Epidemiologic studies suggest higher risk in patients with history of inguinal or umbilical hernia.

GENERAL PREVENTION

There are no known preventive measures.

PATHOPHYSIOLOGY

- Rearrangement of the EWSR1 gene on chromosome 22 is detected in >95% of cases.
 - 85% of cases have a t(11;22) translocation resulting in a fusion EWS-FLI1 protein.
 - 10% of cases have a t(21;22) translocation between EWS and ERG.
 - Other translocation partners occur in <1% of cases and include other members of the ETS transcription factor family, such as ETV1.
- Fusion proteins thought to play a role as aberrant transcription factor

DIAGNOSIS

HISTORY

- Pain is most common symptom.
- Pain is often attributed to minor injuries that are common in this age group.
- Other presenting symptoms are as follows:
 - Palpable mass
 - Fever
 - Limp
- Systemic symptoms (fever, weight loss) are more common among patients with metastatic disease and more common compared to patients with osteosarcoma.

PHYSICAL EXAM

- Palpable mass (35%)
- Local tenderness (70%)
- Painful movement of joint (35%)
- Fever (30%)

- Regional node involvement uncommon, although more likely with a soft tissue primary tumor

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC as a screen for bone marrow involvement
- Serum lactate dehydrogenase (LDH) is often elevated at diagnosis and may be prognostic.
- Prechemotherapy labs include liver function tests and tests of renal function.

Imaging

- To evaluate primary site:
 - Plain radiographic findings may include the following:
 - Destructive lesion with “moth-eaten” appearance
 - Periosteal reaction with layers of reactive bone can give an “onionskin” appearance.
 - Raised periosteum may result in a Codman triangle.
 - When arising in long bones, tends to arise from diaphysis rather than metaphysis
- CT or preferably MRI scan in addition to radiograph is essential to fully characterize the extent of the primary tumor.
- 25% have detectable metastases at diagnosis.
 - Lung
 - Bone
 - Bone marrow
- To evaluate for distant metastases:
 - Chest CT scan
 - Fluorine-18-fluorodeoxyglucose positron emission tomography (FDG PET) or 99m-Tc-diphosphonate bone scan

Diagnostic Procedures/Other

- Biopsy
 - Consultation with a pediatric oncologist and orthopedic oncologist is essential before biopsy.
 - Should be performed by an experienced orthopedic surgeon
 - Avoid contamination of surrounding tissues.

- Include testing for EWSR1 translocation, either by fluorescence in situ hybridization (FISH), cytogenetics, or reverse transcription-polymerase reaction (RT-PCR).
- Small round blue cell tumor with nearly universal membranous CD99 expression
- PNET shows evidence of neural differentiation.
- Bilateral bone marrow aspirates and biopsies to complete metastatic staging
- Echocardiogram in anticipation of starting chemotherapy

DIFFERENTIAL DIAGNOSIS

- Malignant
 - Osteosarcoma
 - Neuroblastoma
 - Non-Hodgkin lymphoma
 - Rhabdomyosarcoma
 - Other soft tissue sarcoma
 - Bone metastasis from other malignancy
- Benign
 - Osteomyelitis
 - Tendonitis
 - Trauma
 - Langerhans cell histiocytosis
 - Other benign bone tumor

TREATMENT

CHEMOTHERAPY

- Chemotherapy is essential for cure.
 - Prior to the use of chemotherapy, only 10% of patients survived.
 - Patients with nonmetastatic disease now have an overall survival rate approaching 70% with the use of chemotherapy and appropriate local control.
 - Suggests that patients have small amounts of occult micrometastatic tumor cells that cannot be detected by current technology

- In North America, standard chemotherapy traditionally includes vincristine, doxorubicin, and cyclophosphamide alternating every 2 weeks with etoposide and ifosfamide.
- Other agents under investigation include camptothecins (irinotecan and topotecan) as well as IGF-1R inhibitors.

ADDITIONAL TREATMENT

General Measures

- In addition to systemic treatment with chemotherapy, patients need local control treatment to the site of the primary tumor and metastases (if present) with surgery, radiation, or both.
- The type of local control used depends on the location and extent of the tumor, the morbidity associated with resection, and the presence of tumor cells at the resection margin in those who have surgery.
- The usual sequence of treatment is
 - Neoadjuvant chemotherapy
 - Local control
 - Adjuvant chemotherapy
- Most children are treated on or according to large cooperative group clinical trials.
- Myeloid growth factor (e.g., granulocyte colony-stimulating factor [G-CSF]) is usually given following chemotherapy to shorten the duration of neutropenia.

SURGERY/OTHER PROCEDURES

- If surgical local control is pursued, goal is to remove the entire tumor with negative tissue margins.
- Limb salvage surgery is often possible but may not be best in some cases.
- Amputation is less commonly performed given the radiosensitive nature of Ewing sarcoma.

RADIATION

- Definitive radiation provides reasonable local control in cases not amenable to surgical resection.
- Radiation also used for
 - Attempted surgical resection, but margins positive

- Treatment of cytology-proven malignant pleural effusions in patients with chest wall tumors
- Treatment of metastatic disease, including whole lung radiotherapy for patients with lung metastasis
- Carries risk of second malignancy

ADDITIONAL THERAPIES

- Physical therapy
 - All patients who receive surgery should be referred to physical therapy following surgery.
 - Patients regardless of surgery may need physical therapy for deconditioning associated with treatment.
- Reproductive endocrinology
 - Given the role of alkylating chemotherapy in the treatment of Ewing sarcoma, all patients should be encouraged to meet with reproductive endocrinology to discuss fertility preservation strategies prior to initiating therapy.

ISSUES FOR REFERRAL

Consultation with a pediatric oncologist is essential before any attempt is made at a diagnostic biopsy.

ONGOING CARE

PROGNOSIS

- 5-year overall survival rate for all patients is ~60%.
- Presence of metastases is the most important prognostic factor.
 - Estimated overall survival in those with metastatic disease at diagnosis is less than 30% at 5 years.
- Other unfavorable prognostic features:
 - Older age (age >18 years)
 - Pelvic primary tumor
 - Large primary tumor
- Other prognostic factors under investigation:
 - LDH
 - Race

- Aberrations in p53/p16
- Subtype of EWSR1/FLI1 translocation not prognostic

COMPLICATIONS

- Acute toxicity
 - Alopecia
 - Bone marrow suppression
 - ▢ Platelet and packed red blood cell transfusions are usually necessary.
 - ▢ Neutropenia: increased risk of bacterial and fungal infections
 - Gastrointestinal side effects
 - ▢ Nausea and vomiting
 - ▢ Mucositis
 - Kidney and bladder side effects
 - ▢ Electrolyte wasting
 - ▢ Hemorrhagic cystitis
 - Complications from radiation
 - ▢ Skin breakdown and erythema
 - ▢ Bone marrow suppression
 - Complications from surgery
 - ▢ Wound dehiscence
 - ▢ Infection

Late Effects

- Cardiotoxicity (See “[Cancer Therapy Late Effects.](#)”)
 - Anthracyclines (doxorubicin) can lead to cardiomyopathy and heart failure.
 - Risk depends on cumulative dose of doxorubicin.
 - Radiation to the heart can increase the risk of cardiotoxicity.
 - Patients should have yearly echocardiogram for evaluation.
 - Reduced fertility
- Second malignancy
 - Sarcomas may occur within the radiation field.
 - Myelodysplastic syndromes and acute myeloid leukemia may occur secondary to chemotherapy.

CODES

ICD10

- C41.9 Malignant neoplasm of bone and articular cartilage, unsp
- C41.4 Malignant neoplasm of pelvic bones, sacrum and coccyx
- C40.20 Malignant neoplasm of long bones of unspecified lower limb

FAQ

- Q: At what time point is a child with Ewing sarcoma considered cured?
- A: Most cases of recurrence in Ewing sarcoma occur within 2 years of initial diagnosis. However, late relapses beyond 5 years from initial diagnosis have been seen with Ewing sarcoma.
- Q: Should an Ewing sarcoma be completely resected at the time of

diagnosis?

- A: Ewing sarcoma tumors are typically large at initial diagnosis. The standard approach is to treat with chemotherapy first, both to reduce the size of the tumor and to treat any distant tumor cells.
- Q: Is surgery or radiation better for local control of the primary tumor in Ewing sarcoma?
- A: This is an area of controversy. Most specialists favor surgical resection when feasible without significantly jeopardizing function, reserving radiation for cases that are less amenable to surgical resection with negative margins.
- Q: Why do Africans and African Americans have such low rates of Ewing sarcoma?
- A: It is not known why these populations are at lower risk for developing Ewing sarcoma, although it suggests a genetic component that influences the risk of developing this disease. Studies are ongoing to investigate this consistent finding.

EXSTROPHY–EPISPADIAS COMPLEX

Brian M. Inouye • John P. Gearhart

BASICS

DESCRIPTION

The exstrophy–epispadias complex is a rare spectrum of multisystem birth defects involving the genitourinary and gastrointestinal tracts, musculoskeletal system, pelvic floor, and bony pelvis. It is composed of epispadias, bladder exstrophy, and cloacal exstrophy. The latter two conditions present with an open bladder through the anterior abdominal wall.

- The least common variant of the complex, complete epispadias presents with a closed bladder and dorsally open urethral meatus.
- Cloacal exstrophy is the most severe variant, presenting with a large omphalocele, imperforate anus, shortened colon, bladder halves with cecum interposed between, associated cord defects, and multiple upper urinary tract and limb anomalies. All three forms are associated with a pubic diastasis.

EPIDEMIOLOGY

Incidence

- Bladder exstrophy
 - Male-to-female ratio is between 2:1 and 4:1.
 - Between 1:10,000 and 1:50,000 live births
 - Risk in offspring of individuals with bladder exstrophy and epispadias is 1:70 (500-fold greater than general population).
 - Risk of recurrence in family is approximately 1:100.
- Epispadias
 - Risk of male epispadias: 1:117,000 live births
 - Risk of female epispadias: 1:484,000 live births
- Cloacal exstrophy
 - Male-to-female ratio is between 1:1 and 2:1.
 - Cloacal exstrophy is exceedingly rare, with an incidence between 1:200,000 and 1:400,000 births (decreasing incidence with prenatal

diagnosis and termination).

RISK FACTORS

Bladder exstrophy: only known association is related to offspring of in vitro fertilization pregnancies

PATHOPHYSIOLOGY

Embryology

- Normal development
 - By week 2 of gestation, the cloacal membrane is located at the caudal end of the infraumbilical abdominal wall.
 - At week 4 of gestation, mesenchyme from the primitive streak migrates between the layers of the cloacal membrane to reinforce the abdominal wall while the cloacal membrane regresses.
- Bladder exstrophy
 - Unclear pathogenesis, but there is an error in embryogenesis
 - The cloacal membrane may overdevelop and prevent mesenchymal migration, which inhibits formation of normal lower abdominal wall.
 - Without reinforcement, the cloacal membrane ruptures. The timing of this rupture determines the variant of the exstrophy–epispadias complex. In bladder exstrophy, rupture of the membrane occurs after the urorectal septum has descended, dividing the genitourinary and gastrointestinal tracts.
- Cloacal exstrophy
 - Abnormally large cloacal membrane ruptures prior to division of the cloaca by the urorectal septum.

DIAGNOSIS

PHYSICAL EXAM

- Bladder exstrophy
 - All cases have pubic diastasis (mean of 4.8 cm) caused by outward rotation of the innominate bones and iliac wings.
 - The exstrophied bladder and posterior urethra are exposed through a triangular defect in the anterior abdominal wall and are bound by

- the umbilicus superiorly, the two separated pubic bones laterally, and the anus inferiorly.
- The anus is anteriorly displaced, shortening the distance between it and the umbilicus.
 - Boys commonly have indirect inguinal hernias that are prone to incarceration because the perineum is short and broad due to the compromised pelvic floor. Less common when osteotomy is used.
 - Male genital anomalies
 - Penis is 50% shorter and 30% wider than non-exstrophy boys.
 - Corpora cavernosa are short and widely separated secondary to the pubic diastasis.
 - There is a short urethral plate and a marked dorsal chordee causing the penis to curve upward.
 - Epispadias always presents with the lower tract open from the tip of the penis to the dome of the bladder.
 - Female genital anomalies
 - Mons pubis is laterally displaced, with a bifid clitoris secondary to the diastasis.
 - Vagina is short and wide.
 - Vagina and introitus are displaced anteriorly, with the cervix in the anterior vaginal wall.
 - All female patients are at an increased risk for uterine prolapse in adolescent and adult life.
 - Urinary defects
 - Bladder mucosa at birth usually appears normal but may be ectopic or contain polyps.
 - Exstrophic bladder may develop slowly prior to closure.
 - Upper urinary tract usually normal but may observe horseshoe, pelvic, hypoplastic, solitary, or dysplastic kidney.
 - Most children have vesicoureteral reflux requiring correction at the time of their continence procedure.
 - Cloacal exstrophy
 - Two halves of the exstrophied bladder are separated by an exstrophied ileocecal bowel segment with various amount of hindgut present.

- Omphalocele usually present; varies in size.
- Imperforate anus is usually present.
- Vertebral and neurologic abnormalities (lumbar myelodysplasia, hemivertebrae) are present in >50% of children.
- Upper urinary tract anomalies (duplicated systems, horseshoe kidney, pelvic kidney) are seen in up to 70% of children.
- Penis may be duplicate or diminutive.
- Bifid vagina and uterine abnormalities

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- Prenatal sonographic findings between 15th and 32nd weeks of pregnancy demonstrating absence of normal fluid-filled bladder, an anterior abdominal mass increasing in size, low-set umbilicus, and wide pubic ramus are suggestive of bladder exstrophy.
- A baseline renal ultrasound and KUB after birth will demonstrate renal abnormalities and the pubic diastasis, respectively.

TREATMENT

SURGERY/OTHER PROCEDURES

Goals: Provide urinary continence with a compliant bladder, preserve renal function, and surgically reconstruct the phallus for cosmesis.

- Modern staged repair of bladder exstrophy (MSRE)
 - In the early neonatal period, bladder, posterior urethra, and abdominal wall closure is performed with or without osteotomy.
 - Closure of the urethra occurs at 6–12 months of age.
 - Bladder capacity is annually measured with gravity cystogram.
 - If bladder has adequate capacity and patient desires continence (between 5 and 9 years), a continence procedure is performed with ureteral reimplantation.
 - Noncandidates or those who fail continence may require bladder neck transection, augmentation cystoplasty, and continent urinary diversion.
 - Results and complications: Daytime continence in 60–80%

following bladder neck surgery may require clean intermittent catheterization (long-term follow-up). Minimal risk for upper urinary tract changes or hydronephrosis.

- Small bladder capacity and failed primary closure are predictors of postsurgical incontinence.
- Complete primary repair of exstrophy (CPRE)
 - Bladder and abdominal wall closure, bladder neck reconstruction, and epispadias repair completed in single procedure. May be performed with or without osteotomy.
 - Total penile disassembly dissects the urethral plate from corporal bodies to posteriorly position the bladder neck into the pelvis.
 - Results and complications: Daytime continence and volitional voiding in selected patients in up to 20% over 5 years of age; additional bladder neck surgery to gain continence is usually required; >50% require subsequent hypospadias repair and bladder neck fistula rate is up to 40%. Penile disassembly may cause penile soft tissue loss.
- Role of osteotomy and immobilization in all closures
 - Recommended in patients with a diastasis >4 cm who no longer have a malleable pelvis, which usually occurs after 72 hours of age
 - Bilateral transverse anterior innominate and vertical posterior iliac osteotomies performed by pediatric orthopedic surgeon.
 - Fixator pins and external fixation devices can be placed and left postoperatively for 4–6 weeks.
 - Pelvis immobilized and patient is placed in modified Buck or Bryant traction to increase chance of success.
 - Complications: increased risk of transient nerve and muscle palsies (which typically resolve), delayed ileal union, and superficial infection at pin sites
- Complications for both types of closure:
 - Dehiscence, bladder prolapse, bladder outlet obstruction, stone formation, hydronephrosis, and vesicocutaneous fistula formation may occur. Patients must be followed carefully.
 - Chance of long-term continence decreases with each additional closure attempt.

- Failed bladder neck repair in 20–50% may require further reconstruction.
- 60–95% cosmetic and functional success of epispadias repair with a straight penis with erections
 - Urethral strictures and urethrocutaneous fistula are the most common complications of epispadias repair seen in $\leq 25\%$ of patients.
- Adenocarcinoma of the bladder is 400 times more likely than in the normal population. This disease is not reported in adults who have had bladder closure after infancy.
- Fertility and pregnancy
 - Following successful repair, sexual function and libido are normal.
 - Following epispadias repair, up to 87% of boys have erections.
 - Expect retrograde and small-volume ejaculation.
 - Males can have successful impregnation with assisted reproductive techniques.
 - Females can achieve pregnancy, but uterine and cervical prolapse are common following pregnancy. Cesarean section is recommended.

INPATIENT CONSIDERATIONS

Initial Stabilization

Postnatal and nursery care:

- Instead of umbilical clamp, tie umbilical cord with 2-0 silk to avoid trauma
- Cover bladder and other exstrophied bowel/omphalocele with a hydrated gel dressing or plastic wrap to prevent mucosa from sticking to clothing or diapers.
- Transfer immediately to an appropriate center for evaluation and management by a pediatric urologist and an experienced team.

Discharge Criteria

- Prophylactic antibiotics should be continued in all children until antireflux procedure or resolution of vesicoureteral reflux.
- Maintain close follow-up with surgeon.

ONGOING CARE

PROGNOSIS

Current treatments preserve the bladder in nearly every patient and allow for continence through the urethra, providing an excellent overall prognosis. There can be favorable long-term outcome with early intervention by a pediatric urologist.

CODES

ICD10

- Q64.10 Exstrophy of urinary bladder, unspecified

- Q64.0 Epispadias
- Q64.12 Cloacal extrophy of urinary bladder

FAQ

- Q: Will the child have normal sexual function?
- A: Yes. Following a completed, successful repair, the sexual function will be normal.
- Q: Will the child be fertile?
- A: Females commonly achieve pregnancy without the need for in vitro fertilization. Males require in vitro fertilization to impregnate.
- Q: Can an exstrophy patient play sports?
- A: After successfully exstrophy closure, patients are able to play sports.
- Q: Is there risk of recurrence of bladder exstrophy in a family?
- A: Yes. There is a 1:100 chance for bladder exstrophy to recur in a family.

FAILURE TO THRIVE (WEIGHT FALTERING)

Tanya Hinds • Allison M. Jackson

BASICS

DESCRIPTION

Failure to thrive (FTT) or weight faltering describes a pattern of growth that is below established standards for age and gender. Anthropometric FTT is defined as any one of the following:

- Weight (or weight for length/height) <2 standard deviations below mean
- Weight deceleration of more than 2 major percentile lines after a previously established pattern
- Weight <75% of median weight for chronologic age
- Weight <80% of median weight for length
- Weight for chronologic age <5th percentile
- Body mass index for chronologic age <5th percentile
- Length for chronologic age <5th percentile

EPIDEMIOLOGY

- FTT often begins in the first 6 months of life but may not be diagnosed until after 1 year of age.
- It is difficult to accurately determine FTT incidence or prevalence as there is neither consensus on the best definition of FTT nor concordance between definitions. Depending on definition selected, prevalence can range from 1% to 22% based on an analysis of infants from a Danish Birth Registry.

RISK FACTORS

No single risk factor uniformly predicts FTT.

- Substantiated child abuse or neglect is 4 times more likely in FTT children compared to non-FTT children. However, maltreatment is a primary concern in only 4–5% of FTT cases.
- Family poverty was traditionally believed to be an important risk for

FTT. However, recent prospective studies of large populations seen in general pediatric clinics have either been equivocal or failed to show poverty to be an important risk factor.

- Maternal mental health vulnerabilities, maternal education, and infant characteristics have also been equivocal.
- Currently, there is consensus that FTT involves a multiplicity of overlapping dietary, developmental, social, and medical concerns.

GENERAL PREVENTION

Advice should be straightforward, practical, and tailored to specific needs.

- Primary prevention
 - Addresses proper formula and food preparation, feeding quantities and frequencies, community-based nutrition support programs, and mental health resources
- Secondary prevention
 - Involves early identification by regular growth monitoring
- Tertiary prevention
 - Requires creation of an individualized treatment plan that addresses specific factors (dietary, developmental, social, and medical) adversely affecting a child's ability to meet caloric needs
 - Long-term, coordinated multidisciplinary efforts involving home visiting nurses, dietitians, social workers, primary care providers, and medical subspecialists are critical to success.

PATHOPHYSIOLOGY

Inadequate Caloric Intake

- Dietary
 - Breastfeeding difficulties
 - Diluted or inappropriately prepared formula
 - Food fads or restrictions
- Developmental/neurologic
 - Oral motor difficulties
 - Central nervous system abnormalities
- Social
 - Unavailability of food
 - Parent–child interaction disorders

- Mental health or behavioral disorders affecting child's appetite
- Mental health disorders affecting caregiver's parenting abilities
- Disorganized meal times
- Neglect (omitting feeds or creating environment not conducive to feeding)
- Medical
 - Adenotonsillar hypertrophy
 - Cleft lip and/or palate
 - Dental pain and decay
 - Congenital cardiac disease
 - Gastroesophageal reflux disease
 - Dysphagia

Inadequate Absorption or Utilization

- Food allergies or intolerances
- Inflammatory bowel disease
- Gastrointestinal malformations
- Pyloric stenosis
- Hepatitis
- Cystic fibrosis
- Parasitic infections
- Inborn errors of metabolism

Increased Caloric Expenditure

- Hyperthyroidism
- Chronic infections
- Chronic immunodeficiencies
- Malignancy
- Pulmonary disease
- Cardiac disease
- Renal disease

ETIOLOGY

- Historically, FTT was classified as organic (secondary to medical illness) or inorganic (secondary to psychosocial concerns). This categorization is obsolete. It places inordinate emphasis on organic conditions. In outpatient primary care settings, an identifiable organic

disease likely contributes to FTT in <18% of children age 2 years or younger.

- Children with FTT may eat less. An undemanding child temperament, low appetite, and disinterest in food may either cause or result in FTT.
- FTT children also have significantly fewer positive mealtime interactions with caregivers. Family dysfunction, caregiver incompetence, lack of knowledge about child development, and caregiver mental health vulnerabilities can affect a caregiver–child feeding relationship.

COMMONLY ASSOCIATED CONDITIONS

Severe, chronic FTT may have significant adverse effects on cognition, attention, and behavior.

DIAGNOSIS

HISTORY

Responses to questions about the following can help guide evaluation:

- Prenatal
 - Multiple miscarriages (suggesting a genetic disorder)
 - Maternal health and/or medical diagnoses
 - Tobacco, alcohol, or illicit substances
 - Other teratogens or toxins (prescribed medication, radiation exposure)
- Birth
 - Gestational age at delivery
 - Weight, length, and head circumference
 - Asphyxia, infection, other perinatal complications
- Medical
 - Newborn metabolic screening results
 - Medical diagnoses: reflux, cardiac disease, obstructive sleep apnea, respiratory infections, urinary tract infections, other chronic or recurrent conditions
 - Hospitalizations, surgeries, immunizations
 - Event(s) at time of significant loss or gain of weight

- Developmental
 - Personal–social, language, fine and gross motor milestones
 - Loss of previously acquired milestones
- Family
 - Weight, height of biologic parents and siblings
 - Parental history of childhood growth delay
 - Medical, mental, and developmental diagnoses of parents and siblings
 - Maternal postpartum depression
 - Caregiver(s) use of illicit substances
- Review of systems
 - Activity level compared to peers
 - Chronic rhinorrhea, congestion, cough
 - Mouth breathing, snoring, frequent awakenings from sleep
 - Difficulty or pain with sucking, chewing, or swallowing
 - Vomiting or excessive spitting up
 - Breathlessness, sweating, or tiring during feeds
 - Frequent, large, bloody, or oily stools
 - Constipation
 - Urinary frequency or dysuria
 - Polyuria, polydipsia, polyphagia
 - Eczema or urticaria exacerbated by select foods
- Psychosocial
 - Difficulty purchasing or preparing food
 - Distractions during feeds/meals
 - Perception of child’s behavior during meals
 - Eating habits of siblings when at a similar age as infant/child with FTT
 - Individual and family stressors and strengths
 - Supplemental food and community resources
 - Travel to less developed countries
- Dietary
 - Frequency, duration of active suck
 - Frequency, type, preparation, quantity of typical formula feed
 - Feeding changes at night or on weekends

- Age of weaning/shift in feeding practices
- Foods consumed over typical 24 hours
- Water, juices, sodas over typical 24 hours
- Food allergies or intolerances
- Feeding habits and techniques (bottle propping, grazing)
- Eating habits outside the home (day care, school)
- Vitamin, herbal, other supplements

PHYSICAL EXAM

Helps identify chronic illness, syndromes

- Weight, length/height, head circumference
- Vital signs, pain
- General: activity level (lethargic, hyperactive), caregiver–child interactions (eye contact, physical approximation, checking), hygiene, dysmorphic features, lymphadenopathy
- Head: dry, dull, or absent hair; fontanelle size
- Eyes: palpebral fissures, conjunctival pallor, strabismus, cataracts, retinal hemorrhages
- Ears: malposition, otitis
- Mouth, throat: anatomic abnormalities of palate or tongue, glossitis, cheilosis, gum bleeding, thrush, dental abnormalities, enlarged tonsils
- Cardiac: murmur; abnormal femoral pulses
- Chest, lungs: retractions, wheezes, crackles
- GI: distention, masses, hepatomegaly
- Anogenital: malformations; severe rashes; anal fissures, hemorrhoids
- Musculoskeletal: frontal bossing, rachitic rosary, extremity bowing, wrist widening, edema, decreased muscle mass
- Skin: eczema; hives; scaling; spoon-shaped nails; patterned bruises, scars, burns
- Neurologic: cranial nerve palsies, hyper- or hypotonia, retention of primitive reflexes

DIAGNOSTIC TESTS & INTERPRETATION

Initial Lab Tests

- CBC: anemia; leukemia
- Comprehensive metabolic panel (CMP), phosphorus: malnutrition;

metabolic abnormalities; chronic endocrine, liver, and renal disease

- Thyroid function tests
- UA and culture: renal tubular acidosis, infection

Follow Up Tests & Special Considerations

- Ferritin
- Lead
- Vitamin D
- Purified protein derivative (PPD)
- HIV, hepatitis B and C
- Stool pathogens, Giardia antigen
- Stool fat
- Sweat test
- Serum IgA, antitransglutaminase antibodies: celiac disease
- Karyotype: Turner syndrome

Diagnostic Procedures/Other

- Wrist x-rays: bone age
- Chest x-ray: cardiac anomalies, cystic fibrosis
- Lateral neck x-ray: adenotonsillar hypertrophy
- Skeletal survey: suspected maltreatment
- Upper GI series, pH probe: anatomic abnormalities, reflux
- ECG

TREATMENT

MEDICATION

Medications that stimulate appetite and growth hormone therapy have not been extensively studied in FTT. Nutritional supplements and calorie-dense foods help promote catch-up growth.

ADDITIONAL THERAPIES

- Community-based nutritional and psychosocial counseling program when no underlying illness. Multidisciplinary interventions including home nursing visits improve weight gain, parent–child relationships, and cognitive development.
- Goal is catch-up growth (growth faster than normal rate for age).

Normal growth rates for age average about 30 g/day until 3 months, 20 g/day from 3 to 6 months, 10 g/day from 6 to 12 months, and 8 g/day from 1 to 3 years.

- Daily multivitamins, zinc, and iron

ISSUES FOR REFERRAL

- **Subspecialty consultation**
 - Minimize risk of refeeding syndrome
 - Genetic syndrome or disease suspected

INPATIENT CONSIDERATIONS

Hospitalize when

- FTT persists despite community-based dietary interventions
- Severe malnutrition. Weight for age <60% of median or weight for height <70% of median increases morbidity.
- Suspicion of abuse or neglect; note, this necessitates mandatory CPS report.

ONGOING CARE

Monitoring should continue until weight for height deficit is repaired and child no longer needs a specialized diet to maintain normal growth. The Centers for Disease Control and Prevention (CDC) suggests World Health Organization growth charts for all children up to age 2 years and CDC growth charts for older children. Specialty growth charts for patients with genetic conditions can supplement these charts.

CODES

ICD10

- P92.6 Failure to thrive in newborn
- R63.4 Abnormal weight loss
- R63.3 Feeding difficulties

FAQ

- Q: How should weight gain while hospitalized be interpreted?
- A: Children with and without medical illnesses will grow with sufficient caloric intake. Growth during hospitalization is not diagnostic of inorganic FTT.
- Q: How often is organic disease the cause of FTT?
- A: Organic disease is rare in children with FTT who are otherwise asymptomatic.

FEEDING DISORDERS

Elizabeth J. Hait

BASICS

DESCRIPTION

- Feeding disorder: inability to consume by mouth in quantity or quality the nutrition that is developmentally appropriate for that child
- Dysphagia: disorder of swallowing characterized by difficulty in oral preparation for the swallow or in moving food or liquid from the mouth to the stomach
- Aspiration: Food or fluid enters the trachea and passes through the vocal cords to lungs.
- Penetration: Food or fluid enters the trachea but remains above vocal cords and can be cleared by patient through coughing to prevent aspiration.
- Oral motor disorder: inability to manipulate age-appropriate diet; often related to incoordination of facial muscles and/or tongue
- Pharyngeal dysphagia: inability to protect airway during swallow; may be due to anatomic abnormality or neurologic dysfunction
- Voluntary food or fluid refusal associated with maladaptive interactions at mealtimes; associated with learned fear when foods or textures are advanced before a child is developmentally or medically ready to swallow without dysfunction

RISK FACTORS

- Congenital heart disease
- Cystic fibrosis
- Metabolic disorders
- Autism spectrum disorder
- Developmental delay/cerebral palsy
- Prolonged tube feeders (>4 weeks)
- Prematurity
- Neuromotor dysfunction
- Anatomic deformities (i.e., Pierre Robin sequence, laryngomalacia,

tracheotomy, cleft palate)

- GI disorders: gastroesophageal reflux, eosinophilic esophagitis, celiac disease
- Tachypnea (respiratory rate >40 breaths per minute)

GENERAL PREVENTION

- Monitor weight, height, head circumference, weight for height, and BMI percentiles at regular interval office visits to identify changes in nutritional status early, especially in high-risk populations.
- Selective eater: Educate parents on age-appropriate portion sizes and foods.
- Provide vitamin and mineral supplementation or refer to nutritionist for complete assessment if patient is at risk for deficiencies.
- Developmental delay: Evaluate diet and feeding skills to manipulate nutrition provided.
- Ensure foods offered match developmental readiness rather than chronologic age.

DIAGNOSIS

HISTORY

- Past and present medical diagnoses
- Therapeutic management or procedures in past or at present, especially those aversive to face and upper body (e.g., suctioning, tracheostomy, intubation)
- 24-hour diet: Recall food and fluid consumed over a 24-hour period.
- Previous hospitalizations, especially those involving respiratory illnesses
- Allergies or food intolerances
- Growth history
- Developmental history
- History of snoring or sleep apnea (may indicate adenoidal or tonsillar hypertrophy)
- GI history: stool pattern, vomiting, gagging, spitting up, pain
- Family history: GI disease, allergies, developmental delays, genetic

abnormalities

- Failure to thrive
 - Poor linear growth
 - Sucking and swallowing incoordination: Infant should demonstrate 1:1:1 suck, swallow, breathe pattern when sucking from breast or bottle.
 - Recurrent pneumonia
 - Coughing during or after feeding
 - Refractory asthma
 - Drooling
 - Refusal to drink or eat
 - Feeding selectivity
 - Difficulty with texture progression

PHYSICAL EXAM

- HEENT: dysmorphic facial features, shape of head and sutures, facial tone, intact soft and hard palate, shape of mandible, tonsillar size, patency of nares, movement of lips and tongue, presence of stridor, mouth closure, dentition, drooling
- Pulmonary: rate of breathing, use of accessory muscles for respiration, rales
- Cardiac: murmur, rate, and rhythm
- GI: bowel sounds, masses, stool palpable, tenderness, distension
- Neurologic: tone, positioning, cranial nerves, gait, affect, head control
- Extremities: subcutaneous stores, muscle development, adipose tissue
- Skin: rashes, alopecia

DIAGNOSTIC TESTS & INTERPRETATION

Perform feeding observation: Watch caregiver feed child, preferably thru 1-way observation mirror. Monitor child's behavioral response to placement in the feeding chair and presentation of bottle, breast, or cup and a variety of food types and textures; observe parental reaction to child's behaviors and child's ability to manipulate foods and fluids.

Lab

- Tailor labs obtained based on nutritional and/or developmental concerns, including the following:

- Failure to thrive: celiac panel, CBC, comprehensive metabolic panel, lead, urine analysis, thyroid function; other tests if suspect vitamin or mineral deficiency (i.e., zinc, iron)
- Developmental and/or genetic concerns: chromosomes, FISH test for 22q11 deletion, FISH test for Prader-Willi syndrome, fragile X (males), serum and urine organic acids, lactate, pyruvate, CPK
- Sweat test if suspected cystic fibrosis: failure to thrive, diarrhea, and/or recurrent pulmonary infections

Imaging

- Tests indicated based on history and physical
- Suspected pharyngeal dysphagia: modified barium swallow study (MBSS) (videofluoroscopic swallow study) evaluates swallow function and can visualize aspiration during swallow; usually performed by radiologist and speech therapist. Study visualizes function of pharyngeal muscles and structures. See below:
 - Upper GI series (including esophagram) ensures normal anatomy of esophagus, stomach, and duodenum (evaluate for TEF, malrotation).
 - Chest x-ray: determine if infiltrates or atelectasis is present; right upper and/or middle lobe changes indicative of potential aspiration.
 - Gastric emptying scan: Assess gastric emptying and assess if gastroparesis is present
 - Salivagram: radionucleotide study to evaluate if patient is aspirating oral secretions
 - Chest CT scan: allows detection of subtle changes from silent aspiration not detectable by pulmonary exam or chest x-ray

Diagnostic Procedures/Other

- MBSS
 - Speech therapist feeds a variety of textures: thin and thickened liquid of honey and nectar consistency, thin and thick purees, and chewable foods to determine safety of oral feeding.
 - Allows visualization of oral and pharyngeal phases of swallowing
 - Can determine appropriate positioning and type of infant bottles and cups to minimize the risk for aspiration
 - Timing of aspiration is evaluated to determine if volume and fatigue result in aspiration; the patient may be safe to drink or eat for short

periods of time before the swallow becomes uncoordinated and leads to aspiration.

- Fiberoptic endoscopic evaluation of swallowing (FEES)
 - Usually performed by ENT specialist; direct visualization of airway structures and swallowing mechanism
 - Provides information on pharyngeal phase of swallowing but not oral phase. Best used if pharyngeal or laryngeal abnormality is suspected, tracheostomy in place, and there is difficulty managing secretions.
 - Can observe food or fluid falling below vocal cords (aspiration)
- Bronchoscopy
 - Visualizes tracheobronchial tree and lungs, sample for lipid-laden macrophages in lungs indicative of aspiration
- Endoscopy
 - To perform esophageal, gastric, and small bowel biopsies to determine presence of eosinophilic esophagitis, celiac disease (positive or inconclusive celiac panel), or presence of gastroesophageal reflux disease (GERD)

DIFFERENTIAL DIAGNOSIS

- Cardiorespiratory
 - Congenital heart disease
 - Infectious pneumonia
 - Bronchopulmonary dysplasia
- Neurologic
 - Diencephalic syndrome
 - Congenital myopathy
 - Arnold-Chiari malformation
 - Hypoxic-ischemic encephalopathy
- GI/nutritional
 - GERD
 - Gastroparesis
 - Eosinophilic esophagitis
 - Failure to thrive
 - Celiac disease
- Metabolic syndromes

- Psychological disorders
 - Behavioral refusal
 - Psychosocial deprivation
 - Anxiety disorder
- Food allergies
- Anatomic
 - Laryngeal cleft
 - Tracheoesophageal fistula
- Genetic disorders
- Developmental disorders:
 - Autistic spectrum disorder
 - Sensory integration disorder

TREATMENT

- Pharyngeal dysphagia: Pulmonary referral, oral stimulation program, NPO as indicated by clinical exam and studies, initiate tube feeds; monitoring by speech therapist
- Feeding disorders are complex and should be evaluated and managed by multidisciplinary team involving medical, nutrition, psychology, occupational therapy, and speech therapy.

MEDICATION

Medications are administered to treat underlying medical condition (e.g., GERD); refer to specific sections for treatment of identified medical issues resulting in feeding disorder.

ADDITIONAL TREATMENT

General Measures

- Calorie counts
- Ensure adequate hydration

ADDITIONAL THERAPIES

- Obtain a list of all supplemental vitamins, minerals, herbs, etc., that the parent may be providing to the patient.
- Investigate if parent is following any special diets (e.g., casein/gluten-

free diet in autistic spectrum disorder).

COMPLEMENTARY & ALTERNATIVE THERAPIES

- Speech therapy: Evaluate oral motor skill and safety of swallowing mechanism; perform MBSS when indicated.
- Occupational therapy: Evaluate fine motor skills, sensory processing, and posture to support feeding.
- Psychology: may identify behaviors interfering with food acceptance and recommend strategies to improve oral acceptance
- Nutrition: Perform complete nutritional assessment, including evaluation of growth parameters, identifying patient's nutrition requirements, and adequacy of current diet. The nutritionist can develop a care plan to meet patient's nutritional requirements and monitor intake and weight gain during hospitalizations.

SURGERY/OTHER PROCEDURES

- Consider gastrostomy tube placement if tube feedings for >3 months are anticipated.
- For GERD not responding to medications, consider bypassing stomach and feeding into intestine with jejunostomy tube or placement of gastrostomy tube in conjunction with Nissen fundoplication.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Prior to initiation of behavioral program, ensure weight gain and growth are adequate.
- Evaluate and treat vitamin and mineral deficiencies.
- If weight-for-height ratio or BMI is <5%, inappropriate weight gain crossing down 2 percentiles on growth chart occurs, or weight loss occurs, consider initiating supplemental nasogastric tube feeds.
- If aspiration pneumonia is suspected, obtain blood cultures, chest x-ray; keep NPO and start IV fluids and antibiotics. Measure oxygen saturation and initiate supplemental oxygen if <95%.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Appointment with multidisciplinary feeding team, if available within reasonable geographic radius

Patient Monitoring

- Patient's weight should be checked within 2 weeks of discharge.
- Pediatrician should monitor patients with respiratory difficulties related to aspiration every 2 weeks until stable.

DIET

- Keep patient NPO if aspiration is suspected until further evaluation (MBSS) can be performed.
- Order diet appropriate for child's current level of feeding skills (i.e., accepts baby food; may trial pureed diet).
- If nutritional intake is inadequate, offer nutritional supplements, monitor calorie counts, and initiate supplemental nasogastric tube feeds if unable to meet nutritional requirements.
- Caregiver education regarding administration of supplemental tube feeds

PROGNOSIS

- Nutritional rehabilitation can be achieved with tube feedings if patient is monitored closely.
- Patients with pharyngeal dysphagia resulting in aspiration may improve over time.
- Static or degenerative neurologic conditions resulting in aspiration generally do not resolve.
- Patient demonstrating dysphagia during illness may improve when healthy.

CODES

ICD10

- R63.3 Feeding difficulties
- R13.10 Dysphagia, unspecified
- T17.928A Food in resp tract, part unsp causing oth injury, init

FAQ

- Q: What is the difference between aspiration and penetration in a swallowing disorder?
- A: Penetration occurs when food or fluid enter the trachea but remains above the vocal cords and is cleared by the patient. Aspiration occurs when the food or fluid falls below the vocal cords, thus entering the lungs.
- Q: How is a modified barium swallow study used to evaluate dysphagia?
- A: A speech therapist in conjunction with the radiologist feeds the patient a variety of textures, including thin and thickened liquids, thin honey and nectar, thick purees, and chopped food if indicated, visualizing the pathway during swallowing to determine if it moves safely into the esophagus without entering the airway. The speech therapist also will engage in therapeutic endeavors, such as repositioning the patient, to determine if they can eliminate aspiration.

FETAL ALCOHOL SYNDROME

Tracey A. McLean • Seth J. Bokser

BASICS

DESCRIPTION

- The four major features of classic fetal alcohol syndrome (FAS) are as follows:
 - CNS neurodevelopmental abnormalities
 - Facial dysmorphisms
 - Growth retardation
 - Maternal alcohol use during pregnancy.
- First described in 1973; classic FAS has since been recognized as one of the fetal alcohol spectrum disorders (FASDs), which include the following:
 - FAS, partial FAS (pFAS), alcohol-related neurodevelopmental disorder (ARND), and alcohol-related birth defects (ARBD)
 - Taken together, FASDs are three times more common than classic FAS, and the effects range from very mild symptoms to very severe.

EPIDEMIOLOGY

Incidence

- Classic FAS: 3.1 per 1,000 live births
- FASDs: 9.1 per 1,000 live births

RISK FACTORS

- Binge drinking seems to be the primary risk factor.
- The highest prevalence of reported alcohol use during pregnancy are among those who are aged 35–44 years, white, college graduates, or employed.
- Poor maternal nutrition appears to increase risk in the presence of maternal binge drinking.
- Maternal polymorphisms of the alcohol dehydrogenase gene (ADH): The presence of the ADH1B*3 allele appears to protect the fetus.
- Concordance of FAS is higher in monozygotic than in dizygotic twins.

GENERAL PREVENTION

- Women who are pregnant or may become pregnant should avoid alcohol. No “safe” level of alcohol consumption has been determined during pregnancy.
- Women with alcohol addiction who are or may become pregnant should enter a treatment program.
- According to the Centers for Disease Control and Prevention (CDC), 7.6% of pregnant women reported alcohol use during the month prior to being surveyed and 1.4% reported binge drinking.
- The highest risk for FAS occurs in children whose mothers consume ≥ 4 drinks per occasion per week (peak blood alcohol level is more important than a lower sustained blood alcohol level).
- In the United States, Alcoholic Beverage Labeling Act passed in 1998 requires health warning labels, including risk of alcohol consumption during pregnancy.

PATHOPHYSIOLOGY

- Malformation of the developing brain is the primary pathophysiologic event resulting in secondary neurodevelopmental pathology and facial dysmorphisms in classic FAS.
- May involve increased susceptibility to cell damage by free radicals in the developing fetus, especially in the first trimester
- Alcohol and its metabolite acetaldehyde are teratogens.

DIAGNOSIS

HISTORY

- Neurodevelopmental and behavioral symptoms. No specific neurobehavioral pattern has been defined. See below for examples of age-specific presentations.
- Fine motor function abnormalities may be present.
- Birth and subsequent growth deficit (weight, height, head circumference)
- Maternal history of alcohol use (binge drinking, average number of drinks per day, timing in pregnancy) and other drug use

- Family history
 - Neurobehavioral abnormalities may not be typical of other family members who were not exposed to alcohol prenatally.
- Neurobehavioral problems in infancy:
 - May or may not have alcohol withdrawal as newborn
 - Irritability, irregular sleep, poor feeding, hypotonia, delayed motor function
- Neurobehavioral problems in preschool and school age:
 - Hyperactivity
 - Slow verbal learning
 - Slow visual–spatial learning
 - Poor abstract thinking (planning and organizing)
 - Perseveration (inability to abandon ineffective strategies)
 - Attention problems
 - Difficulty with peer interactions
- Neurobehavioral problems in adolescence and adulthood:
 - Substance abuse
 - Criminal behavior
 - Inability to work
 - Inability to live independently

PHYSICAL EXAM

- Birth weight (≤ 10 th percentile)
- Birth length (≤ 10 th percentile)
- Microcephaly at birth (≤ 10 th percentile)
- Postnatal growth deficiency persists throughout life.
- Facial manifestations include the following:
 - Short palpebral fissures (measurement from inner to outer canthus of eyes)
 - Long and smooth philtrum (area from nasal septum to vermilion border of lip)
 - Thin vermilion border (upper lip)
- Ptosis, epicanthal folds, and flat face are also common in FAS.

DIAGNOSTIC TESTS & INTERPRETATION

Neuropsychological testing

- Simple IQ tests cannot distinguish children with FAS from those with other developmental disabilities.
- No specific neurobehavioral phenotype yet defined

Lab

No laboratory marker exists for FAS.

Diagnostic Procedures/Other

Classic FAS diagnosis requires all four of the following markers.

- Facial features:
 - Short palpebral fissures (≤ 10 th percentile)
 - Thin vermilion border upper lip (score of 4 or 5 on the lip/philtrum guide [see [Astley](#) reference])
 - Smooth philtrum (4 or 5 on lip/philtrum guide)
 - Other findings such as ptosis; maxillary hypoplasia; and short, upturned nose are not diagnostic but are commonly seen in children with FAS.
- Documentation of growth deficits
 - Height or weight ≤ 10 th percentile at any time in patient's history
- Documentation of CNS abnormality (any 1 below)
 - Structural
 - Structural brain abnormalities (e.g., agenesis of corpus callosum, cerebellar hypoplasia)
 - Neurologic
 - Seizures, poor coordination, impaired memory, or other soft neurologic signs not attributable to postnatal insult or fever
 - Functional: performance substantially below that expected for an individual's age and circumstances, as evidenced by either
 - Global cognitive deficits (IQ or developmental delays in multiple domains) > 2 standard deviations (SD) below the mean OR
 - Functional deficits 1 SD below the mean in at least 3 specific domains (e.g., attention, executive functioning, motor functioning, social skills, language, or specific learning disabilities)
- Maternal alcohol exposure
 - Confirmed maternal exposure to alcohol is defined as substantial regular intake or heavy episodic drinking.

- Evidence may include self-report or that of a reliable informant, medical records showing an elevated blood alcohol level or alcohol-related medical problems (e.g., hepatic disease), and legal problems related to drinking.
- If there is no available history, or conflicting reports, then diagnosis can be “FAS without confirmed maternal alcohol exposure.”

DIFFERENTIAL DIAGNOSIS

- By physical features
 - Normal variant
 - Aarskog syndrome
 - Williams syndrome
 - Noonan syndrome
 - Brachmann-De Lange syndrome
 - Dubowitz syndrome
 - Fetal valproate syndrome
 - Fetal hydantoin syndrome
 - Maternal phenylketonuria fetal effects
 - Toluene embryopathy
- By neurobehavioral features
 - Fragile X syndrome
 - 22q11 deletion syndromes
 - Turner syndrome
 - Opitz syndrome

TREATMENT

GENERAL MEASURES

- The role of the pediatrician is early identification, appropriate referrals, and development of a multidisciplinary case plan, including the pediatrician, specialists, early intervention providers, psychologists, and social and educational resources in the community to support family and child.
- Specific medical referrals should include
 - Comprehensive neuropsychological evaluation (IQ, achievement,

executive function, memory, adaptive function, language, reasoning and judgment, behavior)

- Ophthalmologic exam (consider routine screening prior to school, then every 2 years)
- Hearing test (consider brainstem auditory evoked response [BAER] at 6–12 months)

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Growth and nutrition in infancy: Failure to thrive is a common problem.
- Regular evaluations of vision and hearing: Problems occur at a high rate.
- As indicated by other medical/psychological problems

PROGNOSIS

- 50% have intellectual disability (IQ <70). Average IQ in individuals with FAS is in the 60s (mild mental retardation); however, a wide range of IQ exists, from 16 to 115.
- 62% have severe behavioral problems, even if a normal IQ exists.
- The major disabilities of FAS caused by the neurocognitive/neurobehavioral effects can lead to poor academic performance, legal problems, employment difficulties, and secondary mental health problems.
- Many are unable to live independently as adults.

CODES

ICD10

- Q86.0 Fetal alcohol syndrome (dysmorphic)
- P04.3 Newborn affected by maternal use of alcohol

FAQ

- Q: What is partial FAS?
- A: No diagnostic consensus; however, criteria include two of the key facial features, growth retardation OR CNS involvement, and confirmed prenatal alcohol exposure.
- Q: What is ARND?

- A: No diagnostic consensus; however, criteria include CNS involvement with functional impairment and onset in childhood, facial features and growth retardation not necessary (but may be present), not better explained by other conditions (teratogens, genetic, neglect), and confirmed prenatal alcohol exposure.
- Q: How much alcohol does it take to produce damage?
- A: The highest risk for FAS occurs in children whose mothers consume ≥ 4 drinks per occasion at least once per week. However, NO minimum safe level of alcohol consumption has been determined
- Q: Do most children with FAS have ADHD?
- A: Although hyperactivity appears to be common in FAS, many of these children are misdiagnosed as having ADHD. Instead of difficulty focusing and sustaining attention, children with FAS often have difficulty shifting attention from one task to another. Use of stimulant medication is not routinely supported, although a small proportion may respond to stimulant medication in educational settings.

FEVER AND PETECHIAE

Angela M. Statile • Craig H. Gosdin

BASICS

DESCRIPTION

- Petechiae
 - Small hemorrhages (<3 mm in size) into the superficial layers of the skin
 - Manifest as a reddish purple, macular, nonblanching skin rash
- Purpura
 - Larger skin hemorrhages (>3 mm in size)
 - Often macular like petechiae but may be raised or tender

EPIDEMIOLOGY

- Most patients (70–80%) presenting with fever and petechiae have defined or presumed viral infections, which are often caused by enteroviruses or adenovirus.
 - Parvovirus B19 may also be responsible for many cases of fever and generalized petechiae in children.
- Approximately 0.5–11% of children presenting with fever and petechiae will have an invasive bacterial disease, most commonly *Neisseria meningitidis*.
 - Infants and toddlers are at greatest risk of having an invasive bacterial infection with fever and petechiae.
 - Teenagers and young adults are most commonly affected by outbreaks of meningococemia, presenting with fever and petechiae.
- Streptococcal pharyngitis may cause fever and petechiae in the well-appearing child.
- Other etiologies, such as acute leukemia, idiopathic thrombocytopenic purpura (ITP), and Henoch-Schönlein purpura (HSP), are responsible for a minority of cases of fever and petechiae.

GENERAL PREVENTION

- Vaccine recommendations

- All children should complete the *Streptococcus pneumoniae* and *Haemophilus influenzae* type B immunization series that begins at 2 months of age.
- Routine childhood immunization with meningococcal vaccine is recommended for all children at 11–12 years of age and a booster dose at 16–18 years of age.
- Infants and children at high risk for meningococcal disease such as those with asplenia or terminal complement deficiencies should receive meningococcal vaccine as early as 2 months of age.
- Annual immunization against influenza viruses is recommended for all children >6 months of age.
- Chemoprophylaxis is recommended for close contacts of patients with meningococcal disease. Ideally, treatment should begin within 24 hours; rifampin is the drug of choice in most children (dosing <1 month of age: 5 mg/kg PO every 12 hours × 2 days, ≥1 month of age: 10 mg/kg PO every 12 hours × 2 days). Alternatives include ceftriaxone, ciprofloxacin, and azithromycin.

PATHOPHYSIOLOGY

Petechiae may result from several different mechanisms:

- Disruption of vascular integrity—due to infections, vasculitis, or trauma
- Platelet deficiency or dysfunction—typically thrombocytopenia due to sepsis, disseminated intravascular coagulation (DIC), ITP, or leukemia
- Factor deficiencies, although these are more likely to manifest as ecchymoses or deep bleeding

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Viral infections (see “[Etiology](#)”)
- Invasive bacterial infections
 - Most commonly *N. meningitidis*
 - Less often *Staphylococcus aureus* or other bacteria (see “[Etiology](#)”)
- Streptococcal pharyngitis—due to *Streptococcus pyogenes*

- Rickettsial infections: diagnosis aided by season, history of tick bite accompanied by fever, petechiae, headache, and myalgias
- Petechiae above the nipple line may be noted after significant coughing or vomiting.
- Coining or other traumatic causes
- Acute leukemias: diagnosis aided by clinical findings of pallor, adenopathy, hepatosplenomegaly, and laboratory findings
- ITP: diagnosis aided by findings of mucous membrane bleeding and isolated thrombocytopenia on laboratory testing
- HSP: diagnosis aided by clinical findings consistent with HSP, including palpable purpura on dependent areas such as the buttocks and lower extremities, often without fever
- Endocarditis: diagnosis aided by bacteremia and a history of congenital heart disease, cardiac surgery, or rheumatic fever

ETIOLOGY

Petechiae, when accompanied by fever, most often have an infectious cause. Multiple organisms are associated with fever and petechiae. Less commonly, fever and petechiae may be caused by other entities such as acute leukemia, ITP, HSP, and bacterial endocarditis.

- Bacterial
 - *N. meningitidis*
 - *S. pneumoniae*
 - *H. influenzae* type B
 - *S. aureus*
 - *S. pyogenes*
 - *Escherichia coli*
- Viral
 - Enterovirus
 - Adenovirus
 - Influenza
 - Parainfluenza
 - Parvovirus B19
 - Epstein-Barr virus (EBV)
 - Rubella
 - Respiratory syncytial virus

- Hepatitis viruses
- Rickettsial diseases
 - Rickettsia rickettsii
 - Ehrlichiosis

ALERT

Unsuspected invasive bacterial disease is the most common pitfall in the differential diagnosis of fever and petechiae. A thorough history and physical exam accompanied by laboratory testing, a period of close observation, and empiric antimicrobial therapy may minimize missed serious diagnoses.

HISTORY

Important historical factors to obtain include the following:

- Age of the child
- Any underlying immunodeficiency
- Immunizations received
- Exposure to infectious contacts, particularly N. meningitidis
- Duration and height of fever
- Duration and progression of rash
- Excessive coughing or vomiting
- Pallor or other bleeding
- Level of activity, excess fatigue
- Travel or history of tick bites
- History of trauma in location of rash

PHYSICAL EXAM

- Important components of exam:
 - Vital signs, noting tachycardia, hypotension, or delayed capillary refill
 - Mental status
 - Meningismus/nuchal rigidity
 - Character of rash: petechiae or purpura, body distribution, number of lesions, progression during exam
- Important findings suggesting specific diagnoses:
 - **Finding:** Pallor, adenopathy, organomegaly
 - **Significance:** May suggest leukemia, EBV infection

- **Finding:** Mucous membrane bleeding
- **Significance:** May suggest thrombocytopenia, such as with ITP
- **Finding:** Headache, myalgias, centripetal rash distribution
- **Significance:** May suggest Rocky Mountain spotted fever

DIAGNOSTIC TESTS & INTERPRETATION

Most children with fever and petechiae require laboratory testing. Consider obtaining a CBC with differential, C-reactive protein (CRP), and a blood culture even in non-toxic-appearing children.

- Consider rapid antigen testing for group A Streptococcus and throat culture if with signs of pharyngitis.
- Children who are ill-appearing may warrant lumbar puncture for cerebrospinal fluid (CSF) studies and coagulation studies including prothrombin time (PT), partial thromboplastin time (PTT), and DIC screen.
- Viral testing, including cultures, serology, and antibody immunofluorescence, is not routinely required and may be ordered at the discretion of the managing practitioner based on exposures, need for specific therapeutic interventions, admission to the hospital, and severity of illness.
- Although no one factor is 100% sensitive in identifying children with invasive bacterial disease, a constellation of factors is useful in identifying children with fever and petechiae in whom invasive bacterial disease is unlikely:
 - Multiple studies have demonstrated that well-appearing children with a normal WBC count (between 5,000 and 15,000 cells/microliter), a normal absolute neutrophil count (between 1,500 and 9,000 cells/microliter), an absolute band count <500 cells/microliter, and petechiae limited to above the nipple line are exceedingly unlikely to have an invasive bacterial infection. A CRP <6 mg/L has also been shown to have a high negative predictive value for ruling out invasive bacterial infection.

TREATMENT

MEDICATION

- Empiric antibiotic use should be decided on a case-by-case basis. Due to the high morbidity and mortality of *N. meningitidis*, the most likely bacterial pathogen in this circumstance, empiric ceftriaxone should be strongly considered in children with fever and petechiae who are not at low risk for bacterial infection.
- 3rd-generation cephalosporins such as ceftriaxone and cefotaxime are effective against most bacterial pathogens causing fever and petechiae.
- Doxycycline should be administered if rickettsial disease is considered.
- Vancomycin should be added to the regimen for children with suspected bacterial meningitis to cover penicillin and cephalosporin-resistant strains of *S. pneumoniae*.

INPATIENT CONSIDERATIONS

Initial Stabilization

- The management of children who are ill-appearing and have meningismus or purpura consists of a full sepsis evaluation, admission to the hospital with parenteral antibiotics, and fluids and vasoactive infusions to maintain normal hemodynamics.
- Because sporadic as opposed to epidemic cases of meningococcemia appear to occur in children in the first 2 years of life, and these children have less competent immune systems in fighting encapsulated organisms, full sepsis evaluation and admission for all children in this young age group are recommended.
- The well-appearing child with fever and petechiae and a positive streptococcal antigen test and an illness compatible with streptococcal pharyngitis may be treated as an outpatient with antistreptococcal antibiotics.
- After a several-hour period of observation, children who remain well-appearing, are not tachycardic, have no progression of petechiae, and have normal lab studies may be considered for management as outpatients.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Children managed as outpatients:
 - Give instructions to return immediately for progression of rash or worsening illness.
 - Follow-up in 12–18 hours.
 - Monitor cultures closely.
- Most children with viral causes have little progression of their petechiae and are clinically better within several days with the resolution of fever.

PROGNOSIS

- Depends on the underlying cause
- Because most cases of fever and petechiae are caused by viral infections, particularly enteroviruses and adenovirus, the prognosis is excellent.
- Case fatality rate of meningococemia is 10–14%.

COMPLICATIONS

- Related to the underlying cause
- Most common complications of invasive bacterial disease causing fever and petechiae include sepsis and meningitis.
- Serious sequelae from *N. meningitidis* occur in 11–19% of patients and include neurologic deficits such as hearing loss, digit or limb loss, and skin scarring.

CODES

ICD10

- R50.9 Fever, unspecified
- R23.3 Spontaneous ecchymoses
- D69.2 Other nonthrombocytopenic purpura

FAQ

- Q: What are the most common causes of fever and petechiae in children?
- A: Viruses are the most common overall cause of fever and petechiae in children. The most common invasive bacterial disease causing fever and petechiae in children is *N. meningitidis*.
- Q: Is there ever a role for outpatient management of children with fever and petechiae?
- A: Practitioners may consider outpatient management in well-appearing children >2 years of age with the following criteria after a period of close observation in which they have normal vital signs and no progression of petechiae:
 - A normal WBC count (between 5,000 and 15,000 cells/microliter)
 - A normal absolute neutrophil count (between 1,500 and 9,000 cells/microliter)
 - An absolute band count <500 cells/microliter
 - A CRP <6 mg/L

FEVER OF UNKNOWN ORIGIN

Samir S. Shah

BASICS

DESCRIPTION

Fever of unknown origin (FUO) implies

- A febrile illness (38.3°C on multiple occasions)
- Present for >14 days
- No apparent source despite careful history taking, physical exam, and preliminary lab studies

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

FUO is more often an unusual presentation of a common disease than a common presentation of an unusual disease. Possible causes include the following:

- **Common infectious causes**
 - Respiratory infections (otitis media, mastoiditis, sinusitis, pneumonia, pharyngitis, peritonsillar/retropharyngeal abscess)
 - Systemic viral syndrome
 - Infectious mononucleosis (Epstein-Barr virus [EBV], cytomegalovirus [CMV])
 - Urinary tract infection (UTI)
 - Bone or joint infection
 - Enteric infection (Salmonella, Yersinia enterocolitica, Yersinia pseudotuberculosis, Campylobacter jejuni)
 - Cat-scratch disease
- **Less common infectious causes**
 - Tuberculosis (TB)
 - Lyme disease
 - Rickettsial disease (Rocky Mountain spotted fever, ehrlichiosis, anaplasmosis)

- Malaria
- CNS infection (bacterial or viral meningoencephalitis, intracranial abscess)
- Dental or periodontal abscess
- Subacute bacterial endocarditis (SBE)
- HIV infection
- Acute rheumatic fever
- **Other infectious causes**
 - Q fever
 - Brucellosis
 - Toxoplasmosis
 - Syphilis
 - Parvovirus B19
 - Endemic fungi (histoplasmosis, blastomycosis, coccidioidomycosis)
 - Psittacosis
 - Typhoid (*Salmonella* spp.)
 - Chronic meningococcemia
- **Possible noninfectious causes**
 - Collagen vascular disease (systemic juvenile idiopathic arthritis [JIA], systemic lupus erythematosus, dermatomyositis, sarcoidosis, vasculitis syndrome)
 - Malignancy
 - Kawasaki syndrome
 - Inflammatory bowel disease (IBD)
 - Drug fever
 - Hyperthyroidism
 - Factitious fever or Munchausen syndrome by proxy
 - Centrally mediated fever
 - Periodic fever syndrome
 - Kikuchi-Fujimoto disease (histiocytic necrotizing lymphadenitis)

ETIOLOGY

Etiology has changed as the use of more sensitive tests (e.g., MRI, polymerase chain reaction [PCR] tests) permits earlier detection of many conditions that caused FUO in the past. Fever resolves in 40–60% of children without identification of a specific cause.

APPROACH TO THE PATIENT

Find the cause of the fever and begin treatment of the underlying illness.

- **Phase 1**
 - Document fever.
 - Thorough history and physical exam
 - Determine whether constitutional symptoms (e.g., growth failure, developmental arrest) suggest a serious underlying disease.
 - Create broad differential diagnosis.
 - Begin initial laboratory evaluation while tailoring the cadence of evaluation to patient's severity of illness.
- **Phase 2**
 - Begin invasive studies to seek rarer forms of fever, such as lymphoma, brucellosis, and SBE, only if clinically indicated.
- **Phase 3**
 - Reexamine patient, consider additional testing, and reconsider causes such as systemic JIA, sarcoidosis, and factitious fever.

Repeat history and physical exam combined with the results of previous testing should guide the subsequent evaluation.

HISTORY

Initial studies should include a CBC, liver function tests, blood culture, urinalysis, urine culture, stool culture, and stool ova and parasite testing.

- **Question:** Temperatures and how they were measured (tympanic, oral, axillary, rectal)?
- **Significance:**
 - As many as 50% of children referred for evaluation of FUO have multiple unrelated infections, parental misinterpretation of normal temperature variation, or complete absence of fever at time of evaluation.
 - Parents are sometimes told to add a 1–2°F “correction” onto a temperature measured in the axilla to better approximate the core temperature. Such practices may further cloud the evaluation of the febrile child.
- **Question:** Ethnicity?
- **Significance:** Some hereditary periodic fever syndromes have ethnic predilection. Consider familial Mediterranean fever (Armenian, Arab,

Turkish, Sephardic Jew), hyper-IgD syndrome (Dutch, French), and tumor necrosis factor receptor–associated periodic fever syndrome (TRAPS) (Irish, Scottish)

- **Question:** Exposure to animals?
- Significance
 - Household exposures including pets and rodents
 - Recreational activities (e.g., hunting)
 - Household contacts with occupational exposure to animals
 - Consider cat-scratch disease, brucellosis, tularemia, leptospirosis, and lymphocytic choriomeningitis virus (from mice)
- **Question:** Ingestion of raw meat, fish, or unpasteurized milk?
- Significance: Trichinosis, brucellosis
- **Question:** Travel history, including past residence?
- Significance: Malaria, endemic fungi (e.g., coccidioidomycosis in Southwest, blastomycosis in Southeast, histoplasmosis in Midwest), typhoid (Indian subcontinent), TB
- **Question:** Pica or dirt ingestion?
- Significance: Toxocara canis or Toxoplasma gondii infection
- **Question:** Change in behavior or activity?
- Significance: Brain tumor, TB, EBV, Rocky Mountain spotted fever
- **Question:** Pattern of fever?
- Significance: May correlate with underlying cause. A fever diary kept by the parent or caretaker may provide more objective documentation of the fever pattern than simple recall.
- **Question:** Medications (including OTC medications and eyedrops)?
- Significance: Drug fever, atropine-induced fever, methylphenidate, and antibiotics (especially penicillin, cephalosporins, and sulfonamides)
- **Question:** Well-water ingestion?
- Significance: Giardiasis

PHYSICAL EXAM

- **Finding:** Impaired weight gain or linear growth?
- Significance: Collagen vascular disease, malignancy, IBD
- **Finding:** Toxic appearance?
- Significance: Kawasaki syndrome
- **Finding:** Conjunctivitis?

- Significance: Kawasaki syndrome (limbic sparing), adenovirus, measles
- **Finding:** Ophthalmologic exam?
- Significance: Papilledema—consider CNS mass lesion; uveitis—consider TB, systemic lupus erythematosus, Kawasaki syndrome, and sarcoidosis
- **Finding:** Sinus tenderness, nasal discharge, or halitosis?
- Significance: Sinusitis
- **Finding:** Pharyngitis?
- Significance: Kawasaki syndrome, EBV, CMV
- **Finding:** Tachypnea?
- Significance: SBE, pneumonia
- **Finding:** Rales?
- Significance: Histoplasmosis, sarcoidosis, coccidioidomycosis
- **Finding:** Cardiac murmur, gallop, or friction rub?
- Significance: SBE, acute rheumatic fever, pericarditis
- **Finding:** Hepatosplenomegaly?
- Significance: Hepatitis, EBV, CMV, ehrlichiosis, anaplasmosis
- **Finding:** Rectal abnormalities?
- Significance: Pelvic abscess, IBD
- **Finding:** Arthritis?
- Significance: JIA, IBD, acute rheumatic fever
- **Finding:** Bony tenderness?
- Significance: JIA, leukemia, osteomyelitis

DIAGNOSTIC TESTS & INTERPRETATION

The laboratory evaluation for a child with FUO should be directed toward the most likely diagnostic possibilities. Consider the following initial studies:

- **Test:** CBC with differential and careful examination of WBC morphology
- Significance: Kawasaki syndrome, cyclic neutropenia, malignancy, ehrlichiosis, anaplasmosis (morulae in WBC cytoplasm), and babesiosis
- **Test:** ESR, C-reactive protein, or procalcitonin
- Significance: Collagen vascular disease, IBD, occult infection. ESR is

generally normal in drug fever and central fever.

- **Test:** Blood cultures
- Significance: Endocarditis, salmonellosis, other bloodstream infections
- **Test:** Urinalysis and urine culture
- Significance: UTI, Kawasaki syndrome (sterile pyuria)
- **Test:** Tuberculin skin test (by purified protein derivative)
- Significance: TB
- **Test:** Stool bacterial culture and examination for ova and parasites
- Significance: Salmonella, Giardia
- **Test:** Specific antibody testing
- Significance: Depending on clinical suspicion, consider the following:
 - First line: Streptococcal enzyme titers (antistreptolysin O, anti-DNase B); EBV; CMV; cat-scratch disease; Lyme disease; hepatitis A, B, or C; or HIV (by PCR)
 - Second line: Rocky Mountain spotted fever; ehrlichiosis/anaplasmosis, toxoplasmosis, brucellosis, Q fever, leptospirosis, tularemia, dengue fever
- **Test:** Viral testing of nasopharyngeal aspirates
- Significance: systemic viral syndrome (adenovirus)
- **Test:** Evaluation for immune deficiency
- Significance: underlying predisposition
- **Test:** Bone marrow examination and culture
- Significance: Salmonella infection, Mycobacterium avium complex, histoplasmosis, brucellosis, malignancy
- **Test:** Lumbar puncture
- Significance: CNS infection

Imaging

- Guided by history, physical examination, and epidemiologic factors; indiscriminate use of imaging not likely to be helpful.
- Sinus CT: sinusitis
- Chest radiograph: TB, endemic fungi, pneumonia
- Chest and/or abdominal CT scan: TB, liver abscess, hepatosplenic cat-scratch disease
- Pelvic or extremity MRI: osteomyelitis, pyomyositis
- Gallium or bone scan: osteomyelitis, malignancy

CODES

ICD10

R50.9 Fever, unspecified

FAQ

- Q: Do all of the mentioned tests need to be performed?
- A: A “shotgun” approach to testing is rarely useful in making the diagnosis, and unanticipated abnormalities (e.g., false-positives) may lead to additional invasive tests with potential for harm.
- Q: Is hospitalization required for the diagnosis of FUO?
- A: Many tests, including MRI, can now be performed in the outpatient setting. Hospitalization is not routinely required for diagnosis but should be considered in patients who appear ill, have progression of symptoms, or when fever needs to be documented.
- Q: How is cat-scratch disease acquired?
- A: Cat-scratch disease, caused by *Bartonella henselae*, can be acquired through cat (usually kittens or young cats) scratches or licks. Rarely, dogs may transmit the organism. If the family does not own a kitten or young cat, remember to ask about other sources of exposure (e.g.,

friends, family, school trips).

FLOPPY INFANT SYNDROME

Mayada A. Helal • Ronald D. Cohn

BASICS

DESCRIPTION

- “Floppy infant” refers to the newborn/infant presenting at birth or early in life with hypotonia, a symptom of diminished tone of skeletal muscles associated with decreased resistance of muscles to passive stretching.
- Hypotonia can be caused by abnormalities of the CNS (central hypotonia), peripheral neuromuscular system (peripheral hypotonia), or combined abnormality involving both (combined hypotonia).
- Nonspecific transient hypotonia occurs in nonneurologic conditions and may suggest gastrointestinal (GI), cardiac, pulmonary, infectious, renal, or endocrine disease.

EPIDEMIOLOGY

No comprehensive prevalence known owing to presence of hypotonia as a feature of many distinct disorders; overall, central hypotonia is more common than peripheral hypotonia.

RISK FACTORS

Genetics

Substantial proportion (>50%) of infantile hypotonia cases accounted for by genetic-metabolic disorders.

ETIOLOGY

Causes may be divided into two major categories:

- Central: hypotonia with decreased alertness, developmental delay, and lack of or minimal weakness; caused by upper motor neuron defect
- Peripheral: hypotonia with profound weakness, paucity of antigravity movements, decreased or absent deep tendon reflexes (DTRs), and visual alertness; caused by lower motor neuron defect (i.e., disorders of anterior horn cell, peripheral nerve, neuromuscular junction, or skeletal

muscle)

COMMONLY ASSOCIATED CONDITIONS

- Respiratory problems (apnea/hypoventilation)
- Feeding/swallowing difficulties
- Hip dislocation/contractures/joint laxity
- Seizure disorder
- Cognitive/developmental delay
- Hypersomnolence

DIAGNOSIS

History and physical exam findings used to categorize patients as having central, peripheral, or combined hypotonia.

HISTORY

- Pregnancy and delivery
 - Pregnancy
 - Maternal illness
 - Drug or teratogen exposure
 - Abnormalities on prenatal ultrasound
 - Polyhydramnios (poor prenatal swallow)
 - Reduced fetal movements (neuromuscular disorders)
 - Delivery
 - Gestational age and presentation
 - Birth trauma, anoxia, or complications
 - Shortened umbilical cord
 - Low Apgar scores
 - Maternal perinatal infection
- Medical history
 - Seizures
 - Apnea
 - Feeding difficulties
 - Review of systems for associated malformations or health conditions
 - Delayed motor milestones

- Delayed social, fine motor, or language milestones point to CNS defect.
- Course of hypotonia
 - Age at onset
 - Improved or worsened
- Family history
 - Parental consanguinity
 - Three-generation pedigree specifically inquiring about history of neuromuscular disease, birth defects, intellectual disability, and recurrent infantile deaths

PHYSICAL EXAM

Exam findings will help determine if hypotonia is suggestive of an upper motor neuron versus a lower motor neuron problem or both. Perform the following:

- General physical exam
 - Dysmorphic features (may lead to particular syndromic diagnosis)
 - Alertness: Infants with neuromuscular disease are typically alert.
 - Poor spontaneous movements
 - Abnormal head size and/or shape
 - High-arched palate (neuromuscular disorders)
 - Tongue fasciculations (anterior horn cell)
 - Large tongue (storage disorders)
 - Ophthalmologic exam: cataracts (peroxisomal disorders), pigmentary retinopathy (peroxisomal disorders), cherry red spot (storage disorders), lens dislocation (sulfite oxidase/molybdenum cofactor deficiency)
 - Abnormal fat pads, inverted nipples (congenital disorders of glycosylation)
 - Cardiac enlargement and signs of cardiac failure (Pompe disease)
 - Visceral enlargement (storage disorders)
 - Arthrogryposis (central, neuromuscular, or connective tissue disorders)
 - Hip dislocation (intrauterine hypotonia)
 - Joint laxity (connective tissue disorders)
- Neurologic exam

- Strength
 - Low-pitched or progressively weaker cry
 - Poor suck
 - Paucity of facial expression (“myopathic” facies) indicates facial weakness (myotonic dystrophy, congenital muscular dystrophy, congenital myopathies).
 - Ptosis and external ophthalmoplegia (congenital myasthenic syndromes, congenital myopathies, and congenital muscular dystrophies)
 - Regional strength differences: Spinal muscular atrophy (SMA) spares diaphragm, face muscles, and pelvic sphincters. Neuropathies present with distal limb weakness and proximal sparing. Myasthenic syndromes affect bulbar and oculomotor muscles.
- Muscle tone
 - Abnormal resting posture (abducted, externally rotated legs, flaccid arms) and prominent head lag with pull-to-sit
 - Fisting indicates spasticity.
 - Abnormal posture and tone in supine position, ventral and horizontal suspension, and traction
 - Elbow may easily extend beyond midsternum (scarf sign).
 - Generalized hypotonia with increased tone in thumb adductors, wrist pronators, and hip adductors: early cerebral palsy
 - Fatigability: cardinal feature of myasthenic syndromes but may occur in other neuromuscular diseases
- DTRs
 - Hyperreflexia implies central dysfunction.
 - Diminished DTRs in proportion to degree of weakness in myopathic diseases
 - Absent DTRs in setting of minimal weakness typical of neuropathic disease
- Examination of the mother
 - Signs of myotonia (myotonic dystrophy)
 - Handgrip myotonia (inability to release handgrip quickly)
 - Percussion myotonia (inability to release muscle tapped with

reflex hammer), including tongue myotonia, a more reproducible feature than handgrip myotonia

- ▣ Action myotonia (delayed muscle relaxation after voluntary contraction)

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Initial tests may include the following:
 - Electrolytes (including Ca and Mg)
 - Thyroid function tests
 - Creatine kinase (normal in central, may be high in peripheral or combined cases)
 - Arterial blood gas
- Toxoplasmosis, other viruses, rubella, cytomegalovirus, or herpes (TORCH) screen; blood, urine, and CSF cultures (infection)
- Screen for inborn error of metabolism:
 - Ammonia (high in urea cycle defects, organic acidemias, fatty acid oxidation disorders)
 - Lactate in blood, urine, CSF (high in carbohydrate metabolism and mitochondrial disorders)
 - Quantitative amino acid analysis in blood and urine (aminoacidopathies)
 - Plasma acylcarnitine profiles and urine organic acid analysis (organic acidemias, fatty acid oxidation defects)
 - Plasma very-long-chain fatty acids (peroxisomal disorders)
 - Uric acid (low in molybdenum cofactor deficiency)
 - Transferrin isoelectric focusing (abnormal pattern seen in congenital disorders of glycosylation)
 - 7-dehydrocholesterol (high in Smith-Lemli-Opitz syndrome)
 - WBC lysosomal enzyme assays
 - Urine GAA/GMT(creatine deficiency disorders)
 - Urine purine/pyrimidine (purine/pyrimidine metabolism disorders)
 - CSF neurotransmitters
 - Stools for Clostridium toxin when botulism suspected (endemic in Pennsylvania, some Northwestern states)
- Molecular studies

- Karyotype (Down syndrome)
- Microarray/SNP array (microdeletion/microduplication syndromes)
- DNA methylation/MS-MLPA (Prader-Willi/Angelman syndrome)
- DNA-based molecular testing
- Exome sequencing

Imaging

- MRI for structural brain abnormalities; CT for intracranial calcifications
- Magnetic resonance spectroscopy (MRS): assesses neuronal integrity (N-acetylaspartate [NAA] peaks), intracerebral accumulation of unusual metabolites (lactate, glycine), or deficiency of a key metabolite (creatine)
- Muscle imaging: used in some centers to delineate a neuromuscular problem
- Abdominal/pelvic ultrasound: Assess other organ involvement.

Diagnostic Procedures/Other

- Evaluation of vision and hearing
- Echocardiography
- Anticholinesterase administration in suspected myasthenia may be diagnostic.
- Electromyography (EMG) and nerve conduction velocity: useful tools to assess the lower motor unit and localize involved site
- EEG: if seizures are suspected
- Skin biopsy: for lysosomal enzyme assay in fibroblasts and electron microscopy for abnormal organelles, inclusions, or storage material (Pompe disease)
- Muscle biopsy: for histopathology, electron microscopy and respiratory chain studies (congenital myopathies, storage myopathies [Pompe disease], or muscular dystrophies)

DIFFERENTIAL DIAGNOSIS

Generalized nonneurologic conditions including the following:

- Acute systemic disorders
 - Sepsis
 - Trauma

- Malnutrition
- GI obstruction or bleed
- Toxic (hyperbilirubinemia, maternal sedative, analgesic, and/or anesthetic exposure)
- Chronic systemic disorders
 - Congenital heart disease
 - Endocrinopathies (hypothyroidism, rickets, hypercalcemia)
 - Renal tubular acidosis
 - Cystic fibrosis
 - Malabsorption
 - Connective tissue disorders
 - Ehlers-Danlos syndrome
 - Marfan syndrome
 - Loeys-Dietz syndrome
 - Osteogenesis imperfecta
 - Chondrodysplasia
 - Benign joint laxity

Neurologic diagnoses including the following:

- Central hypotonia
 - Disorders involving cerebral cortex, cerebellum, and brainstem
 - Structural brain abnormalities (lissencephaly, holoprosencephaly)
 - Hypoxic-ischemic encephalopathy
 - Intracranial hemorrhage
 - Infections (meningitis, encephalitis)
 - Chromosomal disorders
 - Down syndrome
 - Williams syndrome
 - Prader-Willi syndrome
 - Angelman syndrome
 - Single-gene disorders
 - Fragile X syndrome
 - Rett/Rett-like syndrome
 - PTEN-related disorders
 - Smith-Lemli-Opitz syndrome
 - Peroxisomal disorders (Zellweger syndrome, infantile Refsum,

- neonatal adrenoleukodystrophy)
 - ▢ Congenital disorders of glycosylation
 - ▢ Creatine deficiency disorders
 - ▢ Purine/pyrimidine metabolism disorders
- Disorders of spinal cord
 - ▢ Myelodysplasias (meningomyeloceles, diplomyelia, diastematomyelia)
- Benign congenital hypotonia: mild transient hypotonia without dysmorphology; weakness; or other neurologic, physical, or laboratory abnormalities
- Peripheral hypotonia
 - Disorders of anterior horn cell including the following:
 - ▢ Spinal muscular atrophy (SMA)
 - ▢ SMA with respiratory distress (SMARD)
 - ▢ Arthrogryposis multiplex congenita
 - ▢ Pompe disease (glycogen storage type II)
 - ▢ Neonatal poliomyelitis
 - Disorders of peripheral nerve
 - ▢ Dejerine-Sottas disease
 - ▢ Guillain-Barré syndrome
 - ▢ Charcot-Marie-Tooth disease
 - ▢ Familial dysautonomia
 - Disorders of neuromuscular junction
 - ▢ Myasthenia gravis (congenital, transient)
 - ▢ Infantile botulism
 - ▢ Toxic (hypermagnesemia, antibiotics [especially aminoglycosides], nondepolarizing neuromuscular blockers)
 - Disorders of muscle
 - ▢ Congenital myotonic dystrophy
 - ▢ Congenital muscular dystrophies
 - ▢ Congenital structural myopathies: central core, nemaline, centronuclear myopathy
 - ▢ Metabolic myopathies (mitochondrial and storage disorders)
 - ▢ Organic aciduria (Barth syndrome)
 - ▢ Fatty acid oxidation disorders

- Combined hypotonia
 - Dystroglycanopathies
 - Leukodystrophies (Canavan disease, Pelizaeus-Merzbacher disease)
 - Marinesco-Sjögren syndrome
 - Mitochondrial encephalomyopathies

TREATMENT

MEDICATION

- Anticholinesterase inhibitors and 3,4-diamino-pyridine in congenital myasthenic syndromes
- IV immunoglobulin and plasmapheresis have been used in treatment of infants with Guillain-Barré syndrome.

ADDITIONAL TREATMENT

General Measures

- Address apnea, hypoventilation, hypoxia:
 - Intubation or positive pressure devices may be required.
 - Chest physiotherapy, antibiotics, bronchodilators, and oxygen may be needed.
 - Hypermagnesemia can cause apnea.
 - Weak infants in car seats may be at risk for acute respiratory problems.
- Underlying toxic or metabolic causes should be addressed and treated appropriately.

COMPLEMENTARY & ALTERNATIVE THERAPIES

- Physical therapy
 - May help maintain maximum muscle function and reduce secondary deformities
 - Orthopedic consultation to evaluate hips and contractures
- Occupational therapy
- Speech therapy

SURGERY/OTHER PROCEDURES

Surgical intervention in later childhood to correct primary as well as

secondary deformities

INPATIENT CONSIDERATIONS

Admission Criteria

Respiratory insufficiency, feeding intolerance, failure to thrive, metabolic abnormality

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Individualized multidisciplinary care including specialists in neurology, pulmonology, orthopedics, development, physiotherapy, and nutrition; attention to vision and hearing; as well as psychosocial support to caregivers/families

DIET

Feeding and swallowing difficulties may necessitate nutritional supplementation and/or feeding tube placement.

PROGNOSIS

Many of the paralytic hypotonias are quite variable in their clinical course. Severity of disease depends on underlying cause and associated respiratory and nutritional factors.

COMPLICATIONS

- Respiratory insufficiency/recurrent pneumonia
- Orthopedic deformities
- Poor nutritional status

CODES

ICD10

P94.2 Congenital hypotonia

FAQ

- Q: By what age should one expect resolution of benign congenital hypotonia?
- A: Hypotonia typically resolves by the time the infant is walking, up to 18 months of age.
- Q: What clinical sign can help distinguish between SMA and infantile botulism?
- A: Tongue fasciculations are seen in SMA. Also, decreased pupillary light reflex is seen in botulism.

FOOD ALLERGY

Jackie P-D. Garrett • Terri Brown-Whitehorn

BASICS

DESCRIPTION

Food allergy has recently been defined as “an adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food.” Most commonly, the protein component of the food is responsible for the adverse immunologic response.

- Classifications of food allergies:
 - IgE mediated, including
 - Anaphylaxis
 - Acute urticaria
 - Oral allergy syndrome
 - Non-IgE mediated (cell mediated), including
 - Food protein–induced enterocolitis syndrome (FPIES)
 - Food protein–induced allergic proctocolitis
 - Celiac disease
 - Mixed IgE and non-IgE mediated, including
 - Atopic dermatitis
 - Eosinophilic gastroenteropathies (eosinophilic esophagitis, eosinophilic gastroenteritis)
- Most common IgE-mediated food allergies:
 - Children
 - Milk
 - Egg
 - Soy
 - Peanut
 - Wheat
 - Fish
 - Adults
 - Peanuts
 - Tree nuts

- Fish
 - Shellfish
- Most common non-IgE-mediated food allergies associated with food protein enterocolitis and proctocolitis:
 - Milk
 - Soy
 - Rice
 - Oat
 - Barley
 - Chicken

EPIDEMIOLOGY

Food-induced anaphylaxis is the most common cause of anaphylactic reactions treated in emergency departments in the United States. The prevalence of food allergy has increased over the past 10–20 years.

Prevalence

- 5% of children <5 years of age, 4% of teens and adults
- Nearly 2.5% of infants have hypersensitivity reactions to cow's milk during 1st year (½ of these cases are thought to actually represent GI diseases); outgrown by most (80%) by 5 years of age.
- 1.6% have egg allergy by 2.5 years (based on population-based studies); 66% of children outgrow egg allergy by 7 years of age.
- 0.6% of U.S. population have peanut allergy.
- 37% of children <5 years of age with moderate to severe atopic dermatitis have a food allergy.
- 34–49% of children with food allergy have asthma.
- 33–40% of children with food allergy have allergic rhinitis.
- Fatal and near-fatal reactions are associated with uncontrolled asthma.

RISK FACTORS

- Genetic
- Family history
- Presence of atopic dermatitis
- Other unknown factors suspected

ETIOLOGY

- Oral tolerance to food proteins believed to develop through T-cell anergy or induction of regulatory T cells. Food hypersensitivity develops when oral tolerance fails to develop or breaks down.
- IgE mediated: T cells induce B cells to produce IgE antibodies that initially bind on the surface of mast cells and basophils; when reexposed, the food protein binds to IgE antibodies, leading to degranulation of those cells and release of histamine and other chemical mediators.
- Non-IgE mediated (cell mediated): T cells react to protein-inducing proinflammatory cytokines, leading to inflammatory cell infiltrates and increased vascular permeability. These factors lead to subacute and chronic responses primarily affecting the GI tract.
- Mixed IgE and non-IgE mediated: Eosinophilic esophagitis and eosinophilic gastroenteropathy are characterized by eosinophilic infiltration of intestinal wall, occasionally reaching to serosa.

COMMONLY ASSOCIATED CONDITIONS

- Asthma (4-fold more likely)
- Allergic rhinitis (2.4-fold more likely)
- Other atopic diseases
- Dermatitis herpetiformis (celiac)

DIAGNOSIS

Varies depending on the individual and the type of food hypersensitivity (see [Table](#) for symptoms of specific illnesses)

- IgE mediated
 - Urticaria
 - Angioedema
 - Immediate GI reactions (emesis, cramping, etc.)
 - Oral allergy syndrome
 - Rhinitis
 - Anaphylaxis (hypotension, dyspnea, dysphonia, wheezing, coughing, angioedema)
 - Nausea, abdominal pain, colic, and vomiting develop within 2 hours

- of ingesting offending foods.
- Diarrhea: develops within 2–6 hours
- Mixed IgE and non-IgE (cell mediated)
 - Eosinophilic gastroenteropathy
 - Weight loss (key feature), pain, emesis, failure to thrive (FTT), anorexia
 - Some infants have a large protein-losing enteropathy component causing low serum albumin and hypogammaglobulinemia.
 - Eosinophilic esophagitis
 - Dysphagia
 - Food impaction
 - Intermittent vomiting
 - Food refusal
 - Abdominal pain
 - Irritability
 - Failure to respond to reflux medication
 - FTT
 - Gastroesophageal reflux
- Non-IgE mediated
 - Food protein enterocolitis
 - Severe vomiting 2 hours after ingestion; profuse diarrhea
 - Shock due to fluid/electrolyte loss
 - Very ill appearing
 - Food protein proctocolitis
 - Blood in stool
 - Food protein-induced enteropathy
 - Diarrhea, bloating, FTT, anemia

PHYSICAL EXAM

- IgE mediated
 - Hives/angioedema (however, in 12% of patients with anaphylaxis, there are no skin findings and often these are most severe cases)
 - Wheezing/dyspnea
 - Hypotension/tachycardia
 - Vomiting, abdominal tenderness
 - Ill-appearing

- Mixed IgE mediated, non-IgE mediated:
 - Eosinophilic esophagitis: abdominal tenderness (variable), growth concerns (in some)
 - Eosinophilic gastroenteropathy
 - Abdominal tenderness
 - Weight loss
- Cell mediated
 - Food protein–induced enterocolitis
 - Abdominal distention
 - FTT
 - Severe dehydration (may present in shock)
 - Celiac disease
 - Abdominal distention
 - FTT

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

Depends on clinical presentation and patient symptoms, may include

- CBC with differential
 - Anemia in patients with enteropathy
 - Eosinophilia may be seen in patients with eosinophilic gastroenteritis, enteropathy, and, on occasion, eosinophilic esophagitis (but cannot be used to monitor therapy).
- Serum IgE: may be elevated in
 - IgE-mediated hypersensitivities
 - Eosinophilic esophagitis, eosinophilic gastroenteritis
- Albumin: low in
 - Protein-losing enteropathies
 - Non-IgE-mediated protein enterocolitis (chronic version)
 - Eosinophilic gastroenteritis
- Serologic tests: may aid in diagnosis of celiac disease
- Tryptase: may be elevated in anaphylaxis; obtain within 4 hours of initial reaction.
- ImmunoCAP assay may be helpful in IgE-mediated illness.

- ImmunoCAP has many false positives (do not send food allergy panels).

Diagnostic Procedures/Other

- Skin prick testing
 - Used in conjunction with clinical history for IgE-mediated food allergies
 - 50% positive predictive value; 95% negative predictive value
 - Performed upon evaluation of patients with eosinophilic esophagitis
- Food challenges
 - Gold standard for diagnosis of food allergy is double-blind placebo-controlled challenge but impractical in many clinical settings.
 - Most sites use single-blind or open food challenge.
 - Used to confirm food allergy in patients when unsure of diagnosis or to assess whether someone has outgrown food allergy (either IgE-mediated or food protein–induced enterocolitis)
 - Challenge must be performed in setting equipped to treat severe allergic reactions.
- Endoscopy with biopsies of esophagus, stomach, and small bowel
 - Patients should be on proton pump inhibitor prior to endoscopy if there are concerns for eosinophilic esophagitis, as GERD may also lead to eosinophils in esophagus.
- Colonoscopy
 - If lower GI symptoms are present
- Patch skin testing
 - May be used to evaluate for mixed (IgE/non–IgE mediated) or cell-mediated sensitivities
 - Standards for interpretation and methods for reliability are under development.
- Elimination diets
 - Should be conducted with care
 - May lack critical nutrients
 - Oral rechallenge should be carefully planned because a more severe reaction may ensue after a food has been temporarily removed.

Pathologic Findings

- Increased eosinophils in eosinophilic gastroenteropathy

- Presence of intraepithelial lymphocytes and variable villous damage in celiac disease

Food Allergy/Hypersensitivity			
Classification	Illness	Symptoms	Diagnosis
IgE mediated	Anaphylaxis	Rapid onset; nausea, vomiting; abdominal pain; hives, coughing, wheezing; involvement of other organ systems—skin, respiratory system	History + skin prick or ImmunoCAP test; oral challenge only in monitored setting with emergency access and anaphylaxis therapy
IgE mediated	Oral allergy syndrome (children and adults); due to cross-reactivity between food protein and pollen	Mild pruritus, angioedema of lips and oropharynx, sense of tightness in throat, rare systemic symptoms	History + skin prick tests; oral challenge: positive with fresh foods and negative with cooked foods
IgE and cell mediated	Allergic eosinophilic gastroenteritis	Failure to thrive, weight loss, abdominal pain, irritability, early satiety, vomiting, protein-losing enteropathy, edema, ascites	History + skin prick, endoscopy and colonoscopy with biopsy, elimination diet; monitor closely, may need immunosuppressants
IgE and cell mediated	Eosinophilic esophagitis	GERD with failure to respond to proton pump inhibitor; vomiting, FTT, dysphagia, intermittent abdominal pain, irritability	History, endoscopy with biopsy, elimination diet based on testing or history, elemental diet, or "swallowed" steroids
Cell mediated	Allergic proctocolitis "breast milk colitis" (infants)	Bloody stool, mekna in first few months of life; no diarrhea or failure to thrive	Elimination of food (cow's milk or soy most commonly) clears bleeding in 72 hours; reexposure causes recurrence; RAST/skin prick not helpful; typically outgrown by 12–18 months of age
Cell mediated	Food protein–induced enterocolitis syndrome (FPIES)	Severe symptoms; vomiting 2 hours after meal; severe vomiting; 6–8 hours later, diarrhea ± blood; abdominal distention, failure to thrive, dehydration, hypotension	Elimination of protein clears symptoms in 1–3 days. ImmunoCAP/skin prick not helpful; patch testing may be helpful
Cell mediated	Food protein enteropathy (infants)	Diarrhea, steatorrhea, abdominal distention, flatulence, failure to thrive or weight loss, nausea/vomiting, oral ulcers	Endoscopy with biopsy, elimination diet resolves symptoms. Similar symptoms to celiac but resolves by 2 years of age.
Cell mediated	Celiac disease (infants to adults)	Diarrhea, steatorrhea, failure to thrive, abdominal distention, flatulence, weight loss, nausea/vomiting, oral ulcers	Endoscopic biopsy when patient is on gluten; gluten-free diet resolves symptoms. Anti-gluten and TTG antibodies; HLA-DQ2 and DQ8 are often found.

TREATMENT

MEDICATION

First Line

- Anaphylaxis
 - Epinephrine for severe allergic reaction or anaphylaxis
 - H₁ antihistamines (diphenhydramine) may be given for milder symptoms.
 - H₂ antihistamines may be given in conjunction with H₁ antihistamines.
 - Systemic steroids
- Eosinophilic gastroenteritis
 - Systemic steroids (briefly)
 - “Swallowed” steroids
 - Refers to having the patient use a corticosteroid inhaler
 - However, the patient swallows after spraying rather than inhaling.
 - Elemental formulas

- Dietary restrictions

ADDITIONAL TREATMENT

General Measures

- Avoidance of food allergen
- Anaphylaxis
 - Full monitoring of vital signs
 - Epinephrine for severe allergic reaction or anaphylaxis given intramuscularly: may be repeated
 - IV fluid bolus
 - Antihistamines may be given for hives or mild skin swelling.
 - Antihistamines (H₁ and H₂ blockers) and bronchodilators may be used as adjunct to epinephrine for severe reactions.
 - Glucocorticoids may prevent biphasic reaction.
 - Trendelenburg positioning: helps decrease risk of empty ventricle syndrome
- Nonanaphylactic food allergies: eosinophilic esophagitis
 - Systemic steroids for a brief course
 - Swallowed steroids (NPO for 30 minutes after use)
 - Hydrolyzed or elemental formulas: Patients may respond to hypoallergenic formulas.

ISSUES FOR REFERRAL

Allergy/immunology and/or gastroenterology and/or nutrition follow-up needed for most patients for diagnosis and long-term management.

ONGOING CARE

DIET

Nonanaphylactic and anaphylactic food allergies: removal of the offending food agent from diet

PATIENT EDUCATION

- Epinephrine self-administration, if anaphylaxis
- Anaphylaxis plan for families to know which medication to use and when, along with education regarding when to go to the emergency

department

- Education regarding specific food avoidance and label reading

PROGNOSIS

- Generally good after offending food antigens are removed from diet and adequate nutrients are ensured
- Tolerance to food allergens may develop over time. Current research trials to help induce tolerance are underway.
- IgE-mediated disease may persist longer than non-IgE mediated.
- Eosinophilic esophagitis and eosinophilic gastroenteritis are considered chronic illnesses.

COMPLICATIONS

- Food protein allergy can be associated with
 - Poor growth
 - Feeding disorder
 - Protein-losing enteropathy
 - Anemia
- Eosinophilic esophagitis
 - Strictures
 - Hiatal hernia concerns
 - Poor growth
 - Feeding disorder
- Respiratory food-hypersensitivity reactions
 - Heiner syndrome: rare food-induced pulmonary hemosiderosis

CODES

ICD10

- T78.1XXA Oth adverse food reactions, not elsewhere classified, init
- T78.00XA Anaphylactic reaction due to unspecified food, init enctr
- L27.2 Dermatitis due to ingested food

FAQ

- Q: What are the most common food allergens leading to IgE-mediated allergic reactions in childhood?
- A: The most common allergens to which children are sensitive are milk, egg, soy, wheat, fish, peanuts, and nuts.
- Q: Do you recommend elimination diets?
- A: Elimination diets are recommended when necessary to treat underlying disease. Nutrition evaluation is often necessary to avoid nutrient-deficient diets and malnutrition. Elimination diets are used only in extreme circumstances because they can result in nutrient deficiency and malnutrition without identifying the offending allergen. Double-blinded food challenges are a better method for identifying the offending agent.

FOOD HYPERSENSITIVITY (NON-IgE-MEDIATED, GASTROINTESTINAL)

Kirsten Kloepfer

BASICS

DESCRIPTION

- A non-IgE-mediated reaction to a food protein that involves the gastrointestinal (GI) tract
- Previously referred to as milk protein intolerance
- Includes the following:
 - Food protein–induced proctocolitis
 - Food protein–induced enteropathy
 - Food protein–induced enterocolitis syndrome (FPIES)

EPIDEMIOLOGY

- Proctocolitis: Over 60% of infants with rectal bleeding have proctocolitis.
- Enteropathy: may occur after infectious gastritis
- FPIES
 - Slight male predominance (60%)
 - 30% of infants with FPIES have atopic disease(s).
 - Family history of atopy present in 40–80%.

RISK FACTORS

- Proctocolitis
 - 40% react to both milk and soy.
 - 50–60% of infants are breastfed and react to milk and/or soy in mom's diet.
- Enteropathy: usually formula-fed and given intact cow's milk prior to 9 months of age
- FPIES: Exclusive breastfeeding appears to protect against FPIES, but a few cases have been reported.
- Currently, no reports that non-IgE-mediated GI food hypersensitivities are inherited.

PATHOPHYSIOLOGY

- Unclear
- Assumed to be a cell-mediated reaction due to delayed onset

ETIOLOGY

- Cow's milk is number 1 cause of proctocolitis, enteropathy, and FPIES, followed by soy, egg and wheat.
- FPIES: can also react to solid foods thought to be hypoallergenic (rice, oat, barley, chicken, turkey, peanut, potato, corn, fruit protein, fish, and mollusks)

DIAGNOSIS

HISTORY

- Proctocolitis
 - Occurs between 1 and 6 months of age (usually between 2 and 8 weeks)
 - Specks or streaks of blood (\pm mucus) in the stool of an otherwise healthy infant
 - Absence of vomiting and diarrhea
 - Blood-tinged stools resolve with elimination of offending food protein.
 - Rare in older children
- Enteropathy
 - Persistent diarrhea (rarely bloody)
 - Vomiting
 - Abdominal pain
 - FTT with hypoproteinemia and anemia
 - Usually formula-fed
 - Do not experience an acute reaction with reexposure
- FPIES
 - Can begin anytime from within a few days of life through 12 months of age
 - FPIES due to solid food usually begins when solids are first introduced (rice cereal).

- Profuse protracted emesis 1–3 hours after exposure to offending food protein
- Profuse diarrhea 4–8 hours after food ingestion in 25% of cases
- May appear acutely ill with 15% of cases presenting with dehydration and shock
- All non-IgE-mediated GI food hypersensitivities resolve when offending food protein removed from diet.

PHYSICAL EXAM

- Proctocolitis: usually healthy-appearing child with normal physical exam
- Enteropathy
 - Diffuse abdominal pain with distention
 - Weight loss
- FPIES
 - Profuse vomiting and watery diarrhea with signs of dehydration
 - Lethargy, may appear septic

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- All non-IgE-mediated GI food hypersensitivities are as follows:
 - Diagnosed clinically
 - No laboratory test available to diagnose hypersensitivity
 - Serum-specific IgE testing and skin testing often negative
- Proctocolitis
 - No endoscopy unless prolonged rectal bleeding, anemia, and/or FTT
 - Eosinophils and lymphoid nodular hyperplasia may be present in the colon.
- Enteropathy
 - Endoscopy shows villous injury with increase in crypt length and villous atrophy.
- FPIES
 - Labs may also show anemia, leukocytosis, eosinophilia, neutrophilia, thrombocytosis, and hypoalbuminemia.
 - If reaction to food is severe, patient may have metabolic acidosis.
 - May see methemoglobinemia in up to 35% of cases that require

hospitalization

- Stool may contain blood, mucus, leukocytes, eosinophils, and/or increased carbohydrate content due to malabsorption.
- Abdominal x-ray may show intramural gas (may be confused with necrotizing enterocolitis [NEC] or ileus).
- With FPIES, if the offending food is discontinued and restarted, the patient will experience vomiting and diarrhea within a few hours (not recommended to be performed at home).

DIFFERENTIAL DIAGNOSIS

- Proctocolitis
 - Anal fissures
 - Vascular malformations
 - Intussusception
 - Meckel diverticulum
- Enteropathy
 - Lactose intolerance
 - Celiac disease
 - Inflammatory bowel disease (IBD)
- FPIES
 - Anaphylaxis
 - Sepsis
 - NEC
 - GI infection
 - Reflux
 - Metabolic disorder
 - Surgical abdomen

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Proctocolitis
 - Exclusively breastfed infant: Continue breastfeeding with mom eliminating all forms of dairy including casein and whey in

packaged food.

- Symptoms should improve within 72 hours, but it may take up to 2 weeks to completely resolve.
- If no improvement, eliminate soy in mom's diet, followed by egg.
- If the infant is formula-fed, consider changing formula to a hydrolysate formula (e.g., Pregestimil, Nutramigen, Alimentum) because many patients are sensitive to both milk and soy protein.
- If bleeding continues, consider changing formula to an amino acid-based formula (e.g., Neocate, PurAmino, EleCare).
- Enteropathy
 - Eliminate milk from diet.
 - Symptoms should improve in 1–3 weeks.
- FPIES
 - Acute episodes should be treated with IV fluids, methylprednisolone (1 mg/kg) to decrease possible cell-mediated intestinal inflammation, plus vasopressors, epinephrine, and/or bicarbonate for shock and possible metabolic acidosis.
 - Long-term management involves strict avoidance of trigger food(s).
 - Stop cow's milk or soy formula and start hydrolysate formula due to possible intolerance to both milk and soy protein.
 - For solid food FPIES:
 - Eliminate trigger food and allow the patient to continue eating foods previously tolerated.
 - Consult allergist for future solid food introduction.

ALERT

If suspect FPIES (patient with vomiting, acute dehydration, lethargy and acidosis), fluid resuscitation and refeeding should be performed in the hospital.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Proctocolitis
 - 95% tolerate reintroduction of food(s) at 9 months of age. Patient

- can reintroduce offending food at home 4–6 months after beginning protein elimination diet.
 - Prognosis: excellent. Nearly all infants tolerate cow’s milk and soy products by 12 months of age.
 - Proctocolitis is not inherited; therefore, subsequent children should not be started on hydrolysate or amino acid formula.
- Enteropathy
 - Most cases resolve spontaneously by 2 years of age.
 - Food can be reintroduced at home 1–2 years after beginning protein elimination diet.
- FPIES
 - The trigger food may be reintroduced 12–18 months after the last reaction, preferably under the supervision of a physician.
 - Cow’s milk and soy FPIES resolve in most patients by 3 years of age.
 - Patients with solid food FPIES may experience protracted courses.
 - Nutritional counseling may be helpful for children with multiple non-IgE-mediated reactions to food.
 - Because close follow-up is needed to determine if tolerance has developed and if an oral food challenge can be performed, an allergy consult is warranted when FPIES is suspected.

CODES

ICD10

- Z91.011 Allergy to milk products
- E73.9 Lactose intolerance, unspecified
- K90.4 Malabsorption due to intolerance, not elsewhere classified

FAQ

- Q: Will my child outgrow this?
- A: For proctocolitis, most children outgrow milk and/or soy intolerance by 12 months of age. For enterocolitis, symptoms resolve within 1–2 years. For FPIES, symptoms may resolve within 1–2 years, however, they may persist which is why food challenges are important to determine if symptoms have improved and the food can be safely reintroduced into the diet.
- Q: Should I refer the patient to an allergist?
- A: Infants with suspected FPIES should be referred to an allergist for both evaluation and future food challenges. A patient with proctocolitis

or enteropathy that resolves with formula change does not need to be seen by a specialist unless symptoms persist despite a strict elimination diet.

- Q: Can my child have FPIES and an IgE-mediated food allergy?
- A: Although not as common as FPIES alone, there are reports of children with FPIES and elevated food-specific IgE levels. These children tend to have a more protracted course of FPIES and are at increased risk of developing IgE-mediated immediate-type symptoms when challenged. This supports the recommendation to refer children with suspected FPIES to an allergist for further evaluation.

FOOD POISONING OR FOODBORNE ILLNESS

Kacy A. Ramirez

BASICS

DESCRIPTION

Any illness resulting from the ingestion of food or drink contaminated with an infectious organism or associated toxin

EPIDEMIOLOGY

Incidence (U.S. Annual Estimates)

- 31 major pathogens caused
 - 9.4 million episodes of foodborne illness
 - 56,000 hospitalizations
 - 1,350 deaths
- Highest incidence in children <5 years
- Hospitalizations and death more common in persons >64 years
- See [Appendix, Table 8](#) regarding epidemiologic aspects by organism.

GENERAL PREVENTION

- Vaccination
 - Oral rotavirus vaccine
 - Hepatitis A vaccine
- Preventive strategies
 - Hand washing (soap and water)
 - Proper food handling (adequate cooking and refrigeration)
 - Avoidance of unpasteurized dairy products and juices
 - Avoidance of raw or undercooked eggs, meat, and shellfish
 - Avoidance of honey in children <1 year old
 - Avoidance of well water, which may contain nitrates, in preparing infant formulas

PATHOPHYSIOLOGY

- Gastroenteritis

- Viral epithelial invasion/replication or ingestion of preformed elaborated toxin
- Noninflammatory diarrhea
 - Selective destruction of absorptive cells in mucosa, leaving secretory cells intact
 - Toxin elaboration (secretory diarrhea)
 - Impairment of brush border enzymes and lactose intolerance (osmotic diarrhea)
- Inflammatory diarrhea/dysentery
 - Direct mucosal invasion of intestinal epithelial cells (colon)
 - Toxin elaboration
 - Inflammatory infiltration destroys villous cells and transporters and leads to exudation of mucus/protein/blood into gut.
- Local/remote invasion (bacteremia, meningitis, dissemination, hepatitis, osteomyelitis)
- Immune-mediated extraintestinal manifestations (hemolytic uremic syndrome, reactive arthritis, Guillain-Barré)

ETIOLOGY

- Viruses
 - Most common cause of foodborne illness
 - Caliciviruses (norovirus)
 - Rotavirus (infant/child)
 - Astrovirus
 - Enteric adenovirus
 - Hepatitis A
- Bacteria
 - Salmonella (typhi, paratyphi, non-typhoidal)
 - Clostridium perfringens
 - Campylobacter
- Other bacteria
 - Salmonella typhi/Salmonella paratyphi
 - Shigella
 - Escherichia coli
 - Enterohemorrhagic E. coli [EHEC] including Shiga toxin–producing E. coli [STEC]

- Enteropathogenic *E. coli* [EPEC]
 - Enterotoxigenic *E. coli* [ETEC]
 - Enteroinvasive *E. coli* [EIEC]
 - Enteroaggregative *E. coli* [EAEC]
- *Vibrio* (*cholerae*, *parahaemolyticus*, *vulnificus*)
- *Staphylococcus aureus* (preformed toxin)
- *Bacillus cereus* (preformed and diarrheal toxin)
- *Clostridium botulinum* (toxin)
- *Listeria monocytogenes*
- *Brucella*
- Parasites
 - *Entamoeba histolytica*
 - *Giardia intestinalis*
 - *Cryptosporidium*
 - *Cyclospora cayentanensis*
 - *Toxoplasma gondii*

DIAGNOSIS

SIGNS AND SYMPTOMS

- Gastroenteritis
 - Sudden onset vomiting
 - Fever and diarrhea may also be present
 - Associated with viral etiology, preformed toxin ingestion
- Noninflammatory diarrhea
 - Acute watery diarrhea, abdominal pain, without fever/dysentery
 - Some may present with fever
 - Consider: ETEC, viral or parasitic etiology
- Inflammatory diarrhea:
 - Bloody stool, abdominal pain and fever
 - Consider: *Shigella*, *Campylobacter*, *Salmonella*, EIEC, EHEC, STEC O157H7, EAEC, *Vibrio parahaemolyticus*, *Yersinia enterocolitica*, *Entamoeba*
- Chronic diarrhea >14 days
 - 3 or more unformed stools/day

- Consider: parasitic etiology
- Neurologic manifestations
 - Paresthesias, respiratory depression, bronchospasm, cranial nerve palsies
 - Consider: Clostridium botulinum toxin, organophosphate, fish toxin poisons, Guillain-Barré [Campylobacter jejuni]
- Systemic illness
 - Fever, weakness, arthritis, jaundice
 - Consider: Listeria, Brucella, Trichinella, Toxoplasma, Vibrio vulnificus, Hep A, S. typhi, S. paratyphi

HISTORY

- Incubation period
- Duration of illness
- Predominant symptoms
- Population involved in outbreak
- Similarly exposed persons with related symptoms
- Suspected similarly ill contacts
- Type of food ingested and type of exposure (location of exposure, pet contact, travel, occupation, institutional/daycare)
- See [Appendix, Table 9](#) regarding clinical symptoms by organism.

PHYSICAL EXAM

- Detailed neurologic examination
- Assessment of dehydration status (examination of mucous membranes, skin turgor)
- Assessment of potential liver involvement (hepatomegaly, jaundice, icterus)
- Assessment of disseminated disease (MS exam for septic arthritis and osteomyelitis)
- Careful abdominal examination

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Routine bacterial stool culture
 - Cultures for Vibrio and Yersinia, EC0157H7, and Campylobacter require additional media or incubation conditions and may require

communication with laboratory if suspected.

- Toxin testing, serotyping, and molecular techniques may only be available from large commercial or public health labs.
- Blood/CSF cultures as clinically indicated
- Serology (hepatitis A, Brucella, Toxo)
- Ova/parasite examination
- Direct antigen testing/DFA (Giardia, Cryptosporidium)
- Polymerase chain reaction (PCR) identification of multiple pathogens in stool (viral, bacterial, parasitic) are most sensitive.
- Careful monitoring of patients with hemorrhagic colitis during illness and 3 days after resolution of diarrhea to detect changes of HUS (CBC with smear, BUN/Cr)

DIFFERENTIAL DIAGNOSIS

- Systemic viral illness (myalgias/arthralgias) or infection (e.g., pharyngitis)
- Appendicitis, peritonitis, pelvic inflammatory disease
- Irritable bowel syndrome
- Inflammatory bowel disease
- Malignancy
- Medication use
- Clostridium difficile enterocolitis
- Malabsorption syndromes (celiac disease, cystic fibrosis, malnutrition)
- Food intolerance or allergy
 - Cow's milk (protein allergy)
 - Carbohydrate intolerance (e.g., lactose)
- Dietary manipulations
 - Hyperosmolar formulas
 - Food additives (dyes, processing materials, coloring)
 - Caffeine
 - Overfeeding
 - Low fat intakes
 - Excessive fluids
 - Munchausen by proxy
- Ingestion of noninfectious foodborne illness (contaminated seafood, mushroom poisoning, chemical poisoning)

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Gastroenteritis
 - Treat dehydration with oral rehydration solution (ORS):
 - Standard ORS contains 75–90 mEq of sodium and 74–111 mmol/L of glucose
 - Alternative ORS, including rice-based carbohydrate or amylase-based solutions, may be more effective for *Vibrio cholerae* infections.
 - Transition rapidly (after 3–4 hours of ORS tolerance) to regular diet (see below).
 - Continue breastfeeding infants if possible.
- Botulism
 - Continuous cardiac and respiratory monitoring, may need assisted ventilation

DIET

Balanced, varied diet; providing easily digestible, complex carbohydrates will promote improved stool consistency.

SPECIAL THERAPY

Botulism: For suspected infant botulism cases, human-derived antitoxin, BabyBIG (Human Botulism Immune Globulin, BIG-IV), may be obtained from the Infant Botulism Treatment and Prevention Program, California Department of Public Health (24-hour line: 510-231-7600).

IV Fluids

If patient is unable to be rehydrated via oral route (because of ileus, circulatory failure, CNS complications) or if >10% dehydration

COMPLEMENTARY & ALTERNATIVE THERAPIES

Supplements with specific probiotic strains (e.g., *Lactobacillus GG*) have been shown to reduce duration of less severe, non-rotaviral diarrhea and hospital stays.

MEDICATION

Use of antibiotics is

- Always indicated
 - Shigella
 - Brucella
 - *L. monocytogenes* (invasive disease)
 - Invasive *Salmonella* (typhi, paratyphi, non-tyhoidal)
 - Typhoid fever (*Salmonella* typhi, paratyphi)
 - *Salmonella* typhi
 - *Salmonella* paratyphi
 - *Vibrio* spp.
 - *Cyclospora cayetanensis*
 - *Cryptosporidium* (severe or children <12 years old)
 - *Trichinella*
 - *E. histolytica*
 - *Campylobacter* (in severe cases, early treatment limits duration, prevents relapse, and shortens duration of shedding)
 - *G. intestinalis*
- Sometimes indicated
 - *E. coli* (severe ETEC in a traveler in resource limited country)
 - Non-typhi *Salmonella*
 - Treatment indicated to reduce risks of bacterial translocation only in a few select populations: patients <3 months old as well as those who are immunocompromised, have a hemoglobinopathy, or have chronic GI condition (IBD)
 - Other patients should not be treated, as antibiotics prolong organism shedding in the stool and promote disease spread.
 - *Y. enterocolitica* (sepsis)
 - *T. gondii* (pregnant and immunocompromised patients)
 - *Cryptosporidium* (severe, <12 years of age)
- Contraindicated
 - *Clostridium botulinum* (aminoglycosides potentiate paralytic effects)
 - No antimotility agents for children with inflammatory or bloody diarrhea

ONGOING CARE

PROGNOSIS

- Most gastroenteritis is mild and self-limited.
- Recovery is complete in 2–5 days in most individuals.
- In the very young, prognosis is more guarded because these patients can become dehydrated quickly.
- After the patient has survived the paralytic phase of botulism, the outlook for complete recovery is excellent.

REPORTING REQUIREMENTS

- Foodborne diseases and conditions generally notifiable at the national level include the following:
 - Botulism, brucellosis, STEC O157H7, hemolytic uremic syndrome, listeriosis, salmonellosis (other than *S. typhi*), shigellosis, typhoid fever (*S. typhi* and *S. paratyphi* infections), *Vibrio*, hepatitis A
- Additional reporting requirements may be mandated by state and territorial laws and regulations: Full reporting instructions are available:
 - 1-800-CDC-INFO (1-800-232-4636)
 - <http://www.cdc.gov/foodsafety/fdoss/reporting/how-to-report.html>

CODES

ICD10

- T62.91XA Toxic effect of unsp noxious sub eaten as food, acc, init
- A05.9 Bacterial foodborne intoxication, unspecified
- A02.0 Salmonella enteritis

FAQ

- Q: What are the most common causes of food poisoning?
- A: Viruses, particularly norovirus, are the leading cause of foodborne illnesses. The most common bacterial infections include Salmonella, Clostridium perfringens, and Campylobacter jejuni.
- Q: How are the signs and symptoms of food poisoning different from those of a viral gastroenteritis?
- A: The signs and symptoms of food poisoning and gastroenteritis are similar in that the patient displays diarrhea, vomiting, and fever. Historically, food poisoning is distinguished by its association with a common food that affects multiple individuals who consumed it.
- Q: Which foods are most likely to be contaminated?
- A: Poorly cooked foods (e.g., eggs, meats, fish, shellfish), unpasteurized milk and juices, inadequately washed fresh produce, home canned goods, soft unpasteurized cheeses. Use of well water, which may be contaminated with nitrates, to prepare infant formula can result in infant methemoglobinemia.

FRAGILE X SYNDROME

Chad R. Haldeman-Englert • Marni J. Falk

BASICS

DESCRIPTION

- Most common cause of inherited intellectual disability (ID)
- Caused by mutations in the FMR1 gene on chromosome Xq27.3

EPIDEMIOLOGY

- Affects ~1 in 4,000–6,000 in males; prevalence in females is ~1/2 that in males
- Carrier prevalence in females for FMR1 premutation is 1:382 and for intermediate allele(s) is 1:143

RISK FACTORS

Genetics

- Caused by loss-of-function mutations in the FMR1 gene on chromosome Xq27.3
- >99% of affected individuals have a trinucleotide (CGG) repeat expansion (>200 repeats) within the 5' untranslated region of the FMR1 gene.
- Repeat size categories (based on guidelines from the American College of Medical Genetics):
 - Normal number of repeats: 5–44
 - Intermediate (“gray zone”): 45–54
 - Premutation: 55–200
 - Full mutation: >200
- Other FMR1 gene mutations may rarely occur (<1% cases).
- Fragile X syndrome is inherited in an X-linked manner.
- Fragile X is a CGG trinucleotide repeat disorder that shows anticipation, in which the phenotype can be more severe in subsequent generations due to an expansion in the number of CGG repeats.
- Expansion only may occur in the germline of mothers who carry a premutation range repeat allele of FMR1.

- Expansion does not always occur in offspring of female premutation carriers. In general, the larger the number of CGG repeats (>50), the higher the probability that expansion to a full mutation will occur.
- A male with a premutation will pass on the premutation to 100% of his daughters and none of his sons.
- Females with a full mutation are typically less severely affected than males because their 2nd FMR1 allele is typically normal and, assuming random X-inactivation occurs, produces variable amounts of fragile X mental retardation protein (FMRP).
- Males with mosaicism for the FMR1 full mutation (some cells with the full mutation and other cells with the premutation) are generally less severely affected (average IQ 60) relative to males with the full mutation in all the cells
- Patients with larger chromosomal deletions involving FMR1 and other nearby genes typically have a more severe phenotype

GENERAL PREVENTION

- Prenatal diagnosis by chorionic villous sampling (~10–12 weeks' gestation) or amniocentesis (~16–20 weeks' gestation) is possible for at-risk pregnancies.
- Preimplantation genetic diagnosis in the setting of in vitro fertilization is possible for at-risk couples when a familial FMR1 mutation is known.

PATHOPHYSIOLOGY

Residual FMRP protein levels directly correlate with the severity of fragile X syndrome manifestations:

- Absence of FMRP results in characteristic craniofacial, neurologic, and connective tissue abnormalities.
- Decreased FMRP levels may cause long-term depression of hippocampal synaptic transmission via specific glutamate receptors, with resulting behavioral and neuronal phenotypes.

COMMONLY ASSOCIATED CONDITIONS

Other FMR1-related disorders include fragile X-associated tremor/ataxia syndrome (FXTAS) and premature ovarian insufficiency (POI):

- FXTAS can be seen in older (age >50 years) male and female

premutation carriers. Clinical features include intention tremors, abnormal gait with frequent falling, cerebral atrophy, and memory deficits.

- POI can be seen in 20–25% of female premutation carriers, with menopause occurring prior to age 40 years.

DIAGNOSIS

HISTORY

- Birth/neonatal history
 - Normal to increased birth weight
 - May have large head circumference at birth
 - Feeding problems and frequent emesis due to gastroesophageal reflux may occur but improves with growth.
 - Irritability may result from sensory integration difficulties and tactile defensiveness.
- Past medical history
 - Strabismus and hyperopia occur in 40%
 - Frequent ear infections in 60%: Conductive hearing loss is possible.
 - Mitral valve prolapse (MVP) and aortic root dilation can occur, typically in adults.
 - Seizures occur in ~20% of children and may resolve by adolescence.
 - Periventricular heterotopia seen on magnetic resonance imaging (MRI)
 - Pes planus
 - Scoliosis
- Developmental/behavioral history
 - Motor delay due to hypotonia
 - Speech may be absent to minimally affected.
 - Autism (60% of males with full mutation)
 - Severe intellectual disability in males (average IQ of males with the full mutation is 41, with range of 30–55)
 - Borderline or mild intellectual disability in 50% of females with the full mutation (IQ range 70–85)

- Tantrums occur around age 2 years.
- Hyperactivity can be severe.
- Obsessive and compulsive behaviors
- Often requires routine for daily activities
- Social anxiety: Patients are shy and easily overwhelmed by noisy environments.
- Family history
 - Fragile X syndrome
 - Intellectual disability or autism, especially in males related through the maternal side
 - Tremors or ataxia developing >50 years
 - Premature ovarian insufficiency in females <40 years
 - No male–male transmission

PHYSICAL EXAM

- Growth parameters
 - Height, weight, and head circumference
- Characteristic facial features
 - Large head, prominent forehead
 - Long face
 - Large and protruding ears
 - High palate
 - Prominent chin (after puberty)
- Murmur or midsystolic click (MVP)
- Large testicles (after puberty)
- Joint hypermobility, pes planus, scoliosis
- Skin often feels soft and smooth

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- Consider FMR1 mutation testing in the following:
 - Males or females with features of autism, developmental delays, or intellectual disability
 - Males or females with clinical findings consistent with fragile X syndrome

- Family history of fragile X syndrome, recurrent intellectual disability or autism, especially through the maternal side
- Males or females with tremor and/or ataxia developing age >50 years
- Females with premature ovarian insufficiency age <40 years
- Southern blot or polymerase chain reaction (PCR)–based analyses are the 1st-line genetic tests to determine if there is a repeat expansion and define the number of CGG repeats within the FMR1 gene.

Follow-Up Tests & Special Considerations

- Methylation status can be determined by using a restriction enzyme that selectively cuts nonmethylated DNA or by methylation-sensitive PCR techniques. This may be considered for higher functioning males with a full mutation to establish their degree of FMR1 methylation.
- Standard karyotype analysis will typically not be able to detect the repeat expansion.
- If the patient has many clinical features of fragile X syndrome and Southern blot analysis is normal, consider further molecular techniques to detect point mutations or whole/partial FMR1 gene deletions.

Diagnostic Procedures/Other

- Echocardiogram if cardiac exam is consistent with MVP (usually in adults)
- Aortic root dilation may be seen but typically does not progress or require specific treatment
- Evaluate for hypertension.
- Assess for seizure activity.
- Developmental evaluations
 - Feeding assessment in infants
 - Education planning
 - Speech and language
 - Hearing assessment
 - Occupational and physical therapy
 - Behavioral/neuropsychological testing

DIFFERENTIAL DIAGNOSIS

- In early childhood, the symptoms of fragile X syndrome are often

nonspecific.

- Other genetic syndromes with overlapping features include the following:
 - Fragile XE syndrome (FRAXE): Patients have a milder degree of intellectual disability as well as less specific physical characteristics compared to patients with typical fragile X syndrome (FRAXA). Mutations of FMR2 on Xq28 are associated with FRAXE.
 - Sotos syndrome: Patients have overgrowth (macrocephaly), intellectual disability, behavioral abnormalities, and cardiac and renal defects. Mutations or deletions of NSD1 are causative of this syndrome.
 - Abnormal parent-specific imprinting of chromosome 15q11-q13:
 - Paternal chromosome affected: Prader-Willi syndrome—infantile hypotonia, obesity, hyperphagia, developmental delay, cognitive deficits, and behavioral abnormalities
 - Maternal chromosome affected: Angelman syndrome—severe developmental delay or intellectual disability, minimal to no speech development, gait ataxia and/or tremulousness of the limbs, and inappropriate happy demeanor that includes frequent laughing, smiling, and excitability
 - A range of other genes is now recognized to cause syndromic autism and X-linked intellectual disability. PTEN mutations can be associated with macrocephaly and autism. Clinical diagnostic testing either individually or through gene panels is available (www.genetests.org).

TREATMENT

MEDICATION

- No specific medications are available.
- Some medications are used to treat specific symptoms in individual patients:
 - Medications for hyperactivity (e.g., methylphenidate, clonidine, others)
 - Selective serotonin reuptake inhibitors (e.g., fluoxetine) for

obsessive and compulsive behaviors, social phobia, anxiety, and depression

- Atypical antipsychotic medications (e.g., risperidone) for psychosis or paranoia
- Valproic acid or carbamazepine for seizures and/or mood stabilization

ADDITIONAL TREATMENT

General Measures

- Treatment is aimed at supportive measures.
- Per American Academy of Pediatrics (AAP) guidelines, routine evaluation for ocular, ENT, skeletal, and neurologic abnormalities. Refer to appropriate specialists as needed.
- Early developmental services
 - Physical therapy for joint laxity/hypotonia
 - Occupational therapy
 - Speech and language therapy
 - Social integration therapy
- Some patients do well in a mainstream school with appropriate support, whereas others require a school for children with special needs.
- Behavioral therapies involve avoidance of overstimulation and providing positive reinforcement.

ADDITIONAL THERAPIES

- Experimental therapies
 - Glutamate receptor antagonists, gamma-aminobutyric acid (GABA) receptor agonists, minocycline, carnitine, valproic acid, and lovastatin have shown some improvement in the neurologic and behavioral symptoms.
- Surgery/other procedures
 - Myringotomy tubes if with frequent ear infections and/or conductive hearing loss
 - Inguinal hernia repair, if present
 - Strabismus repair, if necessary
 - Corrective lenses for refractive errors

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Regular follow-up with a behavioral and developmental pediatrician as well as a psychiatrist/psychologist is recommended for patients with behavioral problems.
- Hypertension can occur in adults with fragile X syndrome. Therefore, annual blood pressure and cardiac exam should be performed. Hypertension can be treated with typical medications used in the general population. If hypertension is refractory to treatment, evaluate for other causes of high blood pressure (e.g., renal).

DIET

No specific dietary requirements.

PROGNOSIS

Most patients generally have a normal lifespan.

CODES

ICD10

Q99.2 Fragile X chromosome

FAQ

- Q. Why is it called “fragile X syndrome”?
- A. Early cytogenetic studies of male patients with intellectual disability identified a site on the X chromosome that would appear constricted when the patient’s cells were grown with special culture techniques to induce “fragile” sites.
- Q. How many repeats are necessary to cause the full mutation resulting in fragile X syndrome?
- A. More than 200 repeats.
- Q. What are typical facial features seen in patients with fragile X syndrome?
- A. Prominent forehead, long face, protruding ears, and a prominent chin.
- Q. When does the macroorchidism associated with fragile X syndrome typically develop?
- A. After puberty.

FROSTBITE

Denise A. Salerno

BASICS

DESCRIPTION

- Localized injury of epidermis and underlying tissue resulting from exposure to extreme cold or contact with extremely cold objects
- Distal extremities and unprotected areas (i.e., fingers, toes, ears, nose, and chin) most commonly affected
- Feet and hands account for 90% of frostbite injuries.
- Classified according to severity:
 - Superficial, 1st degree: partial skin freezing
 - Superficial, 2nd degree: full-thickness skin freezing
 - Deep, 3rd degree: full-thickness skin and subcutaneous tissue freezing
 - Deep, 4th degree: full-thickness skin, subcutaneous tissue, muscle, tendon, and bone freezing
- New classification of severity at day 0 has been proposed based on findings that correlate extent of frostbite with outcome of involved body part along with results of bone scans:
 - 1st degree: leads to recovery
 - 2nd degree: leads to soft tissue amputation
 - 3rd degree: leads to bone amputation
 - 4th degree: leads to large amputation with systemic effects

RISK FACTORS

- Alcohol use
- Arthritis
- Atherosclerosis
- Constricting clothing
- Diabetes mellitus
- High altitude
- Hypothermia
- Immobilization

- Improper use of aerosol sprays
- Previous cold injury
- Smoking tobacco
- Trauma
- Vasoconstrictive drugs
- Body parts most affected:
 - Fingers
 - Toes
 - Nose
 - Cheeks
 - Ears
 - Male genitalia
- Groups at risk:
 - Mentally ill patients
 - Patients with impaired circulation
 - Winter sports enthusiasts and fans
 - Homeless persons
 - Very thin individuals
 - Malnourished people
 - Outdoor laborers
 - Military personnel, especially those of African American and Afro-Caribbean descent, exposed to cold, wet climates
 - Elderly people
 - Very young people

GENERAL PREVENTION

- Avoid prolonged cold exposure whenever possible.
- Maintain adequate nutrition and hydration when spending time in cold weather.
- Dress appropriately for cold weather:
 - Dress in layers: Clothing should be made of material that absorbs perspiration and prevents heat loss, and outerwear should be windproof and water repellent.
 - Cover head, ears, and neck.
 - Mittens help to conserve heat better than gloves do.
 - Footwear should be water-repellent and insulated.

PATHOPHYSIOLOGY

- Tissue damage and cell death result from initial freeze injury and inflammatory response that occurs with rewarming.
- Direct cellular damage can occur from frostbite. As temperature of freezing tissue approaches -2°C , extracellular ice crystals form and cause increased osmotic pressure in the interstitium, leading to cellular dehydration. As freezing continues, these shrinking, hyperosmolar cells die due to abnormal intracellular electrolyte concentrations. With rapid freezing, intracellular ice crystal formation occurs, resulting in immediate cell death.
- Indirect cellular damage results from progressive microvascular insult. Initial tissue response to extreme cold exposure is vasoconstriction. Blood flow to extremities is reduced as freezing continues. Ice crystals form in plasma, blood viscosity increases, and decreased circulation and formation of microthrombi occur in distal extremities, resulting in hypoxia, tissue damage, and ischemia.
- Oxygen free radicals and inflammatory mediators, especially prostaglandin F₂ and thromboxane A₂, contribute to tissue injury following rewarming and reperfusion of damaged tissue.
- Most severe injuries are seen in tissues that freeze, thaw, and freeze again.

DIAGNOSIS

- Depends on severity
- Superficial, 1st degree: transient tingling, stinging, and burning followed by throbbing and aching with possible hyperhidrosis (excess sweating)
- Superficial, 2nd degree: numbness, with vasomotor disturbances in more severe cases
- Deep, 3rd degree: no sensation initially, followed by shooting pains, burning, throbbing, and aching
- Deep, 4th degree: absence of sensation, presence of muscle function, pain, and joint discomfort

HISTORY

- Was there prolonged exposure to cold environment? In frostbite, history of prolonged cold exposure is typical.
- Was there contact with a cold object, especially metal? Metal will drain heat from skin through conduction and increase the risk of frostbite.
- What was the timing and duration of exposure?
- Was there any treatment prior to presentation?
- Does the patient have any underlying conditions or behaviors that put him or her at risk?
 - Peripheral vascular disease, medications, smoking, etc.

PHYSICAL EXAM

- Superficial, 1st degree: waxy appearance, erythema, and edema of involved area without blister formation
- Superficial, 2nd degree
 - Erythema, significant edema, blisters with clear fluid within 6–24 hours
 - Desquamation may occur with eschar formation 7–14 days after initial injury.
- Deep, 3rd degree: hemorrhagic blisters, necrosis of skin and subcutaneous tissues, skin discoloration in 5–10 days
- Deep, 4th degree: initially, little edema with cyanosis or mottling; eventually, complete necrosis, then becomes black, dry, and mummifies; occasionally results in self-amputation

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Usually not necessary but may be indicated when infection is suspected

Imaging

- No diagnostic studies done immediately after rewarming can accurately predict amount of nonviable tissue.
- Radionucleotide angiography with 99m-Tc-pertechnetate or triple-phase bone scanning with 99m-Tc-methylene diphosphonate 1–2 weeks after initial injury is advocated by some to assess tissue viability in cases of 3rd- and 4th-degree frostbite.
- MRI and MRA are being advocated by some as superior techniques for

severe frostbite. They allow for direct visualization of occluded vessels and tissue, giving a more clear-cut demarcation of ischemic tissue injury, which may allow for earlier surgical intervention.

DIFFERENTIAL DIAGNOSIS

- Frostnip: mild form of cold injury with pallor and painful, tingling sensation. Warming of cold tissue results in no tissue damage.
- Hypothermia
- Thermal injury: easily excluded based on history but can result from warming techniques

TREATMENT

MEDICATION

- Tetanus prophylaxis: dT, dTap, or DT/DTaP, depending on age, and tetanus immunoglobulin if patient not fully immunized
- Anti-thromboxane agents (NSAIDs, prostaglandin E₁ [PGE₁]) to prevent intravascular thrombosis
- Pentoxifylline (a phosphodiesterase inhibitor) should be considered with severe frostbite. It has been shown to enhance tissue viability by increasing blood flow and reducing platelet activity.
- Analgesics: as indicated
- Antibiotics: given prophylactically by some; others recommend waiting for signs of infection or necrotic tissue.
- Tissue plasminogen activator (tPA) is being used by frostbite specialists within 24 hours of acute, severe frostbite. It is useful when microvascular thrombosis has already developed. Studies show it can significantly reduce digital amputation rates

ADDITIONAL TREATMENT

General Measures

- Check core temperature to rule out hypothermia, which would need to be addressed first.
- Remove constrictive clothing and jewelry.
- Rapid rewarming in warm water (40–42°C) for 15–45 minutes
 - Do not rewarm slowly.

- Rewarming is complete when skin is soft and sensation returns.
- Usually all that is needed for superficial, 1st-degree frostbite
- Apply dry, sterile dressings to affected areas and between frostbitten toes and fingers.
- Intact nontense clear blisters should be left in place and wrapped with loosely applied dry gauze dressings. Rupturing may increase the risk of infection.
- Tense or hemorrhagic blister may be carefully aspirated, but this increases the risk for infection.
- Ruptured blisters should be debrided and covered with antibiotic ointment and nonadhesive dressings.
- Elevate affected parts to minimize edema.
- Daily hydrotherapy with hexachlorophene or povidone-iodine added to water
- Topical application of aloe vera (for its antiprostaglandin effect) to debrided blisters and intact hemorrhagic blisters to minimize further thromboxane synthesis

ALERT

- Prohibit nicotine use because of its vasoconstrictive properties.
- Full extent of injury may not be apparent at presentation. Close observation is important.

SURGERY/OTHER PROCEDURES

- Conservative surgical intervention: recommended because it usually takes 6–8 weeks for injured tissue to declare viability
- Escharotomy: performed on digits with impaired circulation or movement
- Fasciotomy: performed if significant edema causes compartment syndrome
- Early amputation and debridement with closure of wound site: necessary for uncontrolled infection
- Debridement of mummified tissue: performed after 1–3 months

INPATIENT CONSIDERATIONS

Initial Stabilization

- Do not rub the area; it may cause mechanical injury.

- Do not expose the area to direct heat; it may cause burn injury.
- Refreezing after thawing leads to increased injury.
- Remove wet clothing and constricting jewelry.

ONGOING CARE

PROGNOSIS

- Depends on degree of cold injury
- Superficial, 1st-degree frostbite heals in a few weeks.
- Favorable indicators: sensation in affected area, healthy-looking skin color, blisters filled with clear fluid
- Unfavorable indicators: cyanosis, blood-filled blisters, unhealthy-looking skin color
- Early rehabilitation often needed for functional recovery.
- Long-term follow-up for 6–12 months to monitor for sequelae
- Education to avoid reexposure and reinjury

COMPLICATIONS

- Arthritis
- Changes in skin color
- Chronic numbness
- Chronic pain
- Cold hypersensitivity
- Digital deformities
- Gangrene
- Growth plate abnormalities (only in children)
- Hyperesthesias
- Neuropathy
- Premature closure of the physis (in children)
- Reduced sensitivity to touch
- Rhabdomyolysis
- Squamous cell carcinoma (rare)
- Tetanus
- Tissue loss
- Wound infection

FAQ

- Q: Why did I need to get a tetanus shot when I had frostbite?
- A: Injuries, such as frostbite, that cause dead skin are at risk for causing tetanus. The absence of oxygen in dead tissues allows tetanus spore to reproduce and produce the toxin that leads to tetanus.
- Q: I've heard that your eyes can get frostbite. Is that true?
- A: Frozen corneas (the surface layer of the eye) have been reported in persons partaking in high wind-chill activities such as snowmobiling and skiing. Prevention is possible with the use of protective goggles/sunglasses.

- Q: My children's doctor recommended that we use sunscreen when we go skiing. Will the sunscreen help prevent frostbite?
- A: Although sunscreen is necessary to prevent getting sunburn that can occur from the sunlight's reflection off the snow, it will not decrease the risk for frostbite from the cold exposure.
- Q: I live in Buffalo, New York, where the winters are very cold and the windchill factor is often below zero. My children like playing outside, especially in the snow. How can I prevent them from getting frostbite?
- A: Because there is a risk of frostbite with a wind-chill factor of -25°C , try to encourage indoor play when the temperature dips this low. It is important to have the children come inside frequently to warm up and for you to check for signs of cold injury.
- Q: My family members are avid skiers. While traveling in Europe last winter, I purchased a protective emollient that was sold there. Can protective emollients prevent frostbite if used on the face and exposed areas while skiing?
- A: No. Research has shown that the use of "protective" emollients and creams leads to a false sense of safety and leads to an increased risk of frostbite. This is thought to be due mostly to the failure to use more efficient protective measures when the emollients and creams are used.
- Q: If my child has had frostbite in the past, can she get it again?
- A: Yes. Children who have had a previous frostbite injury are at increased risk for repeat injury, especially in the location of previous damage. Appropriate clothing and limitation of cold exposure should be strictly enforced.
- Q: To prevent frostbite, is there a temperature below which I should not let my child go out to play?
- A: Although body tissue freezes more quickly at lower temperatures, the degree of damage from frostbite is related to the length of time tissue remains frozen. Therefore, the amount of time spent outside during cold weather should never be prolonged.
- Q: How can I tell if my child has frostbite or just cold fingers?
- A: Cold fingers are red and may be painful but do not become numb or white. Frostbitten fingers are painful, white, and waxy prior to rewarming and turn red with rewarming. The sequential development

of digital blanching, occasional cyanosis, and erythema of the fingers or toes following cold exposure and subsequent rewarming is known as Raynaud phenomenon.

- Q: If I suspect frostbite in my child and we are outdoors without access to warm water, are there any options for treatment?
- A: If there is a delay in reaching shelter, you can start to thaw your child's body part by using your body as a warmer by placing the exposed body part under your armpit and keeping it there until further care can be initiated. Before starting the rewarming process, you must be sure refreezing will not recur.
- Q: When should I call the doctor?
- A: The doctor should be called if, after rewarming, the skin is not soft and/or sensation does not return to normal. Call the doctor immediately if the skin is discolored and cold, blisters develop during rewarming, or there are signs of infection, such as the appearance of red streaks leading from the affected area, pus accumulation, or fever.
- Q: We are going on a winter vacation this year and expect to spend a lot of time outside skiing and sledding. What types of clothing should I pack for my 6-year-old son?
- A: It would be a good idea to pack a few pairs of waterproof mittens, a ski suit or ski pants, waterproof boots, thick cotton socks, and cotton thermal under garments. Try to make sure your son stays dry and warm. Take frequent breaks indoors to warm up and check your child for any early signs of cold injury.
- Q: Is frostnip the same thing as frostbite?
- A: No. Frostnip is the mildest form of cold injury, which commonly occurs on exposed parts of the body, such as the fingers, nose, and ears. The symptoms of frostnip are numbness and pallor of the involved body parts. Warming of these areas is the only treatment that is needed, and there is no associated tissue damage.

FUNCTIONAL DIARRHEA OF INFANCY (TODDLER'S DIARRHEA)

Roberto Gugig

BASICS

DESCRIPTION

- Benign chronic diarrhea in a toddler or a preschool child who appears healthy and is normally active and who is growing, without evidence of systemic illness, infection, malabsorption, or malnutrition
- Also known as chronic nonspecific diarrhea of childhood, toddler's diarrhea, and irritable bowel of childhood

RISK FACTORS

Genetics

Family members often report nonspecific GI complaints or functional bowel disorders.

GENERAL PREVENTION

- Limit the consumption and delay the introduction of sorbitol or fructose-rich fruit juices to the infant diet.
- In the treatment of acute gastroenteritis, parents should be instructed to give an oral rehydration solution (ORS) and resume normal feeding early, avoiding diet restrictions.
- Avoid restrictive diets that may cause caloric deprivation.

PATHOPHYSIOLOGY

- Carbohydrate malabsorption
 - Diarrhea is often preceded by acute gastroenteritis or other viral infection that results in dietary restrictions. Increased oral fluids, including juices, are used to compensate for stool losses and to prevent dehydration.
 - Capacity of the small intestine to absorb fructose is limited. Foods that contain equivalent amounts of fructose and glucose are more readily absorbed because of the additive effect of a glucose-

dependent fructose cotransport mechanism.

- Excessive consumption of juices high in sorbitol (which inhibits fructose absorption) and those with a high fructose-to-glucose ratio (e.g., apple juice) result in fructose malabsorption and increased intraluminal gas caused by fermentation. The end result is abdominal distension, excessive flatulence, and diarrhea.
- Colonic function: possibly, disruption of colonic ability to ferment unabsorbed carbohydrates into short-chain fatty acids (SCFA), which maintain colonic function and prevent colon-based diarrhea
- Disturbed motility: short mouth-to-anus transit time
 - Persistence of immature bowel motility pattern. Failure of initiation of normal postprandial delayed gastric emptying
 - Low-fat meals. Meals with high dietary fat delay gastric emptying.
 - Excess fluid intake. Infant's colon already operates in high efficiency (in children, higher volume of fluids reach the cecum). Excessive fluids can lead to diarrhea.
 - Low-fiber diet. Dietary fiber serves as a bulking agent.
 - Excessive fecal bile acids. Rapid transit resulting in excess conjugated bile salt entering the colon. Bacterial degradation produces unconjugated bile salts, which decrease net water absorption in the colon.

ETIOLOGY

- Nutritional factors: excessive consumption of fruit juice; high-carbohydrate, low-fat, and low-fiber diet
- Disordered intestinal motility (i.e., variant of irritable bowel syndrome of infancy) with rapid transit

DIAGNOSIS

- The typical age is 12–36 months, but range is 6 months to 5 years.
- Diagnostic criteria (Rome III):
 - Daily, painless, recurrent passage of ≥ 3 large unformed stools
 - Symptoms that last > 4 weeks
 - Onset of symptoms that begins between 6 and 36 months of age

- Passage of stools that occurs during waking hours
- There is no failure to thrive (FTT) if caloric intake is adequate:
 - There is no definite diagnostic test. The diagnosis is primarily clinical based on age of onset, the history, symptoms, clinical course, and limited number of laboratory tests. Usually, it is an evident condition and not a diagnosis of exclusion.

HISTORY

- Nutritional history is essential, with attention to the 4 Fs (fiber, fluid, fat, and fruit juices) and dietary changes.
- Diarrhea
 - For a toddler, it may not be abnormal to have >3 soft and occasionally loose stools a day with visible food remnants.
 - Children, typically, have intermittent symptoms, and are often diagnosed with recurrent viral gastroenteritis.
- Stool characteristics
 - Stools that smell foul and contain undigested food particles. Presence of blood or mucus suggests another diagnosis.
- Timing of diarrhea
 - No stools passed at night, and typically, the first stool of the day is large and has firmer consistency than those occurring later on in the day.
- Recent enteric infection
 - Presence of other affected family members, history of travel, day care, and infectious contacts suggests infectious cause.
- Signs and symptoms:
 - Thorough history is required because all illnesses in the differential diagnosis are associated with morbidity if diagnosis is delayed.

PHYSICAL EXAM

- Normal: Children look healthy, eat well, and are growing normally according to serial plots on the growth chart.
- There are no signs of malnutrition or malabsorption. Weight might be influenced by the dietary measures.
- Fecal mass(es) found on abdominal palpation may signal constipation.

DIAGNOSTIC TESTS & INTERPRETATION

- The following tests would be helpful only if indicated by history and physical exam:
 - Cystic fibrosis: sweat test, stool for pancreatic enzymes, and genetic testing
 - Celiac disease is common and warrants a serologic testing (antiendomysial antibodies, tissue transglutaminase antibodies with IgA serum levels).
 - CBC, iron studies, vitamin levels, serum albumin
 - Allergy testing for suspected food proteins (commonly milk, soy, egg, and wheat)
 - Inflammatory markers
- Diarrhea as the sole symptom of malabsorption in a normally thriving child is rare.

Lab

- Stool tests and culture: negative for white blood cells, blood, fat, and pathogens including ova, parasites, and Giardia antigen
- Serum electrolytes normal: no dehydration
- Celiac serology: negative
- CBC normal: no anemia
- Food allergen testing: negative

Imaging

Usually unnecessary: Plain abdominal radiograph may demonstrate colonic fecal retention.

Diagnostic Procedures/Other

- A trial of lactose and fruit juice-free diet done separately is practical and diagnostic.
- Breath hydrogen test has limited benefit and is inferior to a trial of milk avoidance.
- Small bowel biopsy is rarely indicated unless strong evidence suggests another cause (e.g., positive celiac serology).

DIFFERENTIAL DIAGNOSIS

- All causes of chronic diarrhea should be considered.
- Infection: bacterial, viral, and parasite (giardiasis, cryptosporidiosis)
- Celiac disease

- Malabsorption: carbohydrate: postinfectious secondary lactose intolerance, sucrase-isomaltase deficiency
- Pancreatic: cystic fibrosis, Shwachman-Diamond syndrome, Johansson-Blizzard syndrome, chronic pancreatitis
- Bile acid disorders: chronic cholestasis, terminal ileum disease, bacterial overgrowth
- Immunologic: cow's milk and soy protein intolerance, food allergy, immunodeficiency
- Food allergies
- Miscellaneous: antibiotic-associated diarrhea, laxatives, fecal retention constipation, UTI, abetalipoproteinemia, inflammatory bowel disease, short-bowel syndrome, hormone-secreting tumors, Munchausen by proxy
- Common conditions that may cause diarrhea without FTT: constipation, lactose intolerance, and persistent infective diarrhea
- Constipation-related diarrhea is frequently overlooked. Consider it if diarrhea alternates with hard stools.

TREATMENT

MEDICATION

- Medications are unwarranted for a condition primarily caused by food that does not hamper growth.
- Metronidazole may be beneficial for patients with undetected giardiasis.
- Loperamide is effective in normalizing bowel patterns, but only for duration of therapy.
- Studies have shown that certain probiotic preparations such as *Lactobacillus rhamnosus* and *Saccharomyces boulardii* may be effective at reducing symptoms.

ADDITIONAL TREATMENT

General Measures

Daily diet and defecation diary may document a specific food responsible for loose stools.

ADDITIONAL THERAPIES

Reassure parents that there is no underlying GI disease, infection, or inflammation.

ISSUES FOR REFERRAL

- Failure of response to diet
- Weight loss despite adequate intake
- Presence of other symptoms (e.g., anorexia, irritability, fever, vomiting)
- Fat, blood, and mucus in the stool

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Improvement with dietary changes confirms the diagnosis and reassures the parents.
- Follow up phone call to parents within a few days of instituting diet. If no improvement within 2 weeks despite good compliance with dietary recommendations, then reconsider diagnosis; consider more diagnostic tests and referral to a specialist.

Patient Monitoring

- Follow growth parameters.
- Monitor symptoms indicating nonfunctional illness.

DIET

- The child's feeding pattern should be normalized according to the 4 Fs:
 - Overconsumption of fruit juices should be discouraged, especially those that contain sorbitol and a high fructose-to-glucose ratio (e.g., apple juice, pear nectar).
 - Cloudy apple juice or white grape juice may be safe as alternatives.
 - Fiber intake should be normalized by introduction of whole-grain bread and fruits.
 - Increase dietary fat to at least 35–40% of total energy intake. Substitution of low-fat milk with whole milk may be sufficient.

- Restrict fluid intake to <90 mL/kg/24 h if history is significant for fluid consumption >150 mL/kg/24 h.
- Improvement occurs within a few days to a couple of weeks after initiating the earlier discussed therapy.

PROGNOSIS

- Good
- Symptoms resolve by school age.
- Long-term benefit of low-carbohydrate diet: contributes to balanced nutrition and the prevention of obesity

COMPLICATIONS

Although children tend not to suffer from the symptoms, parents are often worried and frustrated and require frequent reassurance.

CODES

ICD10

- K59.1 Functional diarrhea
- K90.4 Malabsorption due to intolerance, not elsewhere classified

FAQ

- Q: How do I know that my toddler's diarrhea is not serious?
- A: Growth is usually normal and your child looks and feels well. His or her activity and development seem unaffected by the diarrhea. The change of diet results in improvement.
- Q: What are the components of a successful treatment plan?
- A: Attention to the 4 Fs in the diet: decreased fruit juice intake, increased fat intake, decreased fluid, and increased fiber intake
- Q: Are probiotics useful in the treatment of toddler's diarrhea?
- A: There is no adequate data to support such a recommendation, but evidence is emerging that probiotics may be effective in treating "irritable bowel syndrome like diarrhea and bloating."
- Q: When should care by a pediatric gastroenterologist be sought?
- A: If no response after 2 weeks of compliance with dietary therapy, if growth is delayed, or if other GI or systemic complaints are present, seek a pediatric gastroenterologist's care.
- Q: Did my child get diarrhea because he goes to child care or because he is not clean?
- A. No. Functional diarrhea is not caused by infection.

FUNGAL SKIN INFECTIONS (DERMATOPHYTE INFECTIONS, CANDIDIASIS, AND TINEA VERSICOLOR)

Sonal Shah • Renee Howard

BASICS

DESCRIPTION

Superficial fungal infections of the skin, hair, and nails are characterized by erythema, scaling, changes in color, and pruritus.

EPIDEMIOLOGY

- Dermatophyte infections
 - Tinea capitis
 - Most common fungal infection in pediatric population
 - Occurs mainly in prepubescent children (between ages 3 and 7 years)
 - Asymptomatic carriers are common and contribute to spread.
 - Tinea corporis is usually seen in younger children or in young adolescents with close physical contact to others (i.e., wrestlers).
 - Onychomycosis: Overall prevalence is 0–2.6% in children; often occurs with concomitant tinea pedis or in 1st-degree relatives with infection
- Candidiasis: majority of infants colonized with *Candida albicans*
- Tinea versicolor: seen in adolescents and young adults

GENERAL PREVENTION

- Measures should be taken to avoid transmission between hosts, including not sharing combs, brushes, hats, etc.
- Hair utensils and hats should be washed in hot, soapy water at onset of therapy.
- Pets should be watched and treated early for any suspicious lesions.
- In patients in whom appropriate therapy has not led to improvement in symptoms, siblings and close contacts should be examined and fungal

cultures performed.

- Isolation of hospitalized patient is unnecessary.

PATHOPHYSIOLOGY

- Fungal elements (arthroconidia) adhere to stratum corneum or hair shaft. Proteases work to degrade keratin, which allows for invasion of dermatophytes.
- Predisposing factors may include moisture, macerated skin, and immunocompromise.
- Host immune response is usually able to contain infection.
- Inflammatory response is variable; highly inflammatory forms may lead to pustules and kerion (large inflammatory mass) formation.

ETIOLOGY

- Varies by geographic region
- Dermatophyte infections
 - Tinea capitis: >90% caused by *Trichophyton tonsurans* in North America; spread from human to human (anthropophilic); increasing incidence of *Microsporum canis* infection spread from animals such as cats and dogs to humans (zoophilic).
 - Tinea corporis: preadolescent children: *M. canis*, *Microsporum audouinii*; older children: *Trichophyton rubrum*, *Trichophyton mentagrophytes*, *T. tonsurans*
 - Onychomycosis: *T. rubrum*, *T. mentagrophytes*
- Candidiasis: usually *C. albicans*
- Tinea versicolor: *Malassezia furfur*

DIAGNOSIS

HISTORY

- Determine onset and duration.
- Elicit signs and symptoms such as expanding areas of erythema, scaling, or color change with associated pruritus.
- Determine contacts, including exposure to pets.
- Determine if patient is immunocompromised.
- List of medications previously prescribed or used

PHYSICAL EXAM

- Dermatophyte infections
 - Tinea capitis: Presentation varies.
 - Round patches of alopecia with erythema or black dots (broken hair shafts at surface of skin)
 - Diffusely dry scalp with scaling
 - Follicular pustules resembling bacterial folliculitis
 - Boggy, tender plaque with follicular pustules or purulent discharge (kerion): represents exaggerated immune response
 - Cervical or occipital lymphadenopathy
 - Tinea corporis
 - One or more, asymmetrically distributed, annular, well-demarcated erythematous scaling plaques with central clearing
 - Inflammatory forms may be frankly pustular or vesicular at the borders.
 - Lesions may occur anywhere on the body.
 - Onychomycosis
 - Distal subungual type: invasion of the underlying nail bed and inferior portion of the nail plate, which leads to detachment of the nail plate from the nail bed and subungual thickening and debris with yellowing of the plate
 - Proximal subungual type: invasion of the nail unit at the proximal nailfold (most common in HIV patients)
 - White superficial type: Superficial infection presents with white plaques on the dorsal nail plate.
- Candidiasis
 - Diffuse erythema (often “beefy” red) with sharp, marginated border
 - Pinpoint satellite pustules at edge of erythema
 - Prefers warm, moist environments
 - Favors skinfolds/creases (axillae, groin, below breasts, and, in infants, diaper area)
- Tinea versicolor
 - Scaling, oval patches that are either hypo- or hyperpigmented
 - Distributed on upper trunk, neck, and proximal arms and in areas where there is high amount of sebum and free fatty acids, which the

organism requires; occasionally on face

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- KOH preparation
 - Clean area with alcohol.
 - Using a no. 15 scalpel blade, gently scrape the outer edge of the active border, broken off hairs, or subungual debris.
 - Place material flat on a glass slide in a single layer. Apply coverslip on top.
 - Place a few drops of 10–20% KOH to edge of coverslip until space between slide and coverslip is filled, and apply mild pressure.
 - Warm slide gently or let sit for 30 minutes.
 - Examine slide under microscope at low power under low light.
 - Dermatophytes: arthrospores around or within hair shaft; long, branching fungal hyphae with septations
 - Candidiasis: budding yeast, pseudohyphae
 - Tinea versicolor: short hyphae and clusters of spores (“spaghetti and meatballs”)
- Fungal culture
 - Obtain specimen with scalpel blade from outer active edge of scaling.
 - For scalp, gently rub a wet sterile toothbrush, cytobrush, or cotton-tipped swab over the area of scaling, then plate on fungal medium.
 - Results can take up to 4 weeks.
 - Some laboratories provide drug susceptibility testing as well as identification of fungus.

Diagnostic Procedures/Other

- Wood’s lamp examination (~360-nm wavelength of ultraviolet light): Infected hairs may fluoresce (not useful in skin or nail infections).
 - Examine in completely darkened room.
 - Ectothrix infections (organisms outside of hair shaft): bright green fluorescence (*M. canis* and *M. audouinii*); endothrix infections (organisms inside hair shaft): do not fluoresce (*T. tonsurans*)
 - Tinea versicolor: yellow, copper, or bronze fluorescence

DIFFERENTIAL DIAGNOSIS

- Dermatophyte infections
 - Dermatologic conditions
 - Tinea capitis: seborrheic dermatitis, psoriasis, alopecia areata, trichotillomania, folliculitis, impetigo, atopic dermatitis
 - Tinea corporis: herald patch of pityriasis rosea, nummular dermatitis, psoriasis, contact or atopic dermatitis, granuloma annulare
 - Onychomycosis: psoriasis, nondermatophyte infection
 - Systemic diseases: cutaneous T-cell lymphoma, histiocytosis, sarcoidosis
- Candidiasis
 - Dermatologic conditions: contact dermatitis, seborrheic dermatitis, atopic dermatitis, bacterial infection
- Tinea versicolor
 - Dermatologic conditions: pityriasis alba, postinflammatory hypopigmentation, vitiligo, seborrheic dermatitis, pityriasis rosea

TREATMENT

MEDICATION

First Line

- Dermatophyte infections
 - Tinea capitis: systemic therapy warranted to penetrate hair shaft
 - Oral griseofulvin: 20–25 mg/kg/24 h (max 1 g/24 h) once daily or divided b.i.d. of microsize griseofulvin for 6–8 weeks (10–15 mg/kg/24 h [max 750 mg/24 h] once daily or divided b.i.d. if ultramicrosize form is used), taken with high-fat food (e.g., milk or ice cream) for 6–12 weeks. In addition, topical therapy of 2.5% selenium sulfide or ketoconazole shampoo twice weekly suppresses viable spores. Laboratory monitoring is not needed.
 - Tinea capitis with kerion
 - Treat for tinea capitis.
 - Systemic steroids may be needed to treat significant inflammation.

- Tinea corporis
 - Topical azole antifungals (1% clotrimazole, 2% ketoconazole) or 1% terbinafine cream applied twice daily for 2–4 weeks
- Onychomycosis
 - Oral terbinafine 3–6 mg/kg/dose (max 250 mg) once daily for 6–12 weeks; can be associated with hepatic failure; avoid use in patients with liver disease. Check liver enzymes before and during treatment.
 - Oral itraconazole (adolescent and adult) in weekly pulses for 3–4 months; 200 mg twice daily for 7 days, then off for 3 weeks
- Candidiasis: topical nystatin cream or ointment 3–4 times daily for 7–10 days
- Tinea versicolor: selenium sulfide 2.5% applied to affected skin for 10 minutes. Wash off thoroughly. Apply daily for 7–10 days. Monthly applications may help prevent recurrences.

Second Line

- Dermatophyte infections
 - Tinea capitis
 - Oral itraconazole: 3–5 mg/kg once daily for 4–6 weeks. May also use oral terbinafine 3–6 mg/kg once daily for 4 weeks or oral fluconazole 5 mg/kg once daily for 4–6 weeks. All of these may be associated with hepatic failure and should be avoided in patients with liver disease. Liver enzymes should be checked before and during treatment.
 - Tinea corporis
 - Oral griseofulvin 15–25 mg/kg once daily or divided b.i.d. for 4 weeks for persistent or extensive involvement
- Candidiasis
 - Oral fluconazole
 - 6 mg/kg on day 1, then 3 mg/kg once daily for 2 weeks if poor response to topical therapy
- Tinea versicolor
 - Topical azole antifungals (ketoconazole 2% shampoo applied daily for 3 days)
 - Oral ketoconazole (adolescent and adult) 200–400 mg once daily

for 5–10 days or itraconazole (adolescent and adult) 200 mg once daily for 5–7 days if severe, recurrent, or persistent

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Monitor for secondary bacterial infection.
- Highly inflammatory lesions (kerion) may require concomitant systemic steroids.
- Repeated infection may indicate a source that needs to be diagnosed and treated (e.g., family member or pet).

DIET

Griseofulvin is better absorbed with a fatty meal and should be taken with foods such as milk, eggs, or ice cream.

PROGNOSIS

- Dermatophyte: Inflammation improves within several days but may take several weeks to completely resolve; nail infections take 6–12 months to show improvement and are prone to recurrence.
- Areas with significant inflammatory component may become scarred and permanently alopecic.
- Candidal skin lesions improve within 24–48 hours and resolve by 1 week.
- Tinea versicolor: Resolution of dyspigmentation may take months to occur.
- Relapses and recurrences are common.

COMPLICATIONS

- Dermatophyte infections
 - Secondary bacterial infection
 - Kerion formation can lead to permanent alopecia and scarring.
- Candidiasis
 - Scarring in severe disease
 - Fungemia in immunocompromised host

- B35.4 Tinea corporis
- B37.2 Candidiasis of skin and nail

FAQ

- Q: What is the role of combination topical antifungals and corticosteroids in the treatment of superficial fungal infections of the skin?
- A: Combination products containing high-potency topical steroid antifungals should be avoided. High-potency topical steroids may lead to a decrease in inflammation; however, they can mask the clinical features of tinea infection (so-called tinea incognito) and can allow for rapid expansion of infection. In addition, prolonged use of high-potency topical steroids used particularly in intertriginous areas can

lead to side effects such as striae formation and atrophy of the skin.

- Q: What can be done to prevent recurrent tinea versicolor infection?
- A: *M. furfur* is a normal part of skin flora and lives in lipid-rich areas of skin. Tropical climates, humid environments, and excessive sweating result in infection in adolescents and young adults. Recurrences are common and can be prevented by regular application of selenium sulfide 2.5%. In addition, itraconazole has been shown to be effective in prevention of tinea versicolor. In one study, the recurrence of tinea versicolor was prevented in 88% of patients over a 6-month period using itraconazole 200 mg b.i.d. 1 day per month.
- Q: How can a clinician adequately assess for complete clearance when treating tinea capitis?
- A: At the end of treatment course, a repeat fungal culture should be performed to ensure complete clearance of spores.

GASTRITIS

Richard Lirio

BASICS

DESCRIPTION

Microscopic inflammation of mucosa of stomach

EPIDEMIOLOGY

- Most common cause of upper GI tract hemorrhage in older children
- 8 out of every 1,000 people are estimated to have gastritis.
- >2% of ICU patients have heavy bleeding secondary to gastritis.

ETIOLOGY

- Physiologic stress (e.g., chronic disease, CNS disease, overwhelming sepsis, ICU patients)
- Peptic disease
- Drug-induced (e.g., NSAIDs, steroids, valproate; more rarely, iron, calcium salts, potassium chloride, antibiotics)
- Infection (e.g., tuberculosis, *Helicobacter pylori*, cytomegalovirus, parasites)
- *H. pylori* (children more likely to have more severe gastritis, specifically located in antrum of stomach)
- Celiac disease: lymphocytic gastritis
- Major surgery; severe burns; renal, liver, respiratory failure; severe trauma
- Caustic ingestions (e.g., lye, strong acids, pine oil)
- Protein sensitivity (e.g., cow's milk-protein allergy), allergic enteropathy
- Eosinophilic gastroenteritis
- Crohn disease: Up to 40% of Crohn patients have gastroduodenal involvement.
- Gastric Crohn disease may manifest itself as highly focal, non-*H. pylori*, nongranulomatous gastritis.
- Direct trauma (nasogastric tubes)

- Ethanol
- Idiopathic
- Less common causes:
 - Radiation
 - Hypertrophic gastritis (Ménétrier disease)
 - Autoimmune gastritis
 - Collagenous gastritis
 - Zollinger-Ellison syndrome
 - Vascular injury

DIAGNOSIS

HISTORY

- Epigastric pain
- Abdominal indigestion
- Nausea
- Vomiting postprandially
- Vomiting blood or coffee ground–like material
- Diarrhea
- Dark or black stools (or bright red blood from rectum, if bleeding is brisk and intestinal transit time is short)
- Irritability
- Poor feeding and weight loss
- Less often: chest pain, hematemesis, melena

PHYSICAL EXAM

- Epigastric tenderness is physical finding that most closely correlates with gastritis on endoscopy.
- Normal bowel sounds

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
 - Evaluate for anemia with other signs of chronic blood loss (e.g., microcytosis, low reticulocyte count).
- Heme testing stool may be helpful.

- H. pylori identification
 - Noninvasive H. pylori tests, including antibody (from serum, whole blood, saliva, or urine), antigen (from stool), or urea breath testing (UBT)
 - UBT (using C₁₃) and stool antigen tests are more reliable and sensitive than antibody testing; serologic testing is not recommended. However, UBT is not widely available and is used primarily in adults.
 - Rapid urease test from gastric biopsy specimen for H. pylori

Imaging

- Upper GI radiography when endoscopy not available
- Chest radiograph may detect free abdominal air secondary to perforation.

Endoscopy

Upper endoscopy with biopsies

- Greatest sensitivity for gastritis
- Possible gross findings:
 - Erythema, granularity, edema, small ulcerations
 - Thickened hyperemic mucosa
 - Atrophic mucosa
 - Antral micronodules (represent lymphoid follicles) commonly seen in children with H. pylori infection
 - Antral and prepyloric edema with retained gastric secretions
- Biopsies will show chronic and/or active inflammation.
 - Can order special staining (Silver Warthin-Starry stain, Genta stain, modified Giemsa stain, or cresyl violet stain) of gastric biopsy for H. pylori
 - Culture and sensitivities of homogenized gastric biopsy for H. pylori (difficult to perform outside of research setting)

DIFFERENTIAL DIAGNOSIS

- Gastroesophageal reflux with esophagitis
- Peptic ulcer disease
- Biliary tract disorders
- Pancreatitis

- Inflammatory bowel disease
- Genitourinary pathology (renal stones, infection)
- Nonulcer dyspepsia
- Functional pain
- Allergic enteropathy

TREATMENT

MEDICATION

- Proton pump inhibitors: drug of choice as 1st-line therapy. Can also use antacids or H₂ blockers to maintain gastric pH >4–5
 - Ranitidine: 2–3 mg/kg/dose b.i.d.–t.i.d. in children
 - Famotidine: 0.5–2 mg/kg/24 h divided b.i.d.
 - Omeprazole, lansoprazole, rabeprazole, or esomeprazole: 1–2 mg/kg/24 h divided b.i.d.
 - Interactions: Cimetidine is less effective and can increase toxicity when given to patients receiving other medicines metabolized by cytochrome P450 system (e.g., theophylline). Proton pump inhibitors can also interfere with the absorption of other medicines and may interact with other medicines metabolized by specific cytochrome P450 isoenzymes.
- Misoprostol
 - Synthetic prostaglandin E1 (PGE1)
 - May reduce risk of progression of gastritis to ulcers in patients taking NSAIDs
 - Concerns exist for increased cardiovascular events in adults when using misoprostol.
- Discontinue NSAIDs.
- Treatment of H. pylori:
 - Triple therapy with proton pump inhibitor and antibiotics (e.g., omeprazole, amoxicillin, and clarithromycin)
 - If eradication unsuccessful, quadruple therapy is recommended for 7–14 days, including the following:
 - Bismuth (of note, may need to avoid bismuth subsalicylate and choose instead bismuth subcitrate)

- Metronidazole
- A proton pump inhibitor
- Another antibiotic (either amoxicillin, clarithromycin, or tetracycline)
- Drug regimens change frequently; clarithromycin resistance becoming increasingly problematic

ALERT

- Antacids are not palatable to children and can lead to diarrhea or constipation. Prolonged use of large doses of aluminum hydroxide-containing antacids may lead to phosphate depletion and aluminum-related CNS toxicity (particularly in patients with renal disease).
- If *H. pylori* eradication is attempted, important to use a tested regimen. Untested substitutions in the triple or quadruple regimens should be avoided.

ONGOING CARE

FOLLOW-UP-RECOMMENDATIONS

Patient Monitoring

- For stress gastritis with hemorrhage, provide vigilant supportive care with close monitoring of hemodynamics, fluids, and electrolytes.
- Monitor for Hemoccult-positive stools.
- Follow CBCs.
- May elect to repeat endoscopy in severe cases

DIET

- Benefit of changes in diet is inconclusive.
- Eliminate alcohol, tobacco, and caffeine, as well as NSAIDs.

PROGNOSIS

Significant gastritis relapse rates for children who remain infected with *H. pylori*

COMPLICATIONS

- Bleeding (from mild to hemorrhagic)
- When gastritis caused by acid/alkali ingestions, outlet obstruction may

result from prepyloric strictures (4–8 weeks after ingestion).

- K29.71 Gastritis, unspecified, with bleeding
- K29.60 Other gastritis without bleeding

FAQ

- Q: Will a bland diet help to resolve gastritis?
- A: Dietary changes have not been shown to affect the natural course of gastritis.
- Q: What is *H. pylori*?
- A: *H. pylori* is a bacterium frequently found in the gastric mucosa of patients with gastritis and peptic ulcer disease. It can be diagnosed by a variety of means, often including a combination of upper endoscopy and urea breath tests. Relapse rates for gastritis secondary to *H. pylori* are high when the infection is left untreated.
- Q: Is it appropriate to treat cases of gastritis with antibiotics not proven to be *H. pylori*?
- A: No. It is important to treat only confirmed *H. pylori* infections, not to treat on suspicion of infection, especially with increasing issues with antibiotic resistance.
- Q: If a patient is treated for *H. pylori* and they still have symptoms and a positive stool *H. pylori* Ag, what would be the next course of action?
- A: Consider retreating with a proton pump inhibitor, amoxicillin, and Flagyl, as clarithromycin resistance in *H. pylori* infection is an increasingly frequent cause for treatment failure.
- Q: What are newly recognized complications of treating patients with proton pump inhibitors?
- A: Some adult studies show hypomagnesemia, increased risk of pneumonia, hip fracture, and *Clostridium difficile* infection are associated with proton pump inhibitor use.

GASTROESOPHAGEAL REFLUX

Peter D. Ngo

BASICS

DESCRIPTION

- Effortless regurgitation of gastric contents. Occurs physiologically at all ages, and most episodes are brief and asymptomatic
- Divided into physiologic and pathologic processes:
 - Some degree of physiologic gastroesophageal reflux (GER) is normal at all ages.
 - Physiologic infant reflux (normal GER of infancy) is very common. Symptoms peak around 4 months of age and generally have resolved by 1 year of age.
 - Pathologic reflux or gastroesophageal reflux disease (GERD) is defined by troublesome symptoms or complications of GER.
 - Complications may include reflux esophagitis, bleeding, esophageal stricture, failure to thrive, chronic/recurrent respiratory tract disease, or vomiting.

EPIDEMIOLOGY

Pathologic GERD: 10% of adults, 2–8% of children

RISK FACTORS

- Neurologic disorders (cerebral palsy/quadruplegia)
- Esophageal atresia
- Tracheoesophageal fistula
- Cystic fibrosis
- Asthma
- Gastroparesis
- Hiatal hernia

PATHOPHYSIOLOGY

Transient relaxation of the lower esophageal sphincter during episodes of increased abdominal and gastric pressure. GERD is a multifactorial

process involving number of reflux events, acidity, esophageal clearance, gastric emptying, mucosal barriers, visceral hypersensitivity, and airway responsiveness.

DIAGNOSIS

HISTORY

- General symptoms of GERD:
 - Vomiting
 - Irritability
 - Chest/abdominal pain
 - Heartburn
 - Hematemesis, melena
 - Blood loss
 - Dysphagia
 - Food refusal
 - Cough, wheezing
 - Obstructive apnea
 - Dysphonia
 - Aspiration pneumonia
 - Posturing (Sandifer syndrome)
- GERD may be asymptomatic and still carry risk of complications.
- Infant
 - Many common conditions in infancy such as physiologic GER, infant colic, milk protein allergy, or multifactorial feeding difficulties/aversion can present with symptoms that can be difficult to distinguish from GERD and history should also assess for these conditions.
 - Pay attention to feeding volume and frequency in addition to weight gain, failure to thrive, and irritability in association with regurgitation events.
 - Identify episodes of pneumonia, obstructive apnea, chronic cough, stridor, wheezing.
 - Identify additional signs/symptoms that suggest food protein allergy (hematochezia, rash, diarrhea, irritability, failure to thrive).

- Evaluate for evidence of bowel obstruction (forceful emesis, polyhydramnios during pregnancy).
- If vomiting is atypical or associated with other signs/symptoms, rule out infection, metabolic disease, anatomic abnormality, or neurologic disease.
- Special questions:
 - Presence of polyhydramnios or bilious emesis?
 - Family history of metabolic disease?
 - Family history of allergies/atopy?
 - Perinatal asphyxia (and other neurologic disorders)?
 - History of prematurity?
- Older child
 - Identify typical adult GERD complaints (chest pain, heartburn, regurgitation, dysphagia), but recognize that children describe discomfort poorly (often isolated abdominal pain).
 - Identify episodes of pneumonia, choking, chronic cough, laryngitis, stridor, and wheezing (may need to assess swallowing function).
 - Assess for solid food dysphagia (more common with eosinophilic esophagitis).
 - Evaluate for presence of nocturnal GERD symptoms.
 - Special questions:
 - Family history of GERD?
 - Family history of allergies/atopy?
 - Family history of eosinophilic esophagitis or other chronic GI disease such as celiac disease or inflammatory bowel disease.

PHYSICAL EXAM

- May be normal
- Growth failure
- Reactive airway disease and other manifestations of pulmonary complications
- Anemia or blood in stool (uncommon)
- Erosive dental disease (possibly linked to GERD, but common unrelated finding)

DIAGNOSTIC TESTS & INTERPRETATION

- Diagnosis of GERD is frequently made clinically.
- Testing is typically only needed to evaluate for other conditions, evaluate questionable cases, potential causes, complications, or symptom-reflux correlations. Evaluation may include the following:
 - Common screening laboratories (CBC, routine chemistries, transaminases)
 - Allergen testing (i.e., milk, soy, egg, etc.)
 - Celiac serology
 - Stool occult blood
 - Stool *Helicobacter pylori* antigen

Imaging

- Upper GI contrast study: Evaluate anatomy.
- Chest x-ray: Evaluate for recurrent pneumonia (if warranted by respiratory symptoms).
- Modified barium swallow: Evaluate swallowing function and for aspiration.
- Gastric-emptying study (gastric scintigraphy): Evaluate gastric motility and/or pulmonary aspiration.

Diagnostic Procedures/Other

- Empiric trial of medication (recommended for 4 weeks)
- pH probe study
 - To quantify and correlate esophageal acid exposure with symptoms over a 24-hour period (commonly performed off of acid blockade therapy)
- Combined pH/multichannel intraluminal impedance (MII):
 - Allows detection of both acid and nonacid GER events. May detect more pathologic reflux than pH probe alone (can be performed on or off of acid blockade)
 - Wireless pH monitoring (disposable probe placed endoscopically and clipped to esophageal mucosa)
- Esophagogastroduodenoscopy with biopsies
- Laryngoscopy
- Bronchoscopy
- Esophageal manometry
- Antroduodenal manometry

Pathologic Findings

Evidence of reflux esophagitis, allergic esophagitis, Barrett esophagus, adenocarcinoma, stricture

DIFFERENTIAL DIAGNOSIS

- Toxin
 - Lead
 - Fe
 - Medications
- Renal
 - Obstructive uropathy
 - Uremia
- Infection
 - Gastroenteritis
 - H. pylori
 - Urinary tract infection
 - Sepsis
 - Pneumonia
 - Hepatitis
 - Otitis media
 - Pancreatitis
 - Cholecystitis
- Neurologic
 - Meningitis/encephalitis: intracranial injury
 - Brain tumor
 - Hydrocephalus
 - Subdural hematoma
- Metabolic
 - Urea cycle defects
 - Aminoacidopathies (phenylketonuria, maple syrup urine disease)
 - Adrenal hyperplasia
 - Galactosemia, fructosemia
- Allergy/food intolerance
 - Milk/soy protein allergy
 - Eosinophilic esophagitis
 - Celiac disease

- Hereditary fructose intolerance
- Anatomic malformation
 - Diaphragmatic hernia
 - Gastric outlet obstruction
 - Esophageal atresia
 - Pyloric stenosis
 - Antral/duodenal web
 - Volvulus/malrotation
 - Meconium ileus
 - Enteral duplications
 - Intussusception
 - Trichobezoar
 - Foreign body
 - Incarcerated hernia
- Drugs that affect lower esophageal sphincter pressure:
 - Nitrates
 - Nicotine
 - Narcotics
 - Caffeine
 - Theophylline
 - Anticholinergic agents
 - Estrogen
 - Somatostatin
 - Prostaglandins
- Other:
 - Pregnancy
 - Cyclic vomiting syndrome

TREATMENT

Treatment should be individualized, and cost effectiveness should be considered.

MEDICATION

First Line

H₂ blockers: Good for intermittent or PRN dosing. Can be used for maintenance of chronic GERD in some patients and/or promote mucosal healing.

- Ranitidine (PO)
 - < 1 month: 6 mg/kg/24 h divided t.i.d.
 - ≥ 1 month to 16 years of age: 5–10 mg/kg/24 h divided b.i.d.–t.i.d. (max 300 mg/24 h)
 - Adults 150 mg b.i.d. or 300 mg nightly
- Famotidine (PO)
 - <3 months: 0.5 mg/kg daily
 - 3 months to 1 year: 0.5 mg/kg b.i.d.
 - 1–12 years: 1 mg/kg/24 h divided b.i.d. (max 80 mg/24 h)
 - 12 years–adults: 20 mg b.i.d.

Second Line

Proton pump inhibitors (PPI):

- Demonstrated to be more effective at blocking gastric acid as compared to H₂ blockers. Can be used for symptoms as well as mucosal injury, refractory to H₂ blockers. May be appropriate for short-term empiric trial of medication
 - Omeprazole (PO)
 - <1 year: 1–2 mg/kg/24 h (daily or divided b.i.d.); multiple studies demonstrate no improvement of clinical symptoms (crying, irritability).
 - >1 year: 1–2 mg/kg/24 h (daily or divided b.i.d.) to adult dose range
 - >20 kg: 20 mg once or twice daily
 - Up to 3.5 mg/kg/24 h have been used.
 - Lansoprazole (PO)
 - <1 year: 0.4–1.8 mg/kg/24 h (daily or divided b.i.d.); multiple studies demonstrate no improvement of clinical symptoms (crying, irritability).
 - 1–11 years: <10 kg 7.5 mg/24 h
 - 10–30 kg: 15 mg/dose daily up to b.i.d.
 - >30 kg: 30 mg/dose daily up to b.i.d.
 - Several other PPIs are available.

- Side effects of PPIs may include headache, abdominal pain, and diarrhea.
- Recent reports of increased risk for acute gastroenteritis, *Clostridium difficile* infection, and pneumonia in children. Adult studies report increased risk of osteopenia and bone fracture associated with higher dose and long-term use. Benefits should outweigh risks, especially for long-term use.
- Prokinetics: as adjunctive therapy for more severe GERD complications and hypomotility
 - No single drug has optimal prokinetic effect without significant side effects.
 - Not recommended as routine therapy
 - Erythromycin (PO)
 - 3–4 mg/kg/dose b.i.d.–t.i.d. (used in lower dose than for antibiotic purposes for gastric prokinetic effect)
 - Can prolong QT interval
 - Can develop tachyphylaxis
 - Short-term use can be considered for treatment of GERD symptoms seen in postinfectious gastroparesis which typically resolves spontaneously.
 - Metoclopramide (Reglan)
 - Dosage is significantly less for GERD indication as compared to the antiemetic indication.
 - Side effects: may cause dystonia or oculogyric crisis, black box warning regarding risk of tardive dyskinesia
- Calcium and aluminum/magnesium-containing antacids
 - Offers short-term symptom relief, requires multiple dosing
 - Side effects: carry risk of diarrhea and aluminum toxicity
 - Interactions: may lead to malabsorption of other medications
- Mucosal protective agents: sucralfate (Carafate) for erosive esophagitis; maximally effective at pH 4 and on mucosal lesions

ADDITIONAL TREATMENT

General Measures

- Parental reassurance and education, especially in infants with

physiologic GER

- Small, frequent infant feedings
- Encourage burping in infants.
- Reassure parents that infant GER/GERD is not associated with sudden infant death syndrome.
- Thickening of infant feedings (~2–3 teaspoons cereal/ounce of formula): may help with volume of regurgitation, does not stop GER
- Positioning: keeping infant upright after feeds, head elevation in bed of older children only; prone positioning not recommended

SURGERY/OTHER PROCEDURES

- Fundoplication (open or laparoscopic)
 - To increase lower esophageal sphincter tone by wrapping portion of gastric fundus around lower esophagus
 - Variations may include addition of a gastric emptying procedure (i.e., pyloroplasty).
 - Indications: failure of aggressive medical management and/or persistent, life-threatening complications (i.e., esophageal stricture; intestinal metaplastic changes as in Barrett esophagus), presence of large hiatal hernia, poor airway protection leading to aspiration of gastric contents (i.e., severe neurodevelopmental delay)
- Fundoplication complications include the following:
 - Gas bloating syndrome
 - Intractable retching
 - Bowel obstruction
 - Dumping syndrome
 - Dysphagia
 - Paraesophageal hernia
 - Wrap failure with recurrent GERD (up to 6% failure at 48 months)
 - Limited long-term clinical effectiveness
- Greater morbidity may be associated with fundoplication in children with severe physical and mental disabilities.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

May be appropriate to recommend repeat endoscopy for evidence of pathologic changes of esophagus

DIET

Dietary modifications in older child: Avoid large high-fat meals, especially before bedtime. Avoid caffeine, chocolate, acidic/spicy food, peppermint, but recent adult studies show this is on an individual basis only.

CODES

ICD10

- K21.9 Gastro-esophageal reflux disease without esophagitis
- K21.0 Gastro-esophageal reflux disease with esophagitis
- P78.83 Newborn esophageal reflux

FAQ

- Q: How long will my baby suffer with GERD?
- A: Most infant reflux resolves by 9–12 months of age, but symptoms may persist up to 24 months. If GERD continues after 2–3 years, it is more likely to behave clinically like adult GERD and require chronic management.
- Q: Should all babies with reflux be treated with medication?
- A: No. Often infant reflux is physiologic and education is all that is needed. Conservative treatments such as thickened feedings, frequent small feedings, and postprandial upright positioning can be tried first, especially as data do not support acid blockade therapy in children younger than 12 months. It is often helpful to explain to parents that physiologic infant reflux tends to worsen from 1 to 3 months of age then typically starts to improve when children can sit upright at 6–7 months of age.

GERM CELL TUMORS

Esteban I. Gomez • James Feusner

BASICS

DESCRIPTION

Germ cell tumors (GCTs) are a heterogeneous group with a suspected common cell of origin, the primordial germ cell.

- Their location can be gonadal or extragonadal.
- The numerous histologic subtypes are broadly classified as mature or immature teratomas and malignant GCTs.
- See “[Brain Tumor](#)” chapter for primary CNS GCT.

EPIDEMIOLOGY

The incidence has a bimodal distribution with a smaller peak in early infancy and a larger peak in adolescence.

- In children younger than 15 years of age, GCTs occur at a rate of 2.4 cases per million children, and they account for 2–3% of all malignancies.
- Between 15 and 19 years of age, extracranial GCTs account for approximately 14% of cancer diagnoses.
- Teratomas and germinomas are the predominant histologic subtypes of early infancy and adolescence respectively.
- Sacrococcygeal teratomas account for 50% of childhood teratomas. They are most prevalent in infants (1:40,000 live births); with a female predominance (4:1)

RISK FACTORS

- Sex chromosome abnormalities are associated with an increased risk for GCTs.
- Klinefelter syndrome is associated with an increased risk of mediastinal GCTs.
 - Approximately 50% of adolescent mediastinal GCTs are associated with a cytogenetic diagnosis of Klinefelter syndrome.
- Turner syndrome with any portion of Y chromosome material, Swyer

syndrome, nonscrotal partial androgen insensitivity, Frasier syndrome, and males with Denys-Drash syndrome are all associated with streak gonads at increased risk for developing GCTs.

- History of cryptorchidism is associated with an increased risk of testicular GCT.

Genetics

Familial GCT has been described in 1.5–2% of adult GCTs and a similar contribution to adolescent GCTs is presumed.

GENERAL PREVENTION

- Prophylactic gonadectomy is recommended for streak gonads in the specific syndromes mentioned above because of the increased risk of developing GCTs.
- Guidelines on the management of cryptorchidism recommend the following to decrease the future risk of testicular GCT:
 - Orchidopexy by 18 months of age
 - Consideration of orchiectomy of an undescended testis in all boys with a normal contralateral testis when orchidopexy is not feasible
 - Consider orchiectomy or biopsy in a post pubertal boy with cryptorchidism.
 - Counsel all men with a history of cryptorchidism and/or their parents regarding the long-term risk of testicular cancer.

ETIOLOGY

- GCTs are hypothesized to originate from primordial germ cells containing neoplastic genetic aberrations.
- Arrested migration of primordial germ cells is presumed to explain the midline location of extragonadal GCTs.
- The postpubertal peak in the incidence of GCTs suggests hormonal factors are involved in their growth.
- Isochromosome 12p or i(12)p is present in more than 80% of postpubertal GCTs. GCTs without the i(12)p typically have gain of 12p chromosomal material.
 - Mature and immature ovarian tumors are biologically distinct in their lack of association with the i(12)p.
 - A number of other genetic mutations have been observed in

testicular GCTs.

- Malignant GCTs in children younger than age 4 years typically contain cytogenetic abnormalities of chromosomes 1, 3, 6, and others.
 - The i(12)p is rarely seen in this group.
 - Deletion of 1q36 is present in 80–100% of infantile malignant GCTs in testicular and extragonadal sites.
 - Recurrent genetic changes of infantile yolk sac tumors include loss of 6q24-qter, gain of 20q and 1q, loss of 1p, and c-myc or n-myc amplification.

DIAGNOSIS

HISTORY

- Acute or chronic abdominal pain is the presenting symptom in up to 80% of ovarian GCTs.
 - Vaginal bleeding, amenorrhea, and constipation may also be present.
- Pediatric testicular tumors typically present as nontender scrotal masses.
- GCTs can present with severe, acute abdominal or testicular pain secondary to gonadal torsion.
- A history of abnormal sexual development may be an indication of an underlying sex chromosome abnormality associated with an increased risk of a GCT.
- Sacrococcygeal teratomas typically present with swelling.
 - Pregnancies may be associated with polyhydramnios or high-output cardiac failure.
 - Other congenital anomalies are seen in up to 18% of patients.
- Mediastinal tumors can present with respiratory compromise in younger children, whereas adolescents may have a more insidious presentation.

PHYSICAL EXAM

- A palpable abdominal mass may be present with an ovarian GCT.
- A palpable nontender testicular mass is typical of testicular GCT.

- Sacrococcygeal GCTs can present with a palpable mass or signs of spinal cord compression.
- Especially in younger children, a mediastinal GCT may present with potentially critical respiratory compromise or superior vena cava syndrome.
- Inappropriate absence or presence of sexual development may be seen with hormonally active GCTs.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serum tumor markers include AFP and beta-hCG help to diagnose, monitor, and stage GCTs.
 - An acute rise can be seen after initiating chemotherapy.
- Workup should include a CBC and differential, chemistry panel, liver function tests, uric acid, and LDH to evaluate for other malignancies or organ dysfunction.

Imaging

- Plain radiograph: may reveal mature calcified tissues, such as bone or teeth, within tumor
- Chest radiograph: shows mediastinal mass
- CT scan: necessary to evaluate the primary site and regional disease
- Transscrotal ultrasound: initial imaging of testicular mass, can reveal calcifications or heterogenous features.
- Prenatal MRI: helpful for prenatal counseling and preoperative planning of fetal sacrococcygeal teratomas
- Chest CT and bone scan: indicated to evaluate for metastatic disease when malignancy is suspected

Diagnostic Procedures

Tissue is mandatory, since histology is essential to the classification of GCTs.

Pathologic Findings

- GCTs are broadly classified as teratomas or malignant GCTs.
- Teratomas contain elements of all three germ cell layers (ectoderm, mesoderm, and endoderm).
 - They can be mature, immature, or immature with malignant

elements.

- Major malignant histologic subtypes include yolk sac tumor, embryonal carcinoma, gonadoblastoma, choriocarcinoma, and mixed malignant GCT.
 - Histologic subtype does not necessarily correlate with tumor biology, patient age, site of origin, or patient prognosis.

DIFFERENTIAL DIAGNOSIS

- Sacrococcygeal: pilonidal cyst, meningocele, lipomeningocele, hemangioma, abscess, bone tumor, epidermal cyst, chondroma, lymphoma, ependymoma, neuroblastoma, glioma
- Abdominal: Wilms tumor, neuroblastoma, lymphoma, rhabdomyosarcoma, hepatoblastoma, retained twin fetus
- Vaginal: rhabdomyosarcoma (sarcoma botryoides), clear cell carcinoma
- Ovarian: cyst, appendicitis, pregnancy, pelvic infection, hematocolpos, sarcoma, lymphoma, other ovarian tumors
- Testicular: epididymitis, testicular torsion, infarct, orchitis, hernia, hydrocele, hematocele, rhabdomyosarcoma, lymphoma, leukemia, other testicular tumors
- Mediastinal: Hodgkin and non-Hodgkin lymphoma, leukemia, thymoma

TREATMENT

MEDICATION

- The administration of chemotherapy is based on malignant potential, local tumor extent, surgical outcomes, and the patient's medical history.
- The typical 1st-line chemotherapy regimen for malignant GCTs includes cisplatin, etoposide, and bleomycin or PEB.
 - Cyclophosphamide in addition to PEB is being investigated in the treatment of high-risk GCTs.
 - Cisplatin is associated with a risks of ototoxicity and nephrotoxicity.
 - PEB therapy is associated with a risk of secondary myelodysplasia

or acute myeloid leukemia.

- Bleomycin is associated with a risk of pulmonary toxicity.

SURGERY/OTHER PROCEDURES

- Every effort should be made to preserve fertility in gonadal teratomas. An experienced pediatric–gynecology oncologic surgeon is critical.
- Sacrococcygeal teratoma
 - A complete surgical resection including the coccyx is curative.
 - Close postoperative follow-up should include monitoring of tumor markers.
 - Fetal surgery should be considered if signs of hydrops are seen.
- Mature teratoma
 - Full surgical excision, irrespective of site, is curative in prepubescent patients.
 - Postpubescent patient with testicular teratoma (mature or immature) is at risk for retroperitoneal metastatic recurrence, so adjuvant chemotherapy and retroperitoneal lymph node resection are additional treatment considerations.
- Immature teratoma
 - Complete surgical resection is therapy of choice; close observation and tumor marker evaluation for normalization
 - In cases of elevated AFP and incomplete surgical resection, chemotherapy should be offered given risk of microscopic foci of endodermal sinus tumor.
- Teratoma with malignant components
 - Surgery plus chemotherapy with etoposide, cisplatin or carboplatin, and bleomycin
 - Patients with residual disease should have additional surgery and additional chemotherapy if total resection is not possible.
 - High-dose chemotherapy with autologous stem cell support and radiation are reserved for salvage therapy in recurrent disease.

ONGOING CARE

- Serial physical exams and imaging studies of primary site

- Tumor markers (AFP or β -hCG) if elevated at diagnosis
- If chemotherapy or radiation therapy used, need to monitor for secondary malignancies, long term (See “[Cancer Therapy Late Effects](#)” chapter); short term, need to monitor blood counts, chemistries, renal function, and audiology

CODES

ICD10

- C80.1 Malignant (primary) neoplasm, unspecified
- D48.0 Neoplasm of uncertain behavior of bone/artic cartl
- C38.3 Malignant neoplasm of mediastinum, part unspecified

FAQ

- Q: What is the chance of cure for immature/malignant teratomas?
- A: With current chemotherapy as outlined earlier, overall survival is 85–97% (dependent on disease stage).
- Q: Can a benign tumor recur? If so, can it then be malignant?
- A: Yes. If there is residual tissue left behind, the tumor can recur. If there were unrecognized areas of malignancy, the recurrence can be a malignant teratoma. The greatest risk for the latter is with the immature teratomas.

GERMAN MEASLES (THIRD DISEASE, RUBELLA)

Michael J. Smith

BASICS

DESCRIPTION

- Rubella derived from Latin, meaning “little red.”
- Disease initially considered variant of measles
- Viral infection characterized by mild symptoms (often subclinical), with an erythematous rash progressing from head to toes
- Congenital rubella syndrome can be devastating.

EPIDEMIOLOGY

- Spread person to person via airborne transmission; worldwide infection
- Infection most contagious when rash is erupting. However, virus may be shed beginning 7 days before rash to 14 days after.
- Infants with congenital rubella syndrome may shed virus for up to 1 year.
- In temperate regions, peaks in late winter and early spring
- Infection occurs equally in following age groups: <5 years, 5–19 years, and 20–39 years.
 - In prevaccine era, annual incidence of infection in the United States was ~58 per 100,000 population.
 - 2004: No longer endemic in the United States.
 - 2004–2011: 77 reported cases, mostly in unvaccinated individuals born overseas
- Congenital rubella syndrome
 - 1964: 20,000 newborns
 - 1980s: reported rarely, with <5 cases annually
 - 1990–1991: ~30 cases reported annually
 - 2004–2011: Total of 4 cases reported to CDC, only 1 with mother born in the United States.

GENERAL PREVENTION

- Prevention of congenital rubella syndrome is main objective of vaccination programs.
- Rubella vaccine
 - Current strain of vaccine (RA 27/3, developed at the Wistar Institute in Philadelphia) was licensed in 1979 and has replaced all other strains.
 - Given as part of MMR vaccine at 12–15 months and again at 4–6 years
 - Immunity occurs in 95% of those vaccinated and is thought to be lifelong.
 - Important to ensure full vaccination for preschool-aged children
 - Vaccine virus is not communicable: Pregnant women and persons who are immunodeficient (except asymptomatic HIV infection) should not receive vaccine, but household contacts should.
- Isolation
 - Pregnant women should avoid contact with source patient.
 - Postnatal: Droplet precautions and/or school exclusion is indicated for 7 days after onset of rash.
 - Congenital: Contact isolation until 1st birthday, or until 2 nasopharyngeal and urine cultures consecutively negative

PATHOPHYSIOLOGY

- Respiratory transmission
- Replication in nasopharynx and regional lymph nodes
- Viremia 5–7 days after exposure, with spread of virus throughout body
- In congenital rubella syndrome, transplacental infection of fetus occurs during viremia.

ETIOLOGY

- Rubella virus
 - Classified as a Rubivirus in the Togaviridae family
 - RNA virus with single antigenic type
 - First isolated in 1962 by Parkman and Weller

DIAGNOSIS

If rubella is suspected, case should be reported to local public health authorities.

HISTORY

- In children, prodrome is not often recognized.
- In adults, a 1–5-day prodrome of low-grade fever, malaise, and cervical adenopathy may precede rash.
- Inquire about immunizations and exposures.

PHYSICAL EXAM

- Rash
 - Begins on face, then progresses to trunk and extremities
 - Does not usually coalesce
 - Lasts for 3 days
- Adenopathies, especially postauricular, posterior cervical, and suboccipital, are commonly noted along with conjunctivitis.
- Arthralgia/arthritis may be seen in adolescents and adults.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Congenital infection
 - Serologic testing should be performed on both mother and infant.
 - Rubella-specific IgM in infant is highly suggestive.
 - Viral isolation from throat or nasal specimen can confirm diagnosis. Blood, urine, and CSF samples may also be diagnostic.
 - Diagnosis is difficult to verify after neonatal period.
- Postnatally acquired
 - Rubella-specific IgM or a ≥ 4 -fold rise in rubella-specific IgG antibodies between acute and convalescent titers is diagnostic.

DIFFERENTIAL DIAGNOSIS

Infections that are sometimes confused with rubella include the following:

- Modified measles
- Scarlet fever
- Roseola
- Erythema infectiosum (fifth disease, parvovirus B19 infection)
- Enteroviral infections

- Infectious mononucleosis
- Drug eruptions

TREATMENT

Supportive care

ONGOING CARE

PROGNOSIS

- Quite good; as many as 50% of infections are asymptomatic.
- Rubella infection in pregnant woman can be devastating for infant (see [“Complications”](#)).

COMPLICATIONS

- Tend to occur in adults; most are uncommon.
- Arthritis or arthralgia
 - Occur in 70% of adult women, lasting up to 1 month
 - Usually affects small joints
- Encephalitis
 - 1 in 5,000 cases
 - May be associated with mortality
- Bleeding
 - 1 in 3,000 cases
 - Occurs in children more than in adults
- Thrombocytopenia: commonly noted
- Orchitis and neuritis: rare
- Congenital rubella syndrome
 - Rubella infection in early gestation can lead to fetal death, premature delivery, and congenital defects.
 - Severity of defects is worse the earlier in gestation the infection occurs.
 - 85% of infants are affected if infection occurs in 1st trimester.
 - Defects are rare if infection occurs after 20th week.
 - Common defects of congenital rubella syndrome:

- Deafness: most common defect
- Ophthalmologic defects: cataracts, glaucoma, microphthalmia
- Cardiac defects: patent ductus arteriosus, ventricular septal defect, pulmonic stenosis, coarctation of aorta
- Neurologic defects: mental retardation, microcephaly
- Some manifestations of congenital rubella syndrome (diabetes mellitus, progressive encephalopathy) may be delayed for years.

CODES

ICD10

- B06.9 Rubella without complication
- P35.0 Congenital rubella syndrome
- B06.89 Other rubella complications

FAQ

- Q: Although pregnancy is a contraindication to rubella vaccination, if a pregnant woman is inadvertently vaccinated, will there be harm to the fetus?
- A: Data collected since 1979 by the CDC show no evidence of congenital rubella syndrome in 321 susceptible women who were vaccinated while pregnant. Therefore, inadvertent vaccination is not an indication for termination of pregnancy.
- Q: Is there any evidence that the MMR vaccine causes autism spectrum disorder?
- A: No. Multiple epidemiologic studies have shown no difference in the rates of autism spectrum disorder in children who received the MMR vaccine versus those who did not. The original paper that suggested a link between vaccines and autism was retracted in 2010.

GIARDIASIS

Kacy A. Ramirez

BASICS

DESCRIPTION

Infection of small intestine (duodenum and jejunum) and biliary tract with flagellated protozoan *Giardia intestinalis* (formerly *Giardia lamblia* and *Giardia duodenalis*)

EPIDEMIOLOGY

Giardia is the most common parasitic enteric pathogen diagnosed across the world, including in the United States.

Incidence

- U.S. average is 7.3–7.6 cases per 100,000 and approximately 20,000 cases are reported each year.
- Affects all age groups, but peaks at 1–9 years and less so at 35–49 years of age
- Highest in early summer through early fall and among residents of northern United States

Prevalence

- In the United States, nondysenteric diarrheal stool specimens ranges from 5 to 7%, with higher rates in children (up to 15–30% in United States and developing countries, respectively).
- Acquired by ingestion of cysts directly from infected person (rarely animals) or ingestion of fecally contaminated water or food
- Cysts infectious for as long as person excretes them (weeks to months), and infectious dose is low (10 cysts can produce infection).
- Incubation period usually 1–3 weeks
- Direct person-to-person transmission accounts for the very high prevalence rates in institutions, day care centers, and family contacts.
- Waterborne transmission is an important source of endemic or epidemic spread, especially when water is supplied by surface source such as streams and reservoirs (outdoor recreation and international

travel).

- Foodborne infection is less common and generally from food (lettuce) washed by contaminated water source.

RISK FACTORS

- Day care attendance (poor fecal–oral hygiene)
- Travel to endemic areas
- International adoption
- Contact with recreational fresh water, backpacking, camping, swimming (swallowing water)
- Contact with some animal species
- Certain sexual practices
- Hypochlorhydria (previous gastric surgery)
- Hypogammaglobulinemia, immunodeficiency

GENERAL PREVENTION

- Practice good hygiene (hand washing after toileting, changing diapers, handling animal waste, gardening, tending to a person with diarrheal illness, and when preparing food).
- Exclusion from child care and pool/recreational water during diarrheal illnesses
- Avoiding potentially contaminated water (recreational/drinking) and food
- Examine water source in endemic areas.
- Boiling (1 minute) or filter (National Sanitation Foundation [NSF] Standard 53 or 58) water treatments
- Prevent contact with feces during sex.
- Vitamin A given in children of developing countries may improve host defenses against Giardia infection.

ETIOLOGY

- *G. intestinalis*
 - 2-form life cycle: cyst (transmission) and trophozoite (infection)
 - Gastric acid and pancreatic enzymes initiate excystation of ingested cysts.
 - Trophozoites divide asexually and adhere to brush border of proximal small bowel enterocytes.

- Cyst formation (encystation) occurs in the colon and is passed into the environment.

PATHOPHYSIOLOGY

- Trophozoite causes direct damage to intestinal brush border and mucosa (but does not invade mucosa) leading to the following:
 - Disruption of tight junctional zonula occludens
 - Increased permeability via myosin light chain kinase dependent phosphorylation of F-actin
 - Induction of epithelial apoptosis
 - Induction of host immune response that results in secretion of fluid and damage to the gut
 - Secondary lactase deficiency

DIAGNOSIS

- Most (50–75%) infected individuals are asymptomatic, or have acute self-limiting diarrhea (25–50%) lasting 7–10 days.
- Clinical presentation (acute):
 - Sudden-onset watery, foul-smelling diarrhea without blood/pus/mucus
 - Malaise
 - Bloating/flatulence
 - Steatorrhea
 - Abdominal cramps
 - Anorexia/nausea
 - Dyspepsia
- Clinical presentation (chronic):
 - Loose, semifformed stool >14 days
 - Steatorrhea
 - Profound malaise
 - Abdominal distention
 - Weight loss
 - Anorexia
 - Flatulence

- Depression
- Alternation of diarrhea/constipation until spontaneous resolution or treatment begun
- Malabsorption syndrome may include the following:
 - Steatorrhea
 - Deficiencies of iron, D-xylose, vitamins A, B₁₂, and E
 - Protein-losing enteropathy

HISTORY

- Exposures:
 - Habitation or adoption from endemic area
 - Attendants of child care centers or inhabitants of institutions
 - Camping or hiking near fresh water/recreational water exposure
 - Exposure to infected individual
- Underlying immunodeficiency or irritable bowel syndrome (IBS)
- Previous gastric surgery
- Asymptomatic infection can occur.

PHYSICAL EXAM

- Abdominal distention
- Aphthous ulcers in oral mucosa
- Urticaria
- Arthralgia/arthritis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- Identification of trophozoites or cysts in stool specimens (multiple [3] ova/parasite [O/P] samples collected every other day can be sent to microscopy to increase sensitivity) AND
- Direct fluorescent antibody staining (DFA)
- Real-time PCR is most sensitive and preferred test for diagnosis, as available.
- Other immunodiagnostic kits that do not require microscopy (enzyme immunoassay [EIA]) should not replace O/P and DFA.
- If immunodeficiency is suspected, evaluate humoral immunodeficiency (total immunoglobulins includes IgA).

- WBC usually normal and eosinophilia absent

Diagnostic Procedures/Other

- Consider duodenal aspiration or string test (Enterotest) and rarely biopsy.

PATHOLOGIC FINDINGS

Mucosal lesions vary from normal to subtotal villous atrophy, with crypt hyperplasia and proliferation of intraepithelial and lamina propria lymphocytes. Trophozoites may be seen on biopsies.

DIFFERENTIAL DIAGNOSIS

- Celiac disease
- Cystic fibrosis
- Lactose intolerance
- Irritable bowel syndrome
- Inflammatory bowel disease
- Nonulcer dyspepsia

TREATMENT

MEDICATION

- Metronidazole (not approved by FDA)
 - Most effective and best tolerated
 - Dose: 15 mg/kg/24 h divided t.i.d. PO for 5–10 days
- Tinidazole (approved for children ≥ 3 years)
 - 50 mg/kg, max 2 g; single oral dose
 - Available in tablet form only
 - Fewer adverse effects than metronidazole
- Nitazoxanide (approved for ages 1–11 years)
- Furazolidone: lower efficacy but better tolerated than metronidazole
- Paromomycin (for symptomatic infection in pregnant women in the 2nd and 3rd trimesters)
- Asymptomatic giardiasis, in absence of risk factors, should not be treated.
- Treatment failures:

- High dose courses of original agent
- Combination of nitroimidazole plus quinacrine for at least 2 weeks
- Treatment of asymptomatic carriers in patients with IBS or in households of patients with cystic fibrosis or hypogammaglobulinemia may be considered.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Symptom recurrence can be attributable to reinfection, secondary lactose intolerance, insufficient treatment, or drug resistance.
- Detailed exposure history and O/P and antigen detection with recurrence of symptoms
- If reinfection suspected, a course can be repeated with similar drug, otherwise alternative agent if resistance suspected.
- If symptoms persist, with negative diagnostic studies, consider alternative etiology or enteropathogen.

DIET

Consider lactose avoidance to prevent bloating and diarrhea for 1 month after treatment.

PROGNOSIS

- Remains good for symptomatic patients
- Combination therapy with 2 medications has been successful when repeated courses of single drug have failed.

COMPLICATIONS

- Malabsorption syndrome
- Steatorrhea
- Lactose deficiency
- Deficiencies of iron, folic acid, and vitamins A, B₁₂, and E
- Protein-losing enteropathy
- Urticaria
- Arthralgia

- In pediatric patients:
 - Growth retardation
 - Failure to thrive
 - Lower IQ
 - Urticaria

CODES

ICD10

A07.1 Giardiasis [lambliasis]

FAQ

- Q: How is *G. intestinalis* likely contracted?
- A: Most community-wide epidemics occur from a contaminated water

supply (drinking water), as well as person-to-person transmission in child care and institutional settings. Food and food handler–associated outbreaks are less reported.

- Q: What do I do if I suspect Giardia, but the stool sample is negative?
- A: 3 O/P samples are needed and should optimally be done every other day on a diarrheal stool specimen with a DFA to increase diagnostic sensitivity. Stool samples should be examined as soon as possible or placed immediately in a preservative, such as neutral buffered 10% formalin or polyvinyl alcohol. If endemic areas, it may be appropriate to treat empirically. If stool testing is negative and the diagnosis is strongly suspected, you can consider ordering a commercially available string test (designed to obtain bile-stained mucus from duodenum to reveal trophozoites on wet mount) or refer to a pediatric gastroenterologist, who can perform endoscopy with duodenal aspiration and biopsy.

GINGIVITIS

Daniel Walmsley

BASICS

DESCRIPTION

Gingivitis is a reversible dental plaque-induced inflammation of the gingival tissues. Symptoms may include bleeding, swelling, ulceration, and pain, although gingivitis is usually mild and asymptomatic.

EPIDEMIOLOGY

- Affects >90% of children between the ages of 4 and 13 years. Most of these children have low-grade gingivitis.
- 13–40% of children aged 6–36 months have eruption gingivitis, which commonly resolves after teeth eruption.
- The prevalence of gingivitis increases with age; by puberty, nearly 100% of all children are affected. This pubertal peak is likely due to hormonal influences and inconsistent dental hygiene.
- After puberty, the prevalence remains relatively constant at 50% of all adults.

RISK FACTORS

- Behavioral factors: smoking, stress, alcohol consumption
- Medications: antiepileptic, cyclosporine, calcium channel blockers
- Hormonal changes: puberty, pregnancy
- Chronic illnesses: diabetes mellitus, chronic renal failure, histiocytosis X, scleroderma, secondary hyperparathyroidism
- Immunologic deficiencies: HIV, Chédiak-Higashi, cyclic neutropenia
- Neurologic problems: cerebral palsy, mental retardation, seizures, and other conditions where routine dental care is difficult
- Miscellaneous: chronic mouth breathing, malnutrition, viral illnesses

GENERAL PREVENTION

- Consistent daily oral hygiene described as the following by age:
 - Infants: gum massage, washcloth to remove plaque; toothbrush

- using baby toothpaste (i.e., enzyme-based; no fluoride)
- Young children: assistance with brushing with a small amount of fluoridated toothpaste
- School-aged children: Supervise brushing and assist if necessary.
- Older children and adolescents: Brush teeth twice a day with fluoridated toothpaste in addition to daily flossing. Some dentists recommended flossing as early as age 4 years.
- Children with fixed orthodontics: Careful brushing and flossing is critical.
- Fluoride: Supplements are appropriate if the water supply is not fluoridated. It is important to be careful to treat with the appropriate amount of fluoride in order to prevent fluorosis.
- Sealants: Adherent plastic coating may be applied to the pits and fissures of the permanent teeth to provide a mechanical barrier.
- The American Academy of Pediatrics (AAP) recommends that children at high risk for dental caries should establish routine dental care by their first birthday. Children should then continue routine dental checkups at a minimum of every 6 months.

ETIOLOGY

- Poor dental hygiene
- Bacterial plaque, calcified and noncalcified
- Caries
- Orthodontic appliances
- Malocclusion
- Crowded teeth
- Mouth breathing
- Erupting teeth margins
- Poor nutrition
 - Vitamin deficiencies (e.g., vitamin C deficiency)
 - Diet low in coarse detergent like foods (e.g., raw carrots, celery, apples)
 - High prevalence of anaerobic microflora
- Infections
 - Herpes simplex virus (HSV) type I
 - Candida albicans

- HIV
- Bacterial pathogens
- Drugs
 - Phenytoin
 - Cyclosporine
 - Nifedipine
 - Oral contraceptive pills
- Trauma

DIAGNOSIS

HISTORY

- Review the frequency of dental care visits and the home dental hygiene regimen.
- Review significant medical history, asking about chronic illnesses, bleeding disorders, and immunodeficiency.
- Review the diet of the child to assess for nutritional deficiencies.
- Dental appliances worn by patient:
 - Orthodontic equipment makes gingiva more difficult to clean, and reactive tissue growth is more common.
- Regular medications taken by patient:
 - Phenytoin may result in gingival hyperplasia, and chemotherapeutic agents, exogenous hormone therapy, and calcium channel blockers may result in gingivitis.
- Signs and symptoms:
 - Edema and erythema of the gingiva
 - Bleeding at gum line
 - Pain near the gingival margin

PHYSICAL EXAM

- Evaluate the gingival tissue for erythema, swelling, ulceration, fluctuance, or drainage. Erythema and edema are the most common findings in gingivitis.
- In severe cases, the gingival tissues may bleed spontaneously from ulcerations in the sulcus and there may be significant gingival

hypertrophy.

- In herpetic gingivostomatitis, there is often significant ulceration and swelling of the gingiva associated with systemic symptoms such as fever and malaise.
- Evaluate the teeth for caries, fractures, looseness, malocclusion, pain, and plaque.
- Examine the face and neck for signs of swelling, erythema, warmth, or enlarged maxillary lymph nodes which may be signs of more extensive bacterial infection.
- Tanner staging: Normal pubertal changes seem to aggravate gingival inflammation, so paying special attention to the gingiva of patients entering puberty is important.
- Assess the patient's oral hygiene technique in the office. This is the single largest contributor to gingivitis.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Most patients will not need laboratory evaluation.
- If there is a concern for excessive bleeding, a CBC with differential, PT, and PTT may be helpful to rule out thrombocytopenia, pancytopenia, or a clotting disorder.
- Blood culture: if there is concern for sepsis
- Direct fluorescent antibody testing for HSV-1: If herpes is suspected (stomatitis is usually present), swab the base of a stoma/vesicle and smear on a slide. HSV culture is the gold standard.
- Biopsy is rarely necessary.

Imaging

Panoramic or individual tooth radiographic imaging is important to assess the bones for evidence of periodontal extension of the gingivitis in the more severe cases.

DIFFERENTIAL DIAGNOSIS

- Infectious
 - Abscess
 - Herpetic gingivostomatitis—ulcerative lesions of the gingiva and mucous membranes of the mouth

- Traumatic
 - Food impaction
 - Orthodontic appliances
 - Self-inflicted minor injury
- Hematologic
 - Gingival bleeding due to hemophilia (factor VIII or IX deficiency)
 - Thrombocytopenia
- Immunologic
 - Neutrophil disorders
 - Leukemia
 - HIV
 - Graft-versus-host disease (infiltrative gingivitis)
- Miscellaneous
 - Gingival hyperplasia due to medications (i.e., phenytoin and nifedipine)
 - Periodontitis
 - Aphthous stomatitis
 - Vitamin C deficiency
 - Behçet disease
 - Acute necrotizing ulcerative gingivitis (ANUG)—painful gingivitis associated with rapid onset and tissue ulceration and necrosis
 - Peaks in adolescence and young adulthood
 - Related to high oral concentrations of spirochetes and/or *Prevotella intermedia*

TREATMENT

MEDICATION

Mouth rinses for plaque inhibition can be used to augment daily oral care routine. The most commonly used rinses include 0.12% chlorhexidine and 0.075% or 0.1% cetylpyridinium chloride.

ADDITIONAL TREATMENT

General Measures

A daily oral care routine, including brushing and flossing, is essential to

prevent gingivitis.

- Mild gingivitis
 - Careful daily dental hygiene, including meticulous brushing and flossing
 - Mechanical plaque and calculus removal by scaling or root planing. This is then followed by frequent dental cleanings every 3–6 months to prevent recurrence.
- Moderate to severe gingivitis
 - Care as outlined for mild gingivitis
 - Should be evaluated by a pedodontist in addition to a general dentist
 - Mouth rinses for plaque inhibition using either 0.12% chlorhexidine or 0.075% or 0.1% cetylpyridinium chloride
 - Irrigation devices
 - Sonic toothbrushes
 - Gingivectomies in cases of overgrowth to permit better cleaning
 - Antibiotics to cover mouth flora in more severe cases when bacterial superinfection is suspected

ISSUES FOR REFERRAL

- It is important for providers to evaluate the oral health of all children. When gingival inflammation is noted, the patient should be referred to a dentist.
- Routine dental care with professional cleaning and plaque removal is recommended for all children and adults.
- If the extent of involvement is great or the underlying disease of the patient requires more aggressive care, a periodontist should be consulted.
- The inability to resolve gingivitis by oral hygiene measures necessitates the consideration of other causes such as leukemia, vitamin C deficiency, or other chronic disease.

SURGERY/OTHER PROCEDURES

Only the most severe cases require gingivectomy.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Routine dental care with professional cleaning and plaque removal is recommended for all children and adults.
- Children with gingivitis should have frequent dental visits; most dentists recommend every 3 months.

Patient Monitoring

Routine dental exam and cleaning should be performed every 6 months to monitor for signs of inflammation.

DIET

- Avoid high sugar content food and beverages.
- Xylitol-containing chewing gum can improve oral hygiene by reducing plaque adherence to the gum line.

PATIENT EDUCATION

- Establish a daily mouth care routine.
- Brushing and flossing each morning and at bedtime will reduce plaque formation.
- Mouth rinses, if recommended by your dentist, can also reduce plaque formation.
- See the dental health professional every 6 months beginning at your child's first birthday for examination and cleaning.

PROGNOSIS

- Good oral hygiene may reverse mild to moderate gingivitis within several months.
- Periodontal disease is not reversible; therefore, prevention is essential.

COMPLICATIONS

- Periodontal disease
- Osteomyelitis
- Tooth decay

CODES

ICD10

- K05.10 Chronic gingivitis, plaque induced
- K05.00 Acute gingivitis, plaque induced
- A69.1 Other Vincent's infections

FAQ

- Q: Are there differences among toothpastes and prevention of gingivitis?
- A: Yes. A study demonstrated that stabilized stannous fluoride toothpaste is effective in preventing gingivitis. When essential oil mouthwashes (e.g., Listerine) are added, there is additional reduction in the amount of gingivitis noted.
- Q: What dietary changes may improve gingival health?
- A: Avoiding frequent carbohydrate intake may reduce gingivitis. Carbonated beverages, sugared chewing gum, and candy often adhere to teeth. When daily dental care is inconsistent, plaque formation is

increased and gingivitis is much more likely.

- Q: Why do children generally not have the significant periodontal disease that adults get?
- A: No one knows for sure; however, it is known that the gingiva of the primary dentition is rounder and thicker and contains more blood vessels and less connective tissue than the gingival seen later in life. Whether these differences mask disease or are helpful is unclear.
- Q: How do intraoral piercings impact gum health?
- A: In addition to fractured teeth, gingival recession and gingivitis are complications of the trauma inflicted by a foreign body in the oral cavity.
- Q: Why is smoking associated with gingival disease?
- A: Nicotine inhibits phagocyte and neutrophil function, reduces bone mineralization, impairs vascularization, and reduces antibody production. Smokers do not respond as well as nonsmokers to surgical and nonsurgical treatments.

GLAUCOMA—CONGENITAL

Hee-Jung Park

BASICS

DESCRIPTION

- Elevation of intraocular pressure (IOP) due to congenital anomalies that prevent outflow of aqueous humor, leading to damage to the optic nerve
- Neonatal primary congenital glaucoma (PCG), presents at birth
- Depending on the degree of the malformation, presentation can occur even later in life.
- About 80% of childhood glaucoma presents in the 1st year of life. Secondary congenital glaucoma is associated with systemic conditions.

EPIDEMIOLOGY

- PCG accounts for ~1/2 of all cases of childhood glaucoma.
- 1:10,000 births (ranging from 1:2,500 in Saudi Arabia to 1:38,000 in Spain)
- Male > female (3:2)
- ~70% bilaterally affected

PATHOPHYSIOLOGY

- PCG is caused by immature anatomic relationship between the iris, trabecular meshwork, and cornea.
- Secondary glaucoma is mostly due to damage or alteration of the trabecular meshwork.

GENETICS

- Most are sporadic, but 10–40% are familial.
- Autosomal recessive is most common.
- PCG is associated with mutations in cytogenic locations 2p22.2 (GLC3A), 1p36.2-p36.1 (GLC3B), 14q24.3 (GLC3C), and 14q24.2-q24.3 (GLC3D).

ETIOLOGY

- Aqueous humor, a clear fluid produced by the ciliary body at the posterior base of the iris, passes through the pupil and exits through the trabecular meshwork and Schlemm canal, which are located at the junction of the cornea and iris.
- Outflow blockage of aqueous humor causes pressure to build in eye.
- The blockage may be microscopic (open-angle glaucoma) or due to obstruction of the outflow by the iris (angle-closure glaucoma).
- High IOP in young children leads to enlargement of eye and destruction of fibers of the optic nerve.

COMMONLY ASSOCIATED CONDITIONS

- Sturge-Weber syndrome
- Neurofibromatosis type 1
- Oculocerebrorenal (Lowe) syndrome
- Marfan syndrome
- Rubinstein-Taybi syndrome
- Stickler syndrome
- Walker-Warburg syndrome
- Hepatocerebrorenal syndrome (Zellweger)
- Pierre Robin syndrome
- Homocystinuria
- Rubella
- Trisomy 13
- Trisomy 21 (Down syndrome)
- Axenfeld-Rieger syndrome
- Ocular Anomalies
 - Aniridia
 - Peters anomaly
 - Sclerocornea
 - Congenital iris ectropion syndrome
 - Congenital cataract

ALERT

Intraocular neoplasms such as retinoblastoma can cause glaucoma. Other causes of secondary glaucoma include trauma and chronic uveitis.

DIAGNOSIS

HISTORY

- Classic triad of symptoms that develop from corneal edema caused by increased IOP
 - Epiphora (excessive tearing)
 - Blepharospasm (squeezing of eyelids)
 - Photophobia (light sensitivity)
- Cloudy corneas
- Red eyes (can be mistaken for conjunctivitis)
- Fussiness
- Large eyes

PHYSICAL EXAM

- Unlike adult glaucoma, PCG presents with physical changes due to high pressure.
- Buphthalmos (ocular enlargement) due to stretching of immature collagen in infants
- Corneal asymmetry or enlargement (diameter >11 mm at birth or >12 mm in the 1st year of life)
- Corneal haze from edema and/or scarring
- Myopic shift in refractive error
- Rapid changes in IOP present with redness and pain but usually painless without redness from gradual change in pressure.
- Optic nerve cupping develops rapidly in infants but may be reversible with control of glaucoma in very young children.
- Nystagmus may be present if there is early sensory deficit.
- Common to develop amblyopia and strabismus from insult on developing visual system
- General signs of many systemic syndromes associated with glaucoma (neurofibromatosis, Sturge-Weber syndrome)

Imaging

Ultrasound: axial length using A-scan

- Eye is usually abnormally long for age.
- Longitudinal data are very useful in determining progression of

glaucoma.

Diagnosis Procedures/Other

- IOP measurement
 - An awake child is ideal; use bottle or breast to quiet, along with low lighting.
 - If examination under anesthesia is needed, check IOP as soon as possible after induction, as IOP decreases with anesthetic agents.
- Corneal inspection
 - Diameter measured with calipers
 - Normal newborn: 10–10.5 mm
 - >11.0 mm suspicious
 - Watch for asymmetry.
 - Clarity: Haze may be due to edema or breaks in the Descemet membrane (Haab striae).
- Optic disc evaluation
 - Increase in cupping of the optic nerve head is early sign.
 - May reverse with good IOP control in the very young
- Refractive error
 - Myopic shift from enlargement of the eye
 - Anisometropia (difference in refractive error between the two eyes)
 - Astigmatism from change in ocular shape or corneal scar
 - Early signs of glaucoma and useful office test for monitoring control of glaucoma
- Gonioscopy: evaluation of anterior chamber angle (between iris and cornea)
 - In trabeculodysgenesis, insertion of iris into corneoscleral angle often flat or concave
 - Iris defects may suggest type of abnormality causing glaucoma.
 - Abnormal iris vessels may influence surgical plan.
 - In angle-closure glaucoma: diagnostic apposition of iris on cornea
- Pachymetry: measurement of corneal thickness to assess corneal edema as an indicator of pressure control

DIFFERENTIAL DIAGNOSIS

- Excessive tearing: commonly due to nasolacrimal duct obstruction in

neonates

- Megalocornea
 - May be associated with high myopia
 - Contralateral microphthalmia
- Corneal haze
 - Birth trauma, forceps
 - Congenital corneal dystrophies
 - Mucopolysaccharidoses
 - Cystinosis
 - Intrauterine inflammation (rubella, syphilis)
- Photophobia
 - Uveitis
 - Retinal cone dystrophy
- Enlarged optic nerve cupping
 - Physiologic cupping
 - Optic atrophy from hydrocephalus can look similar to glaucomatous damage.

TREATMENT

GENERAL MEASURES

- Surgery is considered definitive therapy.
- Medical treatment for glaucoma in children is usually a temporizing measure or adjunctive therapy.
 - In other types of pediatric glaucoma, medical treatment involves use of the same medications as those used in adults such as β -blockers, adrenergic agents, and carbonic anhydrase inhibitors. In general, miotics are not used because they may cause a paradoxical rise in IOP in children.

MEDICATION

ALERT

Topical α -adrenergic agonists are contraindicated in infants and young children, as they can cause CNS suppression leading to apnea, sedation, and fatigue.

First Line

- Carbonic anhydrase inhibitors: Side effects include metabolic acidosis, growth retardation, loss of appetite, paresthesias, polyuria, diarrhea, and nausea.
 - Systemic
 - Acetazolamide (10 mg/kg/24 h PO divided t.i.d.)
 - Methazolamide
 - Topical
 - Brinzolamide
 - Dorzolamide
- β -Blockers, topical: Side effects include bronchospasm, apnea, and bradycardia.
 - Timolol
 - Betaxolol
 - Levobunolol
 - Metipranolol
 - Carteolol
- Prostaglandins, topical: Side effects include iris and eyelid pigmentation and growth of lashes.
 - Latanoprost
 - Bimatoprost
 - Travoprost

SURGERY/OTHER PROCEDURES

- Goniotomy/trabeculotomy: Both procedures open portions of Schlemm canal into anterior chamber, allowing easier outflow of aqueous humor (goniotomy approaches the Schlemm canal from inside the eye and trabeculotomy from the outside).
- Trabeculectomy: creates a sclerotomy covered with a partial-thickness scleral flap to create a controlled outflow that bypasses the Schlemm canal and trabecular meshwork. Fluid drains in the sub-Tenon space.
- Seton procedures: various drainage devices placed in subconjunctival space with tube inserted into the anterior chamber, allowing free flow of aqueous humor from eye
- Cyclodestructive procedures: procedures involving destruction of the ciliary body, which produces aqueous humor

- Iridectomy: If the mechanism of glaucoma is angle closure (limited outflow of aqueous humor due to anatomic blockage with iris), then creating a window in the iris allows bypass for aqueous humor to access the anterior chamber.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Early postoperative

- Postoperative steroids and cycloplegic drops to decrease pain and prevent adhesions due to inflammation
- Corneal edema clears slowly, but IOP falls quickly if surgery is successful.
- Adjusting pressure-lowering medications based on the success of the surgery

Longer term

- Follow-up is needed throughout life.
- Examination under anesthesia may be required frequently during the first 3–4 years of life to ensure adequate control of IOP.
- Contact social services for children suspected of having visual impairment.

PATIENT EDUCATION

Children and parents must understand that glaucoma may recur at any point and that continued, long-term surveillance is essential.

PROGNOSIS

Guarded; even if pressure is well controlled and amblyopia treatment undertaken rigorously, child is still at high risk for visual impairment.

Must be carefully followed for the following:

- Amblyopia
- Abnormal refractive errors
- Recurrence of glaucoma

COMPLICATIONS

- Severe visual impairment or blindness due to optic nerve damage,

amblyopia, and corneal scarring likely if glaucoma is undetected or uncontrollable

- Corneal edema and decompensation requiring corneal transplant especially from Seton procedures
- Development of cataract
- If glaucoma is controlled, the following are relatively common:
 - Unrecognized and untreated amblyopia (most serious threat to child's vision)
 - High degrees of myopia
 - Anisometropia (difference in refractive error between fellow eyes)
 - Buphthalmos and corneal scarring

CODES

ICD10

Q15.0 Congenital glaucoma

FAQ

- Q: Can glaucoma be painful?
- A: If the ocular pressure rises quickly (hours), pain occurs frequently. Very high IOPs may be present without pain if they occur slowly (months to years). However, most patients with glaucoma are asymptomatic until they have advanced vision loss.
- Q: Can glaucoma occur after eye trauma?
- A: Yes. This is a very common cause of glaucoma and may be asymptomatic, thus requiring periodic follow-up ophthalmic examinations for early detection and treatment.
- Q: Can infantile glaucoma be inherited?
- A: Yes. Both primary infantile glaucoma and glaucoma related to systemic or ocular syndromes may be inherited. Siblings and children of affected individuals should be examined for glaucoma.

GLOMERULONEPHRITIS

Kevin V. Lemley

BASICS

DESCRIPTION

- Glomerulonephritis presents with the nephritic syndrome: hematuria with RBC casts, hypertension, azotemia, and edema. Proteinuria and oliguria may also be present.
- Acute glomerulonephritis is associated with inflammation and cell proliferation in the glomerular tuft. It may be rapidly progressive.
- Chronic glomerulonephritis indicates permanent damage has occurred.

EPIDEMIOLOGY

- Acute poststreptococcal glomerulonephritis (APSGN) can occur in anyone >2 years but is most frequently found in boys 5–15 years old. It can be sporadic or epidemic.
- Incidence of APSGN has declined over the last 2 decades.
- Chronic glomerulonephritis occurs more often at the end of the 1st decade of life and in adults.

Genetics

Genetic predisposition: hereditary nephritis (e.g., X-linked Alport syndrome)

ETIOLOGY

Can be categorized based on serum complement levels and presence of renal versus systemic disease

- Low serum complement level: systemic diseases
 - Vasculitis and autoimmune disease (e.g., systemic lupus erythematosus [SLE])
 - Subacute bacterial endocarditis (SBE)
 - Shunt nephritis
 - Cryoglobulinemia
- Low serum complement level: renal diseases
 - APSGN

- Membranoproliferative glomerulonephritis, C3 glomerulopathy
- Normal serum complement level: systemic diseases
 - Microscopic polyangiitis
 - Granulomatosis with polyangiitis (Wegener)
 - Henoch-Schönlein purpura (HSP)
 - Hypersensitivity vasculitis
 - Anti-GBM disease (Goodpasture syndrome)
- Normal serum complement level: renal diseases
 - IgA nephropathy
 - Idiopathic rapidly progressive glomerulonephritis
 - Pauci-immune glomerulonephritis (renal-limited ANCA vasculitis)
 - Immune-complex disease

DIAGNOSIS

HISTORY

- Macroscopic hematuria (tea-colored urine) in many
- Reduced urine output, edema
- Dyspnea, fatigue, lethargy
- Headache
- Seizures (hypertensive encephalopathy)
- Symptoms of a systemic disease such as fever, rash (especially on the buttocks and legs, posteriorly), arthralgia, and weight loss
- Preceding sore throat, upper respiratory infection (7–14 days), or preceding impetigo (14–28 days) suggests APSGN.
- An upper respiratory infection in the few days prior to macroscopic hematuria may suggest IgA nephropathy.

PHYSICAL EXAM

- Hypertension
- Signs of volume overload (e.g., edema, jugular venous distention, hepatomegaly, basal pulmonary crepitation, a gallop rhythm)
- Impetigo or pyoderma
- Signs of vasculitis such as rash, Raynaud phenomenon, and vascular thrombosis

- Signs of other systemic disorder (SLE)
- Signs of chronic kidney disease, such as short stature, pallor, sallow skin, edema, pericardial friction rub, pulmonary rales, breath that smells of urine, clonus

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- Urine
 - Microscopy of the urine for dysmorphic erythrocytes and erythrocyte casts: hallmark of nephritis
 - Proteinuria
- Evidence of prior strep infection
 - Throat culture for β -hemolytic Streptococcus (result is positive in only 15–20% with sporadic APSGN)
 - Antistreptolysin O and anti-DNase B titers: positive result in patients with preceding acute poststreptococcal infection
 - Streptozyme test: A mixed antigen test for β -hemolytic Streptococcus (ASO, anti-DNase, anti-streptokinase, anti-hyaluronidase, etc.) has 85–90% sensitivity and specificity; sensitivity is increased by serial testing.
- Complement C3 serum level will be low in APSGN and in several other causes of acute glomerulonephritis.
- Blood chemistry
 - Can be normal in acute glomerulonephritis
 - Serum creatinine generally $<1.5\times$ normal in uncomplicated APSGN
 - In chronic glomerulonephritis, serum chemistries will reflect the degree of chronic kidney disease (i.e., raised serum urea and creatinine). The serum potassium and phosphate levels may be elevated and the calcium level decreased.
 - In chronic kidney disease: normocytic, normochromic, or hypochromic microcytic anemia

Imaging

- Chest radiograph to look for pulmonary edema and determine cardiac size if severe edema or respiratory symptoms are present

- Renal ultrasound if presentation or course not typical of APSGN. The ultrasound is to assess the size and parenchymal texture.

Diagnostic Procedures/Other

Electrocardiogram to assess ventricular size and for T-wave changes in cases of hyperkalemia

Pathologic Findings

In APSGN, light microscopy reveals enlarged, swollen glomerular tufts and mesangial and endothelial cell proliferation, with polymorphonuclear leukocyte infiltration. There is granular deposition of C3 and IgG on immunofluorescence, and electron-dense subepithelial deposits or humps are seen on electron microscopy. The histology varies in chronic glomerulonephritis and depends on the cause. Rapidly progressive glomerulonephritis is associated with crescent formation.

DIFFERENTIAL DIAGNOSIS

- Acute postinfectious glomerulonephritis (nephritogenic strains of group A β -hemolytic streptococci, Pneumococcus, Staphylococcus, Mycoplasma, Epstein-Barr virus)
- Infection-related (hepatitis B and C, syphilis)
- IgA nephropathy
- Membranoproliferative glomerulonephritis
- Autoimmune glomerulonephritis (e.g., SLE)
- Immune-complex glomerulonephritis
- Hereditary glomerulonephritis
- Tubulointerstitial nephritis
- Hemolytic uremic syndrome
- Pyelonephritis

TREATMENT

Aimed toward treating hypertension, renal failure, and the underlying cause of glomerulonephritis

MEDICATION

- The following may be required:

- Loop diuretics (furosemide) for volume, BP, and potassium control
- Antihypertensive agents; vasodilators such as calcium channel blockers (e.g., nifedipine, isradipine, amlodipine) as 1st-line agents; IV hydralazine, labetalol, nicardipine, or nitroprusside may be required to treat severe refractory hypertension or posterior reversible encephalopathy syndrome (PRES). Avoid ACE inhibitors or angiotensin receptor blockers (ARBs) in case of hyperkalemia or acute kidney injury (AKI).
- Serum potassium-lowering agents (sodium polystyrene sulfonate [Kayexalate], furosemide, bicarbonate, insulin/glucose, β -agonists). IV calcium is used to stabilize the myocardium in severe hyperkalemia (with T-wave changes); dialysis in severe renal failure with significant hyperkalemia
- Phosphate binders (calcium carbonate)
- Immunosuppressive agents such as prednisone, cyclophosphamide, mycophenolate mofetil, and rarely rituximab or eculizumab are used in the treatment of vasculitis-associated glomerulonephritis, membranoproliferative glomerulonephritis, rapidly progressing glomerulonephritis, or disorders of complement regulation. Plasmapheresis may be used to treat rapidly progressing glomerulonephritis, especially with multisystem (pulmonary, CNS) involvement or severe acute renal failure requiring dialysis.
- Penicillin is used in active poststreptococcal glomerulonephritis to prevent rheumatic fever and the spread of nephritogenic strains but generally does not affect the course of the renal disease. It may be indicated in exposed individuals in epidemic APSGN and household contacts of sporadic cases.

ADDITIONAL TREATMENT

General Measures

- APSGN is typically a self-limited disease. Acute supportive therapy is usually sufficient.
- Dietary salt restriction
- The therapy of chronic glomerulonephritis depends on the underlying disease process; it may include immunosuppressive medications and, ultimately, the management of chronic kidney disease.

INPATIENT CONSIDERATIONS

Initial stabilization

Treat hypertensive encephalopathy and life-threatening electrolyte disturbances immediately.

Admission Criteria

- Hypertension
- Severe edema, pulmonary edema
- Acute kidney injury

ONGOING CARE

FOLLOW-UP-RECOMMENDATIONS

In APSGN, improvement usually occurs within 3–7 days, hypertension is not sustained, and macroscopic hematuria is transient. Watch for ongoing oliguria, unresolved hypertension, increasing proteinuria, or progressive azotemia. Complement levels return to normal within 6–8 weeks of the initial presentation.

ALERT

- Microscopic hematuria may be present up to 2 years after an episode of poststreptococcal glomerulonephritis.
- Recurrent gross hematuria calls the diagnosis of APSGN into question.
- If complement levels do not return to normal after presumed APSGN, consider SLE and MPGN.

PATIENT MONITORING

- To control seizures, treat the hypertension; anticonvulsants play a secondary role.
- Look for and treat hyperkalemia.
- Monitor the degree of acute kidney injury.
- Home testing: BP monitoring may be required.
- Be certain to recognize fluid overload.
- Be certain to recognize the type of renal failure: acute versus chronic.
- Long-term monitoring for hypertension and/or progressive proteinuria may be indicated in some populations (5–10% may develop

progressive proteinuria within 20 years).

DIET

Restrictions of intake of fluid, sodium, potassium, and phosphate are initially required.

PROGNOSIS

- Prognosis is excellent in APSGN and variable for other causes of glomerulonephritis in childhood.
- APSGN rarely recurs.

COMPLICATIONS

- Hypertension
- Acute renal failure
- Hyperkalemia
- Volume overload (e.g., congestive cardiac failure, pulmonary edema, hypertension)
- Chronic kidney disease

CODES

ICD10

- N05.9 Unsp nephritic syndrome with unspecified morphologic changes
- N00.9 Acute nephritic syndrome with unsp morphologic changes
- N03.9 Chronic nephritic syndrome with unsp morphologic changes

FAQ

- Q: When do serum complement levels return to normal?
- A: Serum complement levels (C3) return to normal within a 6–8-week period in APSGN. Persistently low C3 levels suggest a cause other than APSGN and renal biopsy should be considered with persistent urinary abnormalities (hematuria and/or proteinuria).
- Q: What are the indications for renal biopsy in acute glomerulonephritis?
- A: Patients in whom there is sustained hypertension, ongoing or progressive azotemia, or persistent proteinuria of >1.5 mg/mg should be biopsied.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

Michele P. Lambert

BASICS

DESCRIPTION

Deficiency of the enzyme glucose-6-phosphate dehydrogenase (G6PD) in the RBC, which may result in hemolytic anemia. Several types of genetic mutations result either in deficient enzyme production or in production of an enzyme with diminished activity.

- Although most patients with this deficiency are never anemic and have mild to no hemolysis, the classic manifestation is acute hemolytic anemia in response to oxidative stress.
- World Health Organization classification of G6PD:
 - Class 1: congenital nonspherocytic hemolytic anemia: rare. Chronic hemolysis without exposure to oxidative stressors—splenomegaly in 40%. Affected individuals tend to be white males of Northern European background.
 - Class 2: severe deficiency (1–10% enzymatic activity): oxidative stress–induced hemolysis. Prototype is G6PD-Mediterranean.
 - Class 3: mild deficiency (10–60% enzymatic activity): most common type. Acute hemolytic anemia uncommon, occurs only with stressors
 - Class 4: nondeficient variant (60–100% enzymatic activity): no symptoms, even during oxidant stressors (e.g., G6PD A+ [variant with normal activity]); 20–40% allelic frequency in Africans
 - Class 5: >150% of normal activity
- Deficient neonates may have hyperbilirubinemia out of proportion to their anemia.
 - May, in part, account for increased prevalence of African Americans among patients with bilirubin encephalopathy
 - Should be considered as cause of hyperbilirubinemia in neonates of appropriate racial background and may contribute to kernicterus

GENERAL PREVENTION

Avoid drugs and toxins known to cause hemolysis. Prompt follow-up with febrile illness and signs of hemolysis.

EPIDEMIOLOGY

Prevalence

- Most common of all clinically significant enzyme defects, affecting ~400 million people worldwide
- X linked (Xq28): primarily affects males
- Almost 400 allelic variants
- Frequency of different mutations varies by population:
 - Africans: 20–40% of X chromosomes are G6PD A⁺ (mutant enzyme with normal activity).
 - Sardinians (some regions): 30% have G6PD-Mediterranean.
 - Saudi Arabians: 13% have G6PD deficiency.
 - African Americans: 10–15% have G6PD A[–] (mutant enzyme with decreased activity).
- High incidence of mutant genes in some regions may relate to survival advantage against malarial infection (*Plasmodium falciparum*).

Genetics

Gene is on the X chromosome (Xq28).

- Males express the enzyme (mutant or normal) from their single X chromosome (hemizygotes).
- Female homozygotes (rare) are more severely affected than female heterozygotes.
- Heterozygote females show variable intermediate expression because of random X inactivation.

PATHOPHYSIOLOGY

- RBCs lose G6PD activity throughout their lifespan; therefore, older cells are more prone to oxidative hemolysis.
- Normal RBC lifespan of ~120 days is unaffected in unstressed states, even with severe enzyme deficiency, but may be shortened during oxidant stress.
- Enzyme-deficient RBCs are destroyed by intravascular hemolysis on exposure to the oxidative stressor and acute hemolytic anemia results.

- Oxidant stressors include infections and chemicals (mothballs, antimalarials, some sulfonamides, methylene blue).
- Hemolysis usually follows stressor by 1–3 days, and nadir occurs 8–10 days postexposure. Obtain hemoglobins for >1 week after the initial exposure.
- Favism: severe hemolytic anemia in patients with more severe forms of G6PD deficiency after fava bean ingestion
- Normal G6PD activity is 7–10 IU/g hemoglobin.

DIAGNOSIS

HISTORY

- Symptoms of anemia include fatigue, irritability, and malaise.
- Dark urine (cola or tea colored) may follow moderate to severe hemolysis. May develop jaundice (particularly scleral icterus).
- Patient may have required phototherapy in newborn period for hyperbilirubinemia.
- Recent drug, chemical, or food (fava bean) exposures may precipitate moderate to severe hemolysis.
- Family history of intermittent jaundice, splenectomy, cholecystectomy, or blood transfusion may indicate an inherited condition.
- Ethnicity may help determine type/severity of disease.

PHYSICAL EXAM

- Tachycardia, a flow murmur, or pallor: signs of anemia
- Jaundice or scleral icterus: signs of hemolysis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
 - Usually reveals a normochromic normocytic anemia with appropriate reticulocytosis
 - Hemoglobin can drop precipitously; should be monitored closely until stable or trending upward; checking a single hemoglobin the day of exposure to the stressor is not sufficient.
- Peripheral blood smear

- Often shows bizarre RBC morphology with marked anisocytosis and poikilocytosis
- Can see schistocytes, hemighost cells (uneven distribution of hemoglobin), bite cells, blister cells, and occasional Heinz bodies (on supravital staining)
- Hemoglobinemia: seen as plasma (pinkish red supernatant) or measured as free serum hemoglobin
- Hemoglobinuria: occurs when hemoglobin-binding sites in the plasma (haptoglobin and hemopexin) are saturated; may be visible as dark urine—heme positive on dipstick and no RBC on microscopy
- Free haptoglobin levels decrease.
- Direct and indirect Coombs tests
 - Must be done to exclude autoimmune hemolytic anemia
 - Should be negative in G6PD deficiency
- Other: Plasma indirect bilirubin, lactate dehydrogenase, and aspartate aminotransferase may be elevated; hemosiderin may be found in the urine several days after hemolysis. Liver function tests should be normal. Renal functions to rule out thrombotic thrombocytopenic purpura and hemolytic uremic syndrome:
 - Rapid screening tests for G6PD activity in RBCs are qualitative; will miss some female heterozygotes with measurable but low enzyme levels
 - Necessary to confirm a deficiency or to diagnose a suspected heterozygote with a test to quantify G6PD activity
 - Normal activity: 7–10 IU/g hemoglobin
 - Accurately detects deficiency in males and homozygous females with no recent hemolysis
 - Helpful with heterozygous women/
- Newborn screening for G6PD deficiency
 - Included in some panels of genetic screening tests performed on newborns
 - Typically performed by DNA-based methods that detect a few of the most common variants in U.S. populations. Does not screen for all G6PD variants and can miss severe but rare variants.
 - Results may be reported in terms of predicted enzyme levels but not

a true measurement of enzymatic activity.

ALERT

- Screening tests may be falsely negative during rapid red cell turnover (reticulocytosis).
- Most cost-effective approach: Defer screening until 1–2 weeks after resolution of hemolysis. Smear may be normal during steady state.
- Heterozygote female detection:
 - 2 RBC populations exist because of mosaicism from random X inactivation.
 - On average, 50% are normal and 50% are deficient, but there may be variability.

DIFFERENTIAL DIAGNOSIS

Intravascular hemolysis is very rare in children, but other causes include the following:

- Acute hemolytic transfusion reactions (Coombs test is positive)
- Microangiopathic hemolytic disease, such as hemolytic uremic syndrome, thrombotic thrombocytopenic purpura, and prosthetic cardiac valves
- Physical trauma (e.g., March hemoglobinuria); severe burns (uncommon)
- Other inherited RBC enzyme deficiencies
- Paroxysmal nocturnal hemoglobinuria
- Extravascular hemolysis can also be confused with G6PD deficiency and includes the following:
 - Hereditary spherocytosis (spherocytes on smear)
 - Autoimmune hemolysis and delayed hemolytic transfusion reactions (both Coombs positive)
 - Hemoglobinopathies
 - Hypersplenism
 - Severe liver disease
 - Gilbert disease

TREATMENT

GENERAL MEASURES

- Removal of the oxidant stressor is of primary importance:
 - Discontinue the suspected drug and/or treat the infection.
 - In class 3 and 4 patients, essential drug therapy may be continued while monitoring for signs of severe hemolysis.
 - Transfusion may be necessary (especially in some class 1 and 2 deficiencies), but any patient who is symptomatic with anemia or has a low hemoglobin and signs of ongoing brisk hemolysis should be transfused immediately with packed RBCs.
 - Supportive care, evaluation of renal function (risk of acute tubular necrosis with brisk hemolysis), and monitoring degree of anemia and ongoing hemolysis are important.
- For the affected neonate:
 - Monitor the bilirubin closely and start phototherapy early.
 - If necessary, exchange transfusion should be carried out.
 - Phenobarbital may decrease bilirubin level.
 - Early discharge is not recommended in newborn infants with jaundice and known risk for G6PD deficiency.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Most deficient individuals remain asymptomatic.
- When hemolysis does occur, it tends to be self-limited and resolves spontaneously, with a return to normal hemoglobin levels in 2–6 weeks.
- Development of renal failure is extremely rare in children, even with massive hemolysis and hemoglobinuria.

DIET

- Avoid fava beans (*Vicia faba*). Fava beans have a variety of names in different cultures (e.g., faba bean, broad bean, tick bean, field bean, bell bean, bakela [Ethiopia], faviera [Portugal], ful masri [Sudan], winter field bean [United Kingdom]).

PROGNOSIS

- For those with the milder forms, the prognosis is excellent.
- Can cause significant morbidity, but rarely mortality, in those with the more severe forms

COMPLICATIONS

Neonates can be at risk for hyperbilirubinemia, requiring treatment. Kernicterus has been reported in infants with G6PD deficiency.

CODES

ICD10

D55.0 Anemia due to glucose-6-phosphate dehydrogenase deficiency

FAQ

- Q: Do I need to follow a special diet or avoid medications if I have G6PD deficiency?
- A: Although most patients will have no symptoms of their disease, certain medications may cause transient hemolytic anemia, and these should be avoided. When prescribing medications, your physician and pharmacist should know about your G6PD, but most necessary

medications are safe and well tolerated. People with severe variants of the deficiency should also avoid fava beans, but otherwise no dietary restrictions are necessary.

- Q: Do I need to know which variant of G6PD I have?
- A: It may be clear which variant you are likely to have based on your clinical symptoms and ethnic background.
- Q: Should my family be screened if someone has G6PD deficiency?
- A: In families of patients with G6PD, screening members may help provide meaningful genetic counseling to female carriers and affected but asymptomatic males.
- Q: How does G6PD affect sickle cell anemia and vice versa?
- A: Having sickle cell disease is somewhat protective in patients with G6PD A deficiency because their RBC population is young and, therefore, has higher enzymatic activity. On the other hand, G6PD has no effect on the clinical characteristics of sickle cell disease.

GOITER

Adda Grimberg

BASICS

DESCRIPTION

Goiter is enlargement of the thyroid gland.

EPIDEMIOLOGY

- The most common cause of pediatric goiter in the United States is chronic lymphocytic thyroiditis.
- The prevalence of goiter in the United States is 3–7%, although the incidence is much higher in regions of iodine deficiency.
- Thyroid cancers make up 0.5–1.5% of all malignancies in children and adolescents.
- Both thyroid tumors and autoimmune thyroid disease are more common in females than males.

Prevalence

World Health Organization (WHO) Global Database on Iodine Deficiency (1993–2003)

- Goiter prevalence globally is 15.8% of the general population.
- Insufficient iodine intake among school-aged children ranges from 10.1% in the Americas to 59.9% in Europe.
- 54 countries had iodine deficiency, 29 countries had excessive iodine intake, and 43 countries achieved optimal iodine intake.

ETIOLOGY

- Multinodular goiter (MNG) loci have been identified on chromosome 14q and on chromosome Xp22 and 3q26.
- Germline mutations in DICER1 (chromosome 14q31) have been found in familial MNG-1, with and without ovarian Sertoli-Leydig cell tumors.
- Germline mutation in thyroid transcription factor-1 (TTF-1/NKX2.1) has been found in patients with papillary thyroid carcinoma and a history of multinodular goiter.

- Other genes implicated in simple goiter formation: thyroglobulin, thyroid-stimulating hormone (TSH) receptor, and Na^+/I^- symporter
- Thyroid peroxidase mutations lead to iodide organification defects and goitrous congenital hypothyroidism.
- Twin and family studies show a modest to major effect of environmental factors, especially iodine deficiency and cigarette smoking.
- Excessive maternal ingestion of iodine during pregnancy can lead to congenital goiter with increased iodine uptake on scan and in some babies, a transient hypothyroidism.
- Autoimmune goiters, such as chronic lymphocytic thyroiditis, occur in children with a genetic predisposition.
- Thyroid cancers are usually sporadic. Medullary carcinoma can be familial (autosomal dominant), as part of multiple endocrine neoplasia (MEN) type 2A and 2B, or as isolated malignancy.
- Pendred syndrome (autosomal recessive) causes congenital sensorineural deafness and an iodine organification defect that leads to goiter.

DIAGNOSIS

HISTORY

- Symptoms of hypothyroidism:
 - Increase in sedentary behavior
 - Lethargy
 - Weight gain
 - Constipation
 - Cold intolerance
 - Dry skin and/or hair
 - Hair loss
- Symptoms of hyperthyroidism:
 - Hyperactivity
 - Irritability
 - Difficulty concentrating or focusing in school
 - Hyperphagia

- Weight loss
- Diarrhea
- Heat intolerance
- Careful dietary and medication history
- History of head, neck, or chest irradiation is associated with increased risk of carcinoma.
- Family history of thyroid carcinoma or MEN syndrome

PHYSICAL EXAM

Inspect, palpate, and auscultate the neck:

- Neck extension aids inspection.
- Palpation is best performed standing behind the child:
 - Determine if the thyroid is diffusely enlarged or asymmetric, evaluate gland firmness, and assess for any nodularity.
 - Check for cervical lymphadenopathy.
 - Pain on palpation suggests acute inflammation.
- Auscultate with the stethoscope diaphragm (while patient holds his or her breath) for a bruit, which indicates hyperthyroidism-associated hypervascularity.
- Careful examination for signs of hypothyroidism or hyperthyroidism
 - Linear growth and weight pattern
 - Pulse
 - Sexual development
 - Deep tendon reflexes
 - Skin
- Have patient drink water during inspection of gland.

DIAGNOSTIC TESTS & INTERPRETATION

- Thyroid function tests: Total T₄ and TSH are best screens for hypothyroidism or hyperthyroidism.
- T₃ radioimmunoassay in cases of suspected hyperthyroidism (note: radioimmunoassay, which measures total T₃, and not resin uptake, which indirectly assesses thyroid hormone-binding capacity)
- In cases of suspected chronic lymphocytic thyroiditis: antithyroglobulin and antimicrosomal (antiperoxidase) antibodies
- In cases of suspected Graves disease: thyroid-stimulating

immunoglobulins (or TSH-receptor antibodies)

- Fine-needle aspiration biopsy in children should be considered only for evaluation of low-risk or purely cystic thyroid nodules. (A higher percentage of solitary thyroid nodules are malignant in children compared with adults.)
- Calcitonin levels: elevated in 75% of patients with medullary thyroid carcinoma

Lab

Urinary iodine (UI) concentration is the best measure of the adequacy of iodine intake.

Imaging

- Ultrasound to determine the number, size, and nature (cystic, solid, or mixed) of nodules
- ^{123}I thyroid scans in cases of solitary nodules to establish whether the nodule concentrates iodide
 - “Cold” nodules (no I uptake) suggest neoplasia and require immediate evaluation by a pediatric endocrinologist and surgeon.
- Barium swallow studies can reveal a fistulous tract between the left piriform sinus and the left thyroid lobe in children with recurrent acute suppurative thyroiditis. Such fistulas are amenable to surgical resection.

DIFFERENTIAL DIAGNOSIS

- Fat neck
 - Adipose tissue
 - Large sternocleidomastoid muscles
- Thyroglossal duct cysts
- Nonthyroidal neoplasms: lymphoma, teratoma, hygroma, ganglioneuroma
- Immunologic
 - Chronic lymphocytic thyroiditis (often referred to as Hashimoto thyroiditis)
 - Graves disease
 - Amyloid deposition (familial Mediterranean fever, juvenile rheumatoid arthritis)

- Infectious
 - Acute suppurative thyroiditis (most often *Streptococcus pyogenes*, *Staphylococcus aureus*, and *Streptococcus pneumoniae*)
 - Subacute thyroiditis (often viral)
- Environmental
 - Goitrogens: iodide, lithium, amiodarone, oral contraceptives, perchlorate, cabbage, soybeans, cassava, thiocyanate in tobacco smoke (smoking is especially goitrogenic in iodine-deficient areas)
 - Iodine deficiency (exacerbated by pregnancy)
- Neoplastic
 - Thyroid adenoma/carcinoma
 - Follicular adenoma: benign
 - Follicular, papillary, or mixed carcinoma: well-differentiated; follicular 90%
 - Medullary carcinoma: 4–10% as part of the MEN type 2 syndrome
 - TSH-secreting adenoma
 - Lymphoma
- Congenital
 - Ectopic gland
 - Unilateral agenesis of gland
 - Dyshormonogenesis
 - T₄ resistance
- Miscellaneous:
 - Simple colloid goiter
 - Multinodular goiter

TREATMENT

ALERT

Possible conflicts: In manic depressive patients on lithium and cardiac patients on amiodarone, medication-induced thyroid abnormalities can be a significant problem that should be addressed by the endocrinologist and appropriate subspecialist.

MEDICATION

- Goiters with hypothyroidism: L-thyroxine
- Goiter with hyperthyroidism: Treatment consists of antithyroid drugs (methimazole); if remission is not achieved after 1 or 2 years, radioactive iodine ablation (^{131}I) or surgery (near-total or total thyroidectomy) may be considered.
- Duration depends on the cause of the goiter.

ALERT

FDA issued a black box warning (6/4/2009) against propylthiouracil (PTU) use in treating Graves disease owing to risk of severe liver injury including life-threatening acute liver failure.

ADDITIONAL TREATMENT

Additional Therapies

Intraamniotic injections of L-thyroxine may treat fetal goitrous hypothyroidism. Large fetal goiters pose a risk of airway compromise at birth.

SURGERY/OTHER PROCEDURES

- Surgery solely to decrease size of goiter indicated only if adjacent structures are compressed.
- Rates of complications after pediatric total thyroidectomy are similar for benign and malignant thyroid diseases; most common is transient hypocalcemia.
- Cancer
 - Surgery is recommended for a nonfunctioning nodule if there is:
 - A history of radiation
 - Rapid growth of a firm nodule
 - Evidence of satellite lymph nodes
 - Evidence of impingement on other neck structures
 - Evidence of distant metastases
- Following surgery, radioiodide therapy is administered if a follow-up iodine scan reveals any residual tissue or metastases.
- Suppressive doses of exogenous thyroid hormone are then given to maintain TSH levels <0.2 mIU/L.
- Thyroglobulin levels are useful as markers of thyroid tissue; calcitonin level serves as tumor marker for medullary carcinoma.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Potential for goiter regression depends on its cause. Goiters associated with chronic lymphocytic thyroiditis and Graves disease may or may not decrease in size with treatment.
- A goiter patient who is clinically and biochemically euthyroid still requires careful follow-up for the detection of the early signs of developing thyroid dysfunction.
- Potential complications of thyroid surgery include laryngeal nerve damage and hypoparathyroidism. Complication rates are lower in high-volume centers.
- Long-term follow-up of patients with thyroid cancer is recommended, as disease can recur decades after initial diagnosis and therapy.

ALERT

- Work up solitary thyroid nodules aggressively. Remember: Incidence of malignancy in these nodules in children is 15–40% (less in adults).
- Malignancy is more likely in euthyroid pediatric patients with nodules that have palpable lymph nodes, compressive signs, microcalcifications, intranodular vascularization, and lymph node alterations.
- Differentiated thyroid carcinoma in prepubertal children, compared to pubertal adolescents, has a more aggressive presentation and more frequently a family history of thyroid carcinoma.

DIET

- Depends on the cause of the goiter
- Incidence of iodine deficiency (endemic) goiter has greatly declined since the addition of potassium iodide to table salt.
- Iodide can also be added to communal drinking water or administered as iodized oil in isolated rural areas.

PROGNOSIS

- Depends on the cause of the goiter

- Thyroid cancers usually follow an indolent course with excellent prognosis, especially the well-differentiated follicular cell carcinoma. Mortality is most common in medullary and undifferentiated carcinomas, which are relatively rare in children.

COMPLICATIONS

- Depending on gland size, goiters can produce a mass effect on midline neck structures. If the goiter is intrathoracic, it may cause pleural effusions or chylothorax.
- Typically, the child is euthyroid, but clinical hypothyroidism or hyperthyroidism may result from certain types of goiters.
- Therapy for thyroid cancer may induce permanent hypothyroidism.

CODES

ICD10

- E04.9 Nontoxic goiter, unspecified
- E04.2 Nontoxic multinodular goiter
- E06.3 Autoimmune thyroiditis

FAQ

- Q: Does a bigger thyroid gland mean increased thyroid functioning?
- A: Goiters can be euthyroid, hypothyroid, or hyperthyroid, depending on cause.
- Q: Will the goiter decrease in size with treatment?
- A: This depends on the cause of the goiter.
- Q: Does a bigger thyroid gland mean cancer?
- A: Most pediatric goiters are benign, and thyroid cancers often are detected as solitary nodules within an otherwise normal gland (in children with solitary nodules, up to 40% are carcinomas). Patients with a history of goiter or benign nodules/adenomas have an increased risk of developing thyroid cancer.
- Q: Does thyroid cancer usually present with hyperthyroidism?
- A: No. The usual chief complaint is a solitary, hard, painless nodule in an euthyroid patient.
- Q: Is there an increased risk of thyroid cancer from diagnostic

radiographs (chest radiographs, lateral neck films)?

- A: Routine diagnostic radiographs should fall well below the levels of radiation thought to increase risk of thyroid neoplasia. During more prolonged radiologic procedures that might expose the thyroid to higher doses of radiation, a lead neck shield is used.
- Q: Should prophylactic thyroidectomy be performed in children identified genetically as having familial medullary carcinoma?
- A: Yes. Because of the poorer prognosis associated with development of this cancer

GONOCOCCAL INFECTIONS

Angela M. Statile • Samir S. Shah

BASICS

DESCRIPTION

Neisseria gonorrhoeae, an aerobic gram-negative diplococcus, is the etiologic agent of gonorrhea.

EPIDEMIOLOGY

- Gonorrhea is the second most common sexually transmitted infection (STI) in the United States.
- Coinfection with *Chlamydia trachomatis* commonly occurs in sexually active patients.

Incidence

- In the United States, there are >800,000 new cases of gonorrhea each year. Rates of infection are highest among adolescents and young adults.
- Racial disparities are present, with a disproportionately high incidence in ethnic minorities.

Prevalence

- Less than half of all infections are estimated to be detected or reported.

RISK FACTORS

- Vaginal delivery to an infected mother is a risk factor for neonatal disease.
- Sexual abuse should be considered in all prepubertal children presenting with gonorrhea.
- Risk factors for sexually active adolescents include multiple sexual partners, lack of condom use, and inconsistent screening by health care providers.
- The risk of male-to-female transmission is 50% per episode of vaginal intercourse; the risk of female-to-male transmission is ~20% per episode. Rectal intercourse is also a mode of transmission.

GENERAL PREVENTION

- Ophthalmia neonatorum: Prophylactic ophthalmic ointment is mandatory in the United States regardless of method of delivery. Instillation of 0.5% erythromycin ophthalmic ointment in both eyes occurs immediately after birth.
- Maternal infection: Routine screening cervical cultures should be performed at the 1st prenatal visit; repeat at term if high risk.

PATHOPHYSIOLOGY

- Incubation period is 2–7 days.
- Transmission results from contact with infected mucosa and secretions, usually through vaginal delivery, sexual activity, and (rarely) household contact in prepubertal children.
- In prepubertal children, genital infection is mild; ascending or disseminated infection rarely occurs. In adolescents, estrogenization protects the vagina from infection and instead serves as a conduit for cervical exudate.
- Immunity is not induced by infection.

COMMONLY ASSOCIATED CONDITIONS

Pediatric gonococcal infections can be categorized by age group: neonates, prepubertal children, and sexually active adolescents.

- Neonatal gonococcal diseases include ophthalmia neonatorum, scalp abscess (complication of fetal scalp monitoring), and, rarely, disseminated disease.
- Prepubertal gonococcal disease usually occurs in the genital tract. Vaginitis is the most common manifestation. Pelvic inflammatory disease (PID), perihepatitis (Fitz-Hugh–Curtis syndrome), urethritis, proctitis, and pharyngitis rarely occur. Consider sexual abuse.
- Gonococcal diseases in sexually active adolescents resemble those found in adults and may be asymptomatic.
 - Both sexes: pharyngitis, anorectal infection, tenosynovitis-dermatitis syndrome, or arthritis
 - Females: Genital tract infection may cause urethritis, vaginitis, and endocervicitis. Ascending genital tract infection may lead to PID and perihepatitis.

- Males: Acute urethritis is the predominant manifestation. Epididymitis also occurs.

DIAGNOSIS

HISTORY

- In neonates, assess for risk factors such as premature or prolonged membrane rupture, presence of fetal scalp monitoring, and maternal history of infection.
- Onset of eye findings in ophthalmia neonatorum is usually between 2 and 5 days of age but ranges from 1 day to several weeks.
- Sexual history should be thoroughly reviewed with all adolescents.
- Vaginal itching and discharge may indicate vaginitis.
- Urethritis: purulent urethral discharge and dysuria without urgency or frequency
- Abdominal pain
 - Ascending infection is characterized by diffuse lower quadrant abdominal pain, including discomfort with ambulation. Low back pain, dyspareunia, and abnormal vaginal bleeding occasionally occur. Fever, chills, nausea, and vomiting may be present. Acute perihepatitis causes right upper quadrant pain and results from direct extension of infection from the fallopian tube to the liver capsule.
- Symptoms of extragenitourinary disease including sore throat, joint pain, or rash

PHYSICAL EXAM

- Ophthalmia neonatorum
 - Bilateral eyelid edema, chemosis, and copious purulent discharge
- Neonatal scalp abscess
- PID
 - Signs include cervical motion tenderness, pelvic adnexal tenderness (usually bilateral), and lower or right upper quadrant abdominal pain (with perihepatitis). Many females with PID also have mucopurulent cervical discharge.
- Cervicitis or urethritis: purulent vaginal or penile discharge

- Rash: classically discrete, tender, necrotic pustules on distal extremities, although macules, papules, and bullae occasionally occur
- Joint findings: tenosynovitis, migratory arthritis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- Gram stain (low sensitivity) and culture of infected exudate or body fluid
 - Intracellular gram-negative diplococci on gram stain. Confirmation depends on isolation of *N. gonorrhoeae* from culture. Specimens are immediately inoculated onto Thayer-Martin or chocolate–blood agar–based media at room temperature and incubated in an enriched CO₂ environment. In cases of suspected sexual abuse, collect genital, rectal, and pharyngeal cultures.
- Nonculture gonococcal tests
 - Nucleic acid amplification tests (NAATs) for urine specimens (freshly voided specimens), male urethral, female endocervical or vaginal (self-administered introital) swabs are highly sensitive and specific but should not be used in investigations of possible sexual abuse (possibility of false-positive results). NAATs also cannot provide antimicrobial susceptibility test results.
- STI panel
 - Test for other STIs including *C. trachomatis*, *Treponema pallidum* (syphilis), *Trichomonas vaginalis*, and HIV in children in whom sexual abuse is suspected or when evaluating sexually active adolescents.
- CBC, ESR, C-reactive protein, and blood culture may be obtained to evaluate for inflammation and disseminated disease.
- Synovial fluid cell count and culture in patients with joint swelling (cell count often >50,000 WBC/μL with differential of >90% PMNs)
- Synovial fluid cultures are positive in 50% with gonococcal arthritis; blood cultures are positive in less than 1/3, although cultures from other sites (e.g., cervix, urethra) are frequently positive.

Imaging

Pelvic ultrasound may detect ectopic pregnancy and, in PID, may reveal thick, dilated fallopian tubes or tuboovarian abscess.

DIFFERENTIAL DIAGNOSIS

- Ophthalmia neonatorum: Other causes of neonatal conjunctivitis include infection with *C. trachomatis*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus* species, chemical conjunctivitis, and herpes simplex virus (HSV).
- Scalp infection: Gonococcal scalp abscesses may be difficult to distinguish from abscesses caused by staphylococcal species, group B *Streptococcus*, *H. influenzae*, *Enterobacteriaceae*, and HSV.
- Vaginitis: In the prepubertal child, other causes include chemical or environmental irritants, pinworms, foreign body, and infections (i.e., streptococci, *T. vaginalis*). In cases of sexual abuse, *C. trachomatis* and syphilis may occur.
- Genitourinary tract infection: In adolescents, other causes include *C. trachomatis*, syphilis, and *T. vaginalis*.
- Arthritis: other bacterial causes of septic arthritis, Reiter syndrome, and reactive arthritis
- Abdominal pain: ectopic pregnancy, appendicitis, cholecystitis, UTI/pyelonephritis, and ovarian torsion

TREATMENT

MEDICATION

First Line

- Changing resistance patterns in the United States led to extended-spectrum cephalosporin as initial therapy.
- Neonates
 - Ophthalmia neonatorum: ceftriaxone 25–50 mg/kg IV or IM (single dose; maximum, 125 mg); alternate agent for infants with hyperbilirubinemia is cefotaxime 100 mg/kg IV or IM (single dose).
 - Neonates with gonococcal ophthalmia also require eye irrigation with sterile saline at presentation and at frequent intervals until mucopurulent drainage has ceased.

- Disseminated infection: cefotaxime for 7 days for bacteremia, 10–14 days for meningitis
- Older children and adolescents
 - Uncomplicated gonococcal infection (including cervicitis, epididymitis, or pharyngeal infection): Cefixime is no longer recommended as 1st-line treatment. Give a single IM dose of ceftriaxone 250 mg. Follow with a treatment regimen for *C. trachomatis*.
 - If ceftriaxone is not available, give single-dose cefixime 400 mg orally, along with *C. trachomatis* treatment. In cases of severe cephalosporin allergy, give single dose azithromycin 2 g. Alternative regimens to ceftriaxone require tests of cure in 1 week.
 - PID: See Pediatric Red Book or 2010 CDC guidelines for treatment regimens.
 - Complicated gonococcal infection: ceftriaxone or cefotaxime for 7 days (arthritis and septicemia), 10–14 days (meningitis), or ≥ 28 days (endocarditis). Include concomitant *C. trachomatis* therapy.
 - Pursue empiric treatment of sexual partners.

INPATIENT CONSIDERATIONS

Admission Criteria

- Neonates: Hospitalize and obtain appropriate cultures (conjunctivae, blood, CSF, or those from any other site of infection).
- Prepubertal children: safety concerns present or complicated disease
- Sexually active adolescents: PID with inability to tolerate oral antibiotics, complicated disease requiring further monitoring

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Provide risk reduction education.
- Sexual contacts (including mother and her partner[s]) of patients with gonorrhea should be counseled and treated.
- Evaluate for concurrent infection with other sexually transmitted diseases, including syphilis, *C. trachomatis*, *T. vaginalis*, hepatitis B,

and HIV. Patients whose age has progressed beyond the neonatal period should be treated presumptively for *C. trachomatis* infection.

- All cases of gonorrhea must be reported to public health officials.
- Contact isolation precautions are recommended for all hospitalized patients with gonococcal disease in the neonatal and prepubertal age groups; no special policies are recommended for other patients.
- Evaluate prepubertal children for abuse.

ALERT

Pitfalls

- Failure to consider the diagnosis of sexual abuse in a prepubertal child with a gonococcal infection. Cases of transmission via nonsexual contact have been reported (i.e., from freshly infected towels/fomites, childhood sexual play, or by digital transmission from an infected caregiver), but such mode cannot be assumed without first excluding sexual abuse.
- Failure to use culture to diagnose infection in cases of suspected abuse
- Failure to differentiate *N. gonorrhoeae* by culture from other *Neisseria* species, especially in prepubertal children, given concern for sexual abuse
- Failure to consider acute gonococcal perihepatitis/Fitz-Hugh–Curtis syndrome in females with right upper quadrant pain

PROGNOSIS

Prognosis has been improved by treating all forms of infection with a 3rd-generation cephalosporin.

COMPLICATIONS

- Gonococcal infection during pregnancy is associated with spontaneous abortion, preterm labor, and perinatal infant mortality.
- Ophthalmia neonatorum may rapidly progress to corneal ulceration and perforation, with subsequent scarring and blindness.
- PID
 - Endometritis, salpingitis, tuboovarian abscess, and pelvic peritonitis occur as a consequence of untreated vaginal disease.
 - Scarring secondary to salpingitis causes sterility in $\leq 20\%$ of women with a single infection and $\leq 50\%$ of women after 3 episodes of

infection.

- Risk of ectopic pregnancy increases 7-fold after 1 episode of PID.
- In males, rare complications include periurethral abscess, acute prostatitis, seminal vesiculitis, and urethral strictures.
- Disseminated disease
 - Consider evaluation for complement deficiency in those with multiple episodes.
 - In neonates, arthritis is the most frequent systemic manifestation; symptoms develop 1–4 weeks after delivery. Involvement of multiple joints is typical, and most infants do not have ophthalmia neonatorum.
 - In older children and adolescents, septic arthritis (1 joint) and a characteristic poly–arthritis-dermatitis syndrome are possible manifestations.
 - Gonococcal meningitis, endocarditis, and osteomyelitis are rare in children.
- Gonococcal infection can serve as a cofactor in increasing HIV infection and transmission.

CODES

ICD10

- A54.9 Gonococcal infection, unspecified
- P39.8 Other specified infections specific to the perinatal period
- P39.1 Neonatal conjunctivitis and dacryocystitis

FAQ

- Q: What are the advantages of the NAATs for making a diagnosis?
- A: The transcription-mediated amplification (TMA) test of urine samples, approved by the FDA for women, can be used to simultaneously test for *C. trachomatis* and *N. gonorrhoeae*.
- Q: When is this test not approved?
- A: For rectal and pharyngeal swabs and for cases of suspected abuse

GRAFT-VERSUS-HOST DISEASE

Valerie I. Brown

BASICS

DESCRIPTION

Graft-versus-host disease (GVHD) is a multiorgan inflammatory process that develops when immunologically competent T lymphocytes from a histoincompatible donor are infused into an immunocompromised host unable to reject them. Divided into acute and chronic, historically based on time of presentation but best delineated by clinicopathologic findings.

- Acute: develops within 100 days after allogeneic hematopoietic stem cell transplant (HSCT); affects skin, GI tract, and/or liver
- Chronic: develops 100 days after allogeneic HSCT; presents with diverse features resembling autoimmune syndromes
- Chronic subtypes
 - Progressive: extension of acute GVHD
 - Quiescent: after resolution of acute GVHD
 - De novo: no prior acute GVHD

EPIDEMIOLOGY

- Acute GVHD (grades II–IV): 10–80% of patients receiving T-cell–replete HSCT
 - 35–45% for human leukocyte antigen (HLA)–identical related donor bone marrow
 - 60–80% if 1-antigen HLA-mismatched unrelated donor bone marrow or peripheral stem cells
 - 35–65% if 2-antigen HLA-mismatched unrelated umbilical cord blood
- Chronic GVHD: most common cause of late morbidity and mortality of allogeneic HSCT
 - 15–25% if HLA-identical related marrow
 - 40–60% if HLA-matched unrelated marrow
 - 54–70% if HLA-matched unrelated peripheral stem cells
 - 20% if unrelated umbilical cord blood

- Flare-ups triggered by infection (usually viral)

RISK FACTORS

- HLA disparity (both major and minor antigens)
- Older donor or recipient age
- Stem cell source and dose
 - Highest risk: with peripheral stem cells
 - Lowest risk: with umbilical cord blood
- Donor leukocyte infusions
- Reactivation of viruses (e.g., HHV-6, CMV)
- T-cell depletion decreases incidence.
- Acute GVHD-specific
 - Higher intensity conditioning regimen
 - Prior pregnancies in female donors
 - Gender mismatch
- Chronic GVHD specific
 - Severity of acute GVHD
 - Malignancy as indication for transplantation
 - Use of total-body irradiation
 - Type of immunosuppressive prophylaxis

Genetics

- HLA gene complex on chromosome 6; inherited as haplotype
- Full siblings: 25% chance HLA identical
- Minor histocompatibility antigen differences likely account for GVHD in HLA-identical sibling stem cell transplants.

GENERAL PREVENTION

- Transfusion: irradiation of all cellular blood products for patients at risk
- Stem cell transplantation
 - Selection of a histocompatible donor
 - Immunosuppression (gold standard): cyclosporine or tacrolimus with a short course of methotrexate
 - Other options: corticosteroids, sirolimus, mycophenolate mofetil, and low-dose cyclophosphamide
 - Donor T-cell depletion with anti-T-cell antibodies ex vivo in graft

or in vivo in recipient

PATHOPHYSIOLOGY

- Acute GVHD: interaction of donor and host innate and adaptive immune responses
 - Severity related to degree of HLA mismatch
 - 3 phases ending in “cytokine storm”
 - Tissue damage by conditioning regimen
 - Priming and activation of donor T cells
 - Infiltration of activated T cells into skin, GI tract, and liver resulting in apoptosis
- Chronic GVHD: findings similar to autoimmune disorders: donor T cells directed against host antigens, donor T-cell autoreactivity, B-cell dysregulation, regulatory T-cell deficiency; marked collagen deposition in target organs and lack of T-cell infiltration

ETIOLOGY

- Hematopoietic stem cell transplantation
- Transfusion of nonirradiated blood products to immunodeficient hosts: caused by viable donor lymphocytes engrafting in the recipient
- Transfusion of nonirradiated blood from a donor homozygous for 1 of the recipient’s HLA haplotypes (1st- or 2nd-degree relative)
- Intrauterine maternal–fetal transfusions and exchange transfusions in neonates
- Solid organ grafts: contain immunocompetent T cells, into immunosuppressed recipient

DIAGNOSIS

HISTORY

- Acute GVHD
 - Rash: usually 1st manifestation; pruritus or burning sensation can precede rash.
 - Diarrhea, abdominal pain, and intestinal bleeding: unusual to precede skin disease
 - Anorexia, nausea, vomiting, and dyspepsia

- Jaundice (liver involvement)
- Chronic GVHD
 - Dry eyes and/or dry mouth, blurry vision, eye irritation, photophobia, eye pain
 - Difficulty swallowing or retrosternal pain
 - Sensitivity to mint, spicy foods, or tomatoes
 - Weight loss, failure to thrive, anorexia, nausea, vomiting, diarrhea
 - Dyspnea, wheezing, cough
 - Poor wound healing, especially post trauma
 - Joint stiffness, muscle cramps
- Infections: pneumococcal sepsis, *Pneumocystis jiroveci*, fungal infections

PHYSICAL EXAM

- Acute/transfusion-associated GVHD
 - Skin (most common site)
 - Maculopapular rash of palms, soles; can become confluent erythroderma
 - Severe form: bullae formation, to even full-thickness necrosis
 - GI tract: weight loss; profuse, watery, often green, and often bloody diarrhea
 - Liver: jaundice; atypical findings: painful hepatomegaly, ascites, rapid weight gain
- Chronic GVHD
 - Skin (involved in almost every patient)
 - Hyper- or hypopigmentation, xerosis (skin dryness), pruritus, scaling, patchy erythema, poikiloderma, skin atrophy; lichenoid, eczematous, and/or sclerodermatous changes
 - Advanced scleroderma: thickened, tight, and fragile skin
 - Hair: thin, fragile; premature graying
 - Scalp: dry or seborrheic
 - Nails: dystrophic, fragile; entire nail loss
 - Mouth: xerostomia, mucositis, ulcers; whitish, lacy plaques on tongue and buccal surfaces, may be painful; tight oral aperture
 - Esophageal strictures, stenosis, webs
 - Blood: thrombocytopenia, anemia, eosinophilia, autoantibodies,

- hypo- or hypergammaglobulinemia
- Joints: stiffness, contractures, swelling
- Muscles: eosinophilic fasciitis, myositis
- Lung: bronchiolitis obliterans (obstructive), bronchiolitis obliterans organizing pneumonia (restrictive), pleural effusions
- Other: pericardial effusions, pericarditis, cardiomyopathy, nephrotic syndrome, peripheral neuropathy, genital ulceration

DIAGNOSTIC TESTS & INTERPRETATION

Diagnosis is often made on clinical grounds.

Lab

- Complete blood count with differential and Coombs test: autoimmune thrombocytopenia (most common), hemolytic anemia, and neutropenia; eosinophilia, resolves with treatment
- Blood smear: Howell-Jolly bodies due to functional asplenia of chronic GVHD
- Elevated ALT/AST without hyperbilirubinemia
- Vitamin D: often low; risk for osteoporosis
- Urinalysis: may show protein, glucose, blood
- Schirmer test: decreased tear production
- Pulmonary function tests
- Echocardiogram/electrocardiogram
- Fluorescein microscopy: punctate keratopathy

Imaging

- High-resolution chest CT: bronchiolitis obliterans
- Barium swallow: strictures, webs

Diagnostic Procedures/Other

- Endoscopy or colonoscopy with biopsy: apoptosis and loss of villi; GI tract GVHD
- Skin biopsy: localized epidermal atrophy
- Liver biopsy: bile duct damage reminiscent of primary biliary cirrhosis
- Rule out viral/fungal infections
- Analysis of pleural, pericardial fluid

DIFFERENTIAL DIAGNOSIS

- Acute GVHD
 - Skin: drug reaction, chemoradiotherapy, viral exanthema, engraftment syndrome; TEN for grade IV skin GVHD
 - Liver: hepatic veno-occlusive disease, total parenteral nutrition, drug toxicity, bacterial sepsis, or viral infection
 - GI: diarrhea secondary to transplant conditioning regimen, infectious causes (e.g., *Clostridium difficile*, CMV, adenovirus), or opiate withdrawal
- Chronic GVHD
 - Skin: keratosis pilaris, eczema, psoriasis

ALERT

- In chronic GVHD, do not give live vaccines; may lead to symptomatic infection
- Sudden high fevers may indicate bacterial sepsis, may be overwhelming. Chronic GVHD patients often functionally asplenic; have profoundly impaired immune function

TREATMENT

MEDICATION

- Acute GVHD (grades II–IV)
 - 1st line: systemic steroids at 2 mg/kg/24 h for 7–14 days then quick taper; cyclosporine or tacrolimus if not taking as prophylaxis
 - 2nd line: mycophenolate mofetil, sirolimus (rapamycin), antithymocyte globulin, and etanercept (experimental)
 - Infliximab: steroid-refractory GI disease
 - Visceral organ involvement requires urgent start of 2nd-line therapy.
 - For isolated, mild skin GVHD, topical tacrolimus ointment and triamcinolone
- Chronic GVHD
 - Steroids alone or with cyclosporine, sirolimus, tacrolimus, or mycophenolate mofetil
 - Goal: steroids <0.5 mg/kg alternating days; with cyclosporine or

tacrolimus

- Steroid-refractory GVHD
 - Mycophenolate mofetil, sirolimus, pentostatin (investigational)
 - Other options many off-label: antithymocyte globulin; rituximab; low-dose methotrexate in liver GVHD; thalidomide; hydroxychloroquine; imatinib; low-dose cyclophosphamide; etanercept; alefacept; alemtuzumab: high infection risk
- Oral rinses with dexamethasone: oral GVHD
- Ursodeoxycholic acid: hepatic GVHD

ADDITIONAL TREATMENT

General Measures

- Prophylaxis for *P. jiroveci* pneumonia and pneumococcal infection
- Antifungal coverage if on multiple immunosuppressive agents
- Hypogammaglobulinemia: IVIG
- Monitor closely for viral reactivation.
- Skin care: Lubricate dry skin with petroleum jelly. Protect skin from injury. Avoid sunburn.
- Correct electrolyte imbalances for muscular aches and cramps.
- Nutrition consults for malnutrition and wasting.
- If chronic GVHD persists past 2–3 months or prednisone is needed at 1 mg/kg/day, alternative therapy should be used.
- Hospitalization may be required for hydration, nutritional support, IV medications, monitoring, treatment of infections, and other supportive care.

ADDITIONAL THERAPIES

- Extracorporeal photophoresis: very effective for chronic skin GVHD; lower response rate if visceral organs involved
- Psoralen plus ultraviolet A is of some benefit in skin GVHD (lichenoid, not sclerotic).
- Mesenchymal stem cells (experimental)
- Artificial tears for sicca syndrome
- Physical therapy/range-of-motion exercises to prevent contractures
- Inhaled corticosteroids and azithromycin (experimental) for bronchiolitis obliterans

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Steroids: osteoporosis, diabetes
- Calcineurin inhibitors: hypertension, renal dysfunction, hypomagnesemia
- Sirolimus: hyperlipidemia, leukopenia, microangiopathic hemolytic anemia
- Mycophenolate mofetil: GI discomfort, diarrhea, leukopenia

PROGNOSIS

Prognosis of GVHD is based on severity.

- Acute GVHD: graded from I to IV based on organ involvement, percent of body surface area involved (skin), volume of diarrhea (gut), and/or elevation of serum bilirubin (liver). The higher the grade, the lower the long-term survival. Grade I survival is the same as for patients without GVHD; grade II, 60%; grade III, 25%; grade IV, 5–15%
- Acute GVHD: 50–60% of patients respond to corticosteroids plus cyclosporine or tacrolimus.
- Poor prognosis for survival: extensive skin involvement, progressive onset, GI involvement, thrombocytopenia, weight loss, and low Karnofsky performance status (40–60% survival)
- 50% of patients still require therapy 5 years after diagnosis of chronic GVHD.

COMPLICATIONS

- Mortality from GVHD after HSCT is usually related to infection.
- Rarely, patients die of hepatic failure or abdominal catastrophe.
- In transfusion-associated GVHD, death is usually from bone marrow aplasia with destruction of the host's marrow by donor lymphocytes.

- D89.810 Acute graft-versus-host disease
- D89.811 Chronic graft-versus-host disease

FAQ

- Q: Do all patients with acute GVHD get chronic GVHD?
- A: No. ~30% of patients <10 years of age who receive HLA-identical sibling HSCT will get acute GVHD, whereas only 13% will develop chronic GVHD. Chronic GVHD can develop in a patient who did not have acute GVHD; the prognosis is much more favorable than for the progressive form.
- Q: Do all severe chronic GVHD patients die?
- A: No. Occasionally, the GVHD will “burn out.” This is rare, and the process by which it happens is not understood.

GRAVES DISEASE

Adda Grimberg

BASICS

DESCRIPTION

Multisystem autoimmune disorder that presents with the classic triad of hyperthyroidism (goiter), exophthalmos, and dermopathy (rare in children)

EPIDEMIOLOGY

- Female > male (4–5:1)
- 10–15% of all childhood thyroid disorders
- Incidence increases with age, peaking in adolescence and in the 3rd–4th decades.

Genetics

- No simple hereditary pattern (i.e., genetic susceptibility plus environmental factors)
 - Up to 60% of patients have a family history of autoimmune thyroid disease (hyperthyroidism or hypothyroidism).
 - Concordance rates of Graves disease: 17% in monozygotic twins (of note, another 17% had chronic lymphocytic thyroiditis and 10% had other nonthyroid autoimmune conditions), 2% in dizygotic twins, 4% of 1st-degree relatives
- Often associated with HLA-DR3
- Increased incidence in genetic syndromes
 - Down syndrome: presents at a younger age, no female predominance unlike the general population; usually milder course
 - Turner syndrome

PATHOPHYSIOLOGY

- Autoimmune process that includes production of immunoglobulins against antigens in the thyroid, orbital tissue, and dermis
- IgG1 anti-TSH (thyroid-stimulating hormone receptor autoantibody, thyroid-stimulating immunoglobulin [TSI]) activates the TSH receptor, causing constitutive stimulation, leading to increased thyroid follicular

cell production and release of thyroid hormone.

DIAGNOSIS

ALERT

Thyroid storm can constitute an endocrinologic medical emergency.

HISTORY

- Growth acceleration that can be associated with precocious puberty (hyperthyroidism can accelerate the bone age)
- Declining school performance, mind racing, difficulty concentrating; may be mistaken for ADHD
- Symptoms of hyperthyroidism and their duration (if child complains of these symptoms, evaluate for possible hyperthyroidism):
 - Restlessness, emotional lability, nervousness
 - Fine tremor
 - Disturbed sleep pattern and insomnia; may result in daytime fatigue
 - Weight loss despite increased appetite
 - Palpitations or chest pain with minimal exertion or at rest; low exercise tolerance
 - Heat intolerance
 - Increased urination and diarrhea
 - Muscle weakness (proximal)
 - Plummer nails (separation of nail from bed)
 - Menstrual irregularities
- Thyroid gland enlargement: Graves disease can present with goiter. Tenderness suggests infectious cause.
- Exophthalmos (bulging of the eyes), increased staring, change in vision or in facial appearance: Exophthalmos due to retro-orbital immune depositions is a hallmark of Graves disease.
- Familial history: increased incidence of Graves disease in families with thyroid disease

PHYSICAL EXAM

- Accelerated growth or height above expected genetic potential due to bone age advancement

- Symmetrically enlarged, smooth, nontender goiter in >95% of cases
- Auscultate the thyroid gland for bruit while patient holds his or her breath (glandular hyperperfusion is associated with hyperthyroidism).
- Resting tachycardia with widened pulse pressure; hyperdynamic precordium: cardiac effects of excessive thyroid hormone
- Slightly elevated temperature: Thyroid hormone controls basal metabolic rate and upregulates catecholamine-induced thermogenesis.
- Lid lag/stare; exophthalmos and proptosis: Severe ophthalmopathy is rare.
- Fine tremor, especially visible in hands and tongue in ~60% of children with Graves disease
- Proximal muscle weakness is common but seldom severe.
- Exaggerated deep tendon reflexes are variable.
- Skin warmth and moisture: heat intolerance and excessive sweating in >30% of children

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Total or free thyroxine: elevated
- Triiodothyronine assessment by radioimmunoassay: elevated (triiodothyronine radioimmunoassay, as direct measurement of triiodothyronine, and not triiodothyronine resin uptake, which indirectly evaluates thyroid hormone-binding capacity)
- TSH: significantly suppressed or undetectable
- TSI titer: positive in 90% of children
- False-positive test results: Elevated total thyroxine levels can also be caused by increased protein binding and so are not necessarily diagnostic for hyperthyroidism: Increased estrogen states (e.g., pregnancy and oral contraceptive use) lead to augmented hepatic thyroid-binding globulin (TBG) production. Familial dysalbuminemic hyperthyroxinemia: Mutation affecting thyroxine binding affinity leads to increased protein-bound pool.

Imaging

I^{123} scan: not needed to diagnose Graves disease. If done, shows diffuse increased uptake at 6 and 24 hours. If palpation suggests nodule, scan may

reveal a hot nodule within a suppressed gland.

DIFFERENTIAL DIAGNOSIS

- Infectious
 - Acute suppurative thyroiditis (i.e., transient thyroxine elevations)
 - Subacute thyroiditis after viral illness (also transient)
- Environmental
 - Thyroid hormone ingestion
 - Ingestion of excess iodine (escape from Wolff-Chaikoff block due to impaired autoregulation)
- Tumors (all rare in childhood)
 - TSH-producing pituitary adenoma
 - Thyroid adenoma/hyperfunctioning autonomous thyroid nodule (most pediatric patients are euthyroid; incidence of nodule hyperfunctioning rises with patient age)
 - Thyroid carcinoma (rarely presents with hyperthyroidism)
- Congenital
 - Neonatal Graves disease (transplacental antibody transfer from mothers with Graves disease or chronic thyroiditis)
- Genetic and developmental
 - Pituitary resistance to thyroid hormones (dominant negative thyroid-receptor gene mutations causing loss of pituitary negative feedback loop and inappropriately elevated levels of TSH; can be isolated, with clinical hyperthyroidism, or associated with peripheral thyroid resistance and clinical euthyroidism or hypothyroidism)
 - TSH-receptor gene mutations (rare; germline activating TSH-receptor mutations cause autosomal dominant nonautoimmune hereditary hyperthyroidism)
 - McCune-Albright syndrome: Activating G-protein mutation can lead to indolent hyperthyroidism in addition to the classic features of this syndrome.
 - Ectopic thyroid tissue
- Other causes of hyperthyroidism: See “[Goiter](#).”

TREATMENT

MEDICATION

ALERT

- Antihistamines and cold medications may worsen sympathetic nervous system symptoms.
- Stopping antithyroid drugs because of low thyroxine values when TSH is still suppressed, reflecting continued TSI activity, will likely result in relapse. Antithyroid medication dosage should be decreased, or L-thyroxine should be added.
- FDA issued a black box warning (June 4, 2009) against propylthiouracil (PTU) use in treating Graves disease owing to risk of severe liver injury including life-threatening acute liver failure.

First Line

- Drug therapy is the 1st-line choice in children. Antithyroid medications (thiourea derivatives): 65–95% effective: Medications block thyroid hormone synthesis but not the release of existing hormone.
 - Methimazole
 - PTU: Note black box warning. Limited, short-term use of PTU may be considered for patients requiring antithyroid medication (neither I¹³¹ ablation nor prompt surgery are options) or after a toxic reaction to methimazole. PTU is preferred during 1st trimester of pregnancy (teratogenic effects of methimazole).
- Propranolol and atenolol block adrenergic symptoms; should be used with antithyroid medications at start of treatment and whenever cardiac symptoms are prominent.
- Duration of treatment:
 - Antithyroid medications can be tapered and potentially discontinued after 2–3 years of therapy, depending on the patient's course.
 - β -Blockers: Continue until thyroxine and triiodothyronine are under control (~6 weeks).
 - If remission not achieved in 1–2 years, ablation with I¹³¹ or total or subtotal thyroidectomy may be considered.

SURGERY/OTHER PROCEDURES

Radiotherapy: I¹³¹ ablation therapy

- 90–100% effective; safe and definitive, with predictable outcome

- Results in permanent hypothyroidism requiring lifelong thyroxine replacement
- Adequate dose should be used ($>150 \mu\text{Ci/g}$ of thyroid tissue) to prevent residual tissue that would be at risk of developing thyroid cancer.
- Current recommendations advise avoiding I^{131} ablation in children <5 years of age owing to theoretical concerns relating radiation exposure and cancer risks.
- Radioiodine ablation may exacerbate ophthalmopathy, but this effect can be prevented with concomitant glucocorticoid administration.

Total or near-total thyroidectomy

- Effective, rapid, and definitive (vs. 30% recurrence rate for subtotal thyroidectomy)
- Lifelong thyroxine replacement needed
- Surgical complication rates higher for children age 0–6 years and for children treated in lower volume centers

ISSUES FOR REFERRAL

Treatment for severe ophthalmopathy: must refer patient to an ophthalmologist:

- 3 options: high-dose glucocorticoids, orbital radiotherapy, or surgical orbital decompression
- Rehabilitative surgery for eye muscles or eyelids is often needed after the ophthalmopathy has been treated.

ONGOING CARE

PROGNOSIS

- Good, if adherent with treatment
- Mortality in severe thyrotoxicosis is possible from cardiac arrhythmias or cardiac failure.
- Spontaneous remission occurs in 20–30% of children after 1–2 years but can relapse in 30%. Large thyroid gland size (by ultrasound) and high titers of TSH-receptor antibody (TRAb) predict lower chance of remission.
- Neonatal hyperthyroidism remits by 48 weeks and more commonly by

20 weeks.

- Propranolol or atenolol should result in rapid relief of symptoms of sympathetic hyperactivity.
- 4–6 weeks of medical treatment should result in normalization of levels of thyroxine and triiodothyronine, although TSH levels may remain suppressed owing to persistent underlying activity of the thyroid-stimulating Ig.
- Persistent suppression of TSH is associated with pretreatment presence of thyrotropin-binding inhibitory Ig, severity of thyrotoxicosis, and time to recovery of thyroid hormone levels.
- Duration and type of treatment depend on patient age and remission and relapse pattern.

COMPLICATIONS

- Endocrine disturbances: delayed/early puberty, menstrual irregularity, hypercalcemia
- Ophthalmologic: 3–5% of patients develop severe ophthalmopathy, including eye muscle dysfunction and optic neuropathy, requiring specific treatment by an ophthalmologist. Pediatric ophthalmologic findings (lid lag, soft tissue involvement, and proptosis) are more common but usually less severe than in adults.
- Bone: low bone mineral density for age/sex common at diagnosis due to high bone turnover. Corrects with Graves disease therapy and return to euthyroid status.
- Fetal/neonatal: intrauterine growth retardation (IUGR), nonimmune hydrops fetalis, craniosynostosis, intrauterine death, goiter that complicates labor and can cause life-threatening airway obstruction at delivery, hyperkinesis, failure to thrive, diarrhea, vomiting, cardiac failure and arrhythmias, systemic and pulmonary hypertension, hepatosplenomegaly, jaundice, hyperviscosity syndrome, thrombocytopenia
- Medication side effects: agranulocytosis (in 0.2–0.5% of patients), rash (most common side effect), gastrointestinal upset, headache, transient transaminitis/hepatitis and life-threatening liver failure with PTU, vasculitis with PTU (frequently associated with perinuclear antineutrophil cytoplasmic antibody [p-ANCA] titers)

CODES

ICD10

- E05.00 Thyrotoxicosis w diffuse goiter w/o thyrotoxic crisis
- E05.01 Thyrotoxicosis w diffuse goiter w thyrotoxic crisis or storm
- P72.1 Transitory neonatal hyperthyroidism

FAQ

- Q: Does Graves disease lead to thyroid cancer?
- A: No, although controversy surrounds the role of TSH and the closely related TSH-receptor antibodies of Graves disease in thyroid cancer's incidence and aggressiveness. There is an increased incidence of benign thyroid adenoma from 0.6–1.9% after therapy involving I¹³¹ ablation.
- Q: Does hyperthyroidism affect long-term growth or final adult height?
- A: No. Hyperthyroidism can cause tall stature and acceleration of skeletal maturity but does not typically affect final adult height.
- Q: Should WBC counts be monitored routinely while patients are on antithyroid medications?
- A: No. Routine monitoring is not cost-effective because agranulocytosis is rare and sudden in onset. WBC counts should be checked when a patient on antithyroid medication develops fever.
- Q: Will the ophthalmopathy correct with antithyroid treatment?
- A: Not necessarily. It may require specific intervention by an ophthalmologist.
- Q: Can mothers breastfeed while they are being treated for Graves disease?
- A: Yes. PTU has a lower milk/serum concentration ratio than methimazole (0:1 and 1:0, respectively). In 1 study, 3 of 11 infants exclusively breastfed by women on 300–750 mg daily PTU had high levels of TSH; of these 3, 1 was just above the normal range and the other 2 completely corrected while the mother was still being medicated.

GROWTH HORMONE DEFICIENCY

Paul Hofman

BASICS

DESCRIPTION

- Growth hormone deficiency (GHD) is a rare cause of growth failure due to a lack of growth hormone action caused by a defect in GH synthesis (insufficient hormone), release, or signaling (decreased responsiveness to normal or high levels of hormone).
- GHD can be associated with other pituitary hormone deficiencies.

EPIDEMIOLOGY

- Prevalence in the United States is approximately 1:4,000.
- Males are more commonly diagnosed than females.
- 2 peak ages of diagnosis:
 - Infancy (<1 year of age) usually because of associated hypoglycemia
 - Childhood at >4 years of age, usually because of poor linear growth

Genetics

- Spontaneous
- Autosomal recessive (AR)
- Autosomal dominant (AD)
- X-linked forms

PATHOPHYSIOLOGY

GH has a number of anabolic actions, but its principal one is increasing linear growth. This occurs predominantly due to direct GH action on the growth plate, although there are also some indirect GH actions on growth via stimulation of secretion of hepatic and growth plate insulin-like growth factor 1 (IGF-1).

ETIOLOGY

- Idiopathic: Although idiopathic GH deficiency is a relatively common diagnosis, it is a diagnosis of exclusion. Sometimes misdiagnosed in

normally growing children

- Congenital
 - Congenital malformation of the pituitary can be associated with the following:
 - Holoprosencephaly
 - Septo-optic dysplasia
 - Midline defects: cleft lip, cleft palate, central maxillary incisor
 - Ectopic posterior pituitary, small anterior pituitary, and/or hypoplastic infundibulum
 - Genetic mutations
 - Familial multiple anterior pituitary hormone deficiency (Pit-1, Prop-1)
 - GH gene mutations (Type Ia, Ib, II, III)
 - GH insensitivity
 - Laron dwarfism, AR disorder classically caused by GH receptor mutations, presents with the phenotype of severe GH deficiency (severe short stature, hypoplastic nasal bridge, sparse hair, high-pitched voice, and delayed bone age).
 - Postreceptor and second messenger defects such as IGF-1 gene deletion, IGF-1 receptor mutation, STAT5b mutation
- Acquired idiopathic
 - CNS tumors: craniopharyngioma, germinoma, medulloblastoma, glioma, pinealoma
 - Pituitary or hypothalamic irradiation
 - Trauma: child abuse or closed head injury
 - Surgical resection/damage of the pituitary gland/stalk
 - Birth injury/perinatal insult
 - Infection: viral encephalitis, bacterial or fungal infection, tuberculosis
 - Vascular: pituitary infarction or aneurysm
 - Infiltration affecting pituitary gland or sella turcica: histiocytosis, sarcoidosis
 - Hypophysitis
 - Psychosocial deprivation

DIAGNOSIS

HISTORY

- Family history
 - Parental heights
 - Family history of short stature (women <4 feet 11 inches [150 cm] or men <5 feet 4 inches [163 cm]) indicates genetic shortness.
 - Family history of delayed puberty “late bloomer” (growth after high school, menarche at ≥ 14 years): Constitutional delay of growth and development tends to occur in family members.
- Birth history
 - Babies born small for gestational age. 10–15% will not show “catch-up growth,” but are not typically GHD.
 - Babies with congenital GHD may not be short at birth but will grow poorly over the next few years.
- Medication history: Look for overuse of corticosteroids, either systemic or inhaled. Ask about nonprescription drugs and health food store supplements.
- Past history of chronic illness (e.g., cyanotic cardiac disease, renal tubular acidosis, asthma, celiac disease, chronic anemia, etc.)
- Psychosocial history: Poor growth occurring at the time of a major stressful event may be due to psychosocial deprivation.

PHYSICAL EXAM

- Measure accurate weight and height with wall-mounted stadiometer. Perform a sitting height and arm span if possible.
- Neurologic examination, including visual fields and funduscopic examination for evaluation of brain tumors
- Assess for signs of Turner syndrome:
 - Cubitus valgus, low posterior hair line, abnormal dentition, abnormal ears, and/or shortened 4th metacarpals in girls suggest Turner syndrome.
 - Turner syndrome is the most common pathologic cause of short stature in girls, and short stature may be the only manifestation.
- Midline facial defects such as submucous cleft, cleft lip, and palate are

associated with hypopituitarism.

- Tanner stage
 - Micropenis is associated with congenital hypopituitarism.
 - Delayed puberty suggests constitutional delay but may also be indicative of panhypopituitarism.
- Cherubic facies with frontal bossing, thin hair, high-pitched voice, and relative truncal obesity with adiposity are seen in GHD.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC with differential: anemia, malignancy, cell-based immunodeficiency, and inflammatory processes
- Sedimentation rate and CRP: inflammatory processes such as Crohn disease
- Hepatic and renal function tests: hepatic or renal disease
- Celiac screen
- Urinalysis including pH
- Thyroid function tests (thyroid-stimulating hormone [TSH] and either a T₄ or a free T₄)
- Chromosomes in females (to exclude Turner syndrome)
- IGF-1 and IGF-binding protein-3 (IGFBP-3) production is regulated directly by GH. However, there is a poor correlation with GH deficiency. IGF-1 values are low early in life and in conditions such as hypothyroidism, diabetes, renal failure, and undernutrition.
- GH-provocative testing (performed by an endocrinologist)
 - A random GH level is of little value to diagnose GHD beyond the neonatal period.
 - After neonatal period, GH is mostly secreted only in brief pulses during deep sleep (at night). However, false-positive results are common.
 - NOTE: Using two GH provocation tests and strict GH cutoffs (<5.0 ng/mL), approximately 5% of normally growing children would be diagnosed as GH-deficient, whereas fully 20% of healthy GH-replete children can fail any one provocative test.

Imaging

- Bone age: radiography of left hand and wrist to assess skeletal maturation
- If provocative testing shows GH deficiency, obtain MRI with contrast of the pituitary and hypothalamus to look for central nervous system tumor or anomaly of the hypothalamus/pituitary.

DIFFERENTIAL DIAGNOSIS

- Abnormal body proportions:
 - Skeletal dysplasia (e.g., hypochondroplasia, achondroplasia)
- Normal skeletal proportions with prenatal growth failure (birth weight <10th percentile):
 - Small for gestational age
 - Congenital infection
 - Maternal drug use (tobacco, alcohol etc.)
 - Chromosomal short stature (Turner, Down syndrome, etc.)
 - Syndromes (Noonan, Prader Willi, Russell Silver syndrome, etc.)
- Normal skeletal proportions with postnatal growth failure (birth weight >10th percentile):
 - Constitutional delay of growth and adolescence
 - Familial short stature
 - Malnutrition
 - Renal failure
 - Inflammatory bowel disease
 - Celiac disease
 - Congenital heart disease
 - Hypothyroidism
 - Hypercortisolism
 - Metabolic disorders
 - Rickets
 - Psychosocial deprivation

ALERT

- Children with constitutional growth delay or pubertal delay show poor growth when peers are going through their pubertal growth spurts, and have a delayed bone age, mimicking GH deficiency.
- GH-provocative testing may yield false-positive or false-negative

results:

- 20% of normal children will fail at least 1 GH-provocative test.
- Obese but otherwise normal children are more likely to fail GH-provocative testing.
- When GH testing is done in a child at high risk for GHD or if the growth pattern is concerning, the predictive value of GH testing is markedly improved. Assessing growth velocity over a 6–12-month period is very useful.
- Malnutrition can cause low IGF-1.
- Psychosocial deprivation mimics GHD. Such deprived patients may have low growth factors and respond poorly to GH-provocative testing.

TREATMENT

MEDICATION

- Recombinant human growth hormone (rhGH) was approved by FDA for use in 1985 by SQ injection daily.
- Duration of therapy (in children and adolescents)
 - Until growth velocity drops to 2.5 cm/year
 - When puberty is complete
 - GH-deficient adults may benefit from lifelong rhGH therapy due to its effects on body composition, lipids, bone density, and general sense of well-being.
 - Before adult GH is initiated, adult patients should undergo repeat GH-provocative testing in all instances, as GH testing can normalize even with known central structural lesions.

ALERT

- rhGH is associated with idiopathic intracranial hypertension (pseudotumor cerebri). This side effect is usually transient and often reverses without cessation of therapy.
- rhGH is usually not given in cancer patients until 1 year has elapsed without recurrence.
- Carefully evaluate any limp or hip or knee pain in patients on rhGH therapy because these symptoms may be associated with slipped

capital femoral epiphysis (SCFE); SCFE necessitates orthopedic consultation.

ONGOING CARE

FOLLOW-UP-RECOMMENDATIONS

Every 3 months by an endocrinologist

- When to expect improvement:
 - Immediate effect on hypoglycemia
 - Growth velocity improves within 3–6 months
- Signs to watch for:
 - Pseudotumor cerebri (headache, vision problems)
 - SCFE
 - Scoliosis
 - In adults, edema and carpal tunnel syndrome, but uncommon in children
 - The risk of malignancy is generally NOT increased in children receiving GH therapy, although there may be a small increased risk of a secondary malignancy in those already who have previously survived a malignancy.

PROGNOSIS

Response to GH therapy is excellent in truly GH-deficient patients. Those who are not GH-deficient have a variable but generally positive growth response. The main cause of poor growth in all children receiving GH therapy, however, is noncompliance. In one national study, 66% of patients missed at least one injection per week, and this affected growth.

COMPLICATIONS

- Short stature
- Lack of self-esteem because of short stature
- Delay in pubertal changes (sexual characteristics and growth spurt) due to delayed bone age
- Hypoglycemia (in the newborn period)
- Osteopenia

CODES

ICD10

- E23.0 Hypopituitarism
- Q89.2 Congenital malformations of other endocrine glands

FAQ

- Q: Does GH improve the body composition in patients with GH deficiency?
- A: Not only is growth impressive in these patients, but there is a normalization of body composition with a loss of fat and increased muscle mass due to the lipolytic and anabolic effects of growth hormone therapy.
- Q: Will GH use cause long-term safety issues?
- A: Although a study from France suggested increased long-term mortality, several similar studies have refuted this observation. Currently, there is no credible evidence suggesting there are long-term safety issues with GH treatment.

GUILLAIN-BARRÉ SYNDROME

Jennifer A. Markowitz

BASICS

DESCRIPTION

Guillain-Barré syndrome (GBS) is an acute monophasic inflammatory disorder of the peripheral nervous system. It causes progressive weakness in the limbs, face, and respiratory muscles. Autonomic and sensory disturbances, including pain, are present. Neurologic deficits peak by 4 weeks or sooner. Various forms include the most common acquired inflammatory demyelinating polyradiculoneuropathy (AIDP), followed by acute motor axonal neuropathy (AMAN), Miller Fisher syndrome, and others.

EPIDEMIOLOGY

Incidence

Overall yearly incidence rate of 0.6–1.9 cases per 100,000. Of 95 reported pediatric GBS patients in one study, 45 were aged 1–5 years, 36 were aged 6–10 years, and 14 were aged 11–15 years. Another found that 67% of pediatric patients had AIDP; 7%, AMAN; and 7%, Miller Fisher syndrome.

RISK FACTORS

Genetics

Particular subtypes of GBS are more common among certain human leukocyte antigen (HLA) types. No data indicate an increase in GBS among 1st-order relatives.

PATHOPHYSIOLOGY

Inflammatory cell-mediated and humoral-mediated immune mechanisms play a role in segmental demyelination on nerve biopsy; lymphocytes and macrophages participate in myelin destruction. Axonal variants of GBS feature axonal degeneration without demyelination. Circulating antiganglioside antibodies (e.g., GM1, GM2, GQ1B) found in particular

subtypes suggest a molecular mimicry mechanism stimulated by infection. Some variants (e.g., Bickerstaff encephalitis) involve central and peripheral demyelination.

ETIOLOGY

- Follows viral infection in >50% of cases; cytomegalovirus, Epstein-Barr virus, varicella-zoster virus, acute HIV infection, H1N1, others
- Also associated with bacterial infection (especially *Campylobacter jejuni*), surgery, and vaccination
- Tetanus toxoid is the only vaccination in common use with a clear link to GBS. Often, no precipitating event can be identified.

COMMONLY ASSOCIATED CONDITIONS

- GBS is seen in a higher than expected rate in patients with sarcoidosis, systemic lupus erythematosus, lymphoma, HIV infection, Lyme disease, and solid tumors.
- Muscle atrophy, joint contractures, pressure ulcers, chronic pain, hypertension, voiding difficulty

DIAGNOSIS

HISTORY

- GBS has a variety of clinical presentations so that index of suspicion is critical. Typical features are progressive motor weakness and areflexia, often following distal sensory changes. Common presentations include decreased ambulation (or crawling in toddlers), unsteady gait (which may be due to sensory ataxia), facial weakness, leg or back pain, or sensory changes in the extremities.
- After respiratory status has been stabilized, address autonomic dysfunction and pain. Close monitoring is required for dysautonomic symptoms: arrhythmias, BP lability/orthostasis, ileus, urinary retention.
- Most patients first note leg weakness or gait instability that progresses over days to weeks. 60% are unable to walk at peak of symptoms.
- Paresthesias and pain typically occur in a stocking/glove distribution frequently early in the course.
- 2/3 of patients will report symptoms of an infection 2–3 weeks earlier.

Consider direct infection (e.g., polio, West Nile virus) if fever is present at symptom onset.

- Weakness may lead to respiratory paralysis in up to 20% of children with GBS.

PHYSICAL EXAM

- Weakness and sensory changes, classically symmetric with distal greater than proximal involvement
- A proximal predominance of symptoms does not preclude the diagnosis (radicular involvement).
 - Deep tendon reflexes are usually lost within 1 week, although retention of reflexes has been reported.
- Respiratory difficulty: impaired upper airway or restrictive/neurogenic, with decreased vital capacity and maximum inspiratory (PiMax) and expiratory (PeMax) pressures
 - Respiratory failure leads to intubation in up to 20% of patients. Bulbar weakness and poor airway protection can also necessitate intubation. Impending respiratory failure can often be unpredictable, and blood gas determination is not a useful indicator of neuromuscular respiratory failure until intubation is imminent. If close monitoring of vital capacity, inspiratory, or expiratory pressures suggests >30% decline in 24 hours, monitor patient in ICU.
- Bilateral facial weakness occurs in $\leq 50\%$ of cases.
- Ophthalmoplegia, ataxia, and areflexia in Miller Fisher variant
- Neonates and infants may (rarely) present as floppy infants.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- In atypical cases, consider heavy metal screen, HIV titer, Lyme titer, porphyria screen, acetylcholine receptor antibodies (myasthenia), tick paralysis, and conversion disorder.
 - See “[Differential Diagnosis](#).”
- IgA level should be considered if the child has a history of frequent pulmonary infections: IgA deficiency could contraindicate intravenous immunoglobulin (IVIG) therapy (risk of anaphylaxis depending on

how IVIG is prepared).

Imaging

MRI of the spine (with gadolinium enhancement). Consider MRI for spinal cord compression syndrome in a child presenting with paraparesis. Spinal nerve root enhancement on MRI can support the diagnosis of GBS.

Diagnostic Procedures/Other

- Electrodiagnosis
 - Nerve conduction studies (NCS) and electromyography (EMG) can confirm diagnosis of GBS and are helpful when clinical or CSF findings are ambiguous. NCS and EMG are abnormal in 50% of patients in the first 2 weeks and in 85% of patients afterward.
 - Initially, needle EMG may be normal; consider serial studies if initially nondiagnostic, high clinical suspicion.
- Lumbar puncture: elevated levels of CSF protein after the 1st week of symptoms; classically an albuminocytologic dissociation with normal cell count. Minimal pleocytosis (<20 leukocytes/mm³), largely mononuclear leukocytes, may occur.

DIFFERENTIAL DIAGNOSIS

- Myasthenia gravis
- Botulism
- Intoxication (e.g., heavy metals, organophosphates)
- Myopathy/myositis
- Poliomyelitis and other acute (i.e., viral) motor neuron diseases
- Acute cerebellar ataxia (sometimes associated with neuroblastoma)
- Transverse myelitis
- Chronic inflammatory demyelinating polyneuropathy (CIDP)
- Vasculitic neuropathy
- Diphtheritic neuropathy (rare)
- Porphyric neuropathy
- Tick paralysis
- Locked-in state
- Conversion, psychogenic weakness, astasia/abasia

ALERT

- Initially, gait instability may mistakenly be interpreted as having a

psychogenic source.

- Reflexes may be preserved in early stages of illness.
- Proximal symptoms may predominate early on.
- Check for reflexes in patients with bilateral Bell palsy. Close observation for further development of symptoms or signs of GBS.

TREATMENT

ALERT

- Respiratory failure may occur quickly and is of a neuromuscular, rather than obstructive, nature (i.e., work of breathing may not be increased).
- Treat hypertension cautiously; catastrophic refractory hypotension may ensue.

A combination of supportive therapy and immunotherapy is the mainstay of treatment for patients with GBS.

- Regular monitoring of vital capacity; strongly consider intubation if vital capacity reaches <50% of normal.
- IVIG and plasmapheresis have equivalent efficacy as 1st-line immunotherapy. Combination of the 2 therapies has not proven more effective than monotherapy alone. Complications and discontinuation of therapy are less common with IVIG.
- Pediatric studies have shown IVIG and plasmapheresis to be well tolerated and efficacious.
- IVIG at 0.4 g/kg (body weight) for 5 consecutive days and initiated in ambulatory patients within 2–4 weeks of symptom onset. Alternatively, dosages of 1 g/kg for 2 consecutive days or 2 g/kg as a single dose may be used.
- Plasmapheresis may be performed peripherally in children big enough for large-bore IVs but requires placement of a central catheter in others. Total plasma exchange volume of 200–250 mL/kg divided in 3–5 treatments over 7–14 days. Therapy initiation is recommended within 4 weeks of symptom onset for patients who cannot walk and 2 weeks for patients who can.
- Corticosteroids have not been shown to be helpful and are not

recommended.

- Pain from nerve root inflammation is common in GBS and should be treated aggressively. Agents such as gabapentin can be useful.

ADDITIONAL THERAPIES

Physical therapy: Avoid contractures with lower extremity splinting and early passive range of motion. Aggressive physical and occupational therapy are essential for good outcomes.

INPATIENT CONSIDERATIONS

Initial stabilization

Key elements center around respiratory management and deciding on hospitalization to monitor/treat progressive symptoms including heart block, hypotension, urinary retention, and neuropathic pain.

Admission Criteria

Admit patients with symptoms progressing over hours to days, with any respiratory or bulbar complaints, or who are nonambulatory.

Nursing

Particular attention to preventing skin breakdown, contractures, venous thrombosis, and secondary compressive neuropathies

Discharge Criteria

- Completion of immunotherapy
- Stabilization of symptoms
- Severity of bulbar, respiratory, and autonomic involvement dictates duration of hospital stay. Consider intensive inpatient rehabilitation.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Improvement typically begins 2–3 weeks after onset of symptoms up to 2 months in some patients.
- Improvement continues for up to 2 years.

PATIENT EDUCATION

Parent Internet information: Guillain–Barré Syndrome GBS/CIDP

PROGNOSIS

- Most children recover, although 25% may have some residual symptoms; ultimate functional recovery depends on the degree of axonal injury. Follow-up electrodiagnostic studies can be helpful in some cases.
- Early prognosticators include the severity of weakness at the disease nadir and fulminant onset.
- Overall prognosis in children is better than in adults.

COMPLICATIONS

- Complications include respiratory failure, BP dysregulation (hypotension and/or hypertension), urinary retention, aspiration, pain syndromes, deep venous thrombosis, and infection.
- Death from early respiratory failure, autonomic instability, or other complications occurs in 3–6%.

G61.0 Guillain-Barre syndrome

FAQ

- Q: Is GBS contagious?
- A: No.
- Q: Will I get GBS again?
- A: Acute relapses occur in 1–5% of patients in large series. Treatment-related fluctuations (worsening after completion of immunotherapy) can also occur in CIDP and can be indistinguishable from GBS initially.
- Q: Do all cases require hospitalization and immunomodulatory treatment?
- A: Some youngsters with mild, nondisabling symptoms may be observed as outpatients ($\leq 10\%$).

GYNECOMASTIA

Chirag R. Kapadia • Zoe M. Gonzalez-Garcia

BASICS

DESCRIPTION

Visible or palpable proliferation of unilateral or bilateral breast glandular tissue in a male

EPIDEMIOLOGY

- 2 age distribution peaks: neonatal, pubertal
- Neonatal gynecomastia occurs in 60–90% of all newborns.
- Peak incidence for pubertal gynecomastia in males is 14 years of age (range: 10–16 years). Onset usually at 5–10-mL testicular size and pubic hair Tanner III or IV.
- ~40% of pubertal boys develop transient gynecomastia (measuring ≥ 0.5 cm). This percentage varies greatly in studies, perhaps due to examination technique.

RISK FACTORS

Any state that leads to an increase in the net effect of estrogen relative to androgens on breast glandular tissue, such as the following:

- Increased endogenous estrogen
- Increased exogenous estrogen or estrogen-like compounds in commercial products
- Increased sensitivity of breast tissue to estrogen action
- Decreased androgen concentrations
- Androgen receptor defects
- Pharmacologic or commercial product interference with androgen receptors
- Increased aromatase action. Aromatase converts androgens to estrogens. This can be intrinsic as in aromatase excess syndrome or as a result of tumors or hyperthyroidism.
- Elevated leptin concentrations, which may increase aromatase enzyme activity, stimulate growth of mammary cells or increase breast receptor

sensitivity to estrogens.

- High serum gonadotropin concentrations altering sex steroid production ratios
- Increased sex hormone–binding globulin, which reduces free testosterone levels
- Hyperthyroidism, which increases aromatization of androgens to estrogens
- Hyperprolactinemia interfering with gonadotropin production, thus altering sex steroid production
- Obesity: may increase leptin levels and may increase aromatization. Obesity correlates with true gynecomastia in some studies only. Other studies find obesity correlates with pseudogynecomastia but not true ductal breast tissue development.

ETIOLOGY

- Physiologic
 - Neonatal: Transient palpable breast tissue develops in newborns, owing to elevated estrogen levels in the fetoplacental unit. Resolves as estrogen levels decline
 - Pubertal: benign transient gynecomastia occurring in otherwise healthy males. In this setting, breast tissue measuring <5 cm in diameter has high likelihood of spontaneous regression.
 - Involutional: Breast enlargement occurs in elderly men.
 - Physiologic gynecomastia usually bilateral
- Pathologic
 - Drug-induced
 - Hormones: estrogen, androgens, gonadotropins, growth hormone, antiandrogens, commercial products containing estrogenic or antiandrogenic compounds
 - Anti-infective agents: Can cause gynecomastia through antiandrogenic properties. Ethionamide, isoniazid, ketoconazole, metronidazole, antiretrovirals
 - Antiulcer drugs: usually cause gynecomastia through antiandrogenic properties. Cimetidine, ranitidine, omeprazole
 - Chemotherapeutic agents: usually cause gynecomastia by causing hypogonadism. Alkylating agents, methotrexate, vinca alkaloids

- Cardiovascular agents: spironolactone—androgen receptor blocker; unknown mechanism of action: amiodarone, captopril, digitoxin, diltiazem, enalapril, methyldopa, nifedipine, reserpine, verapamil
 - Psychotropic agents: may act by increasing prolactin levels or decreasing androgen levels: diazepam, risperidone, haloperidol, phenothiazines, antidepressants
 - Drugs of abuse: alcohol, heroin, amphetamines, marijuana, methadone
 - Miscellaneous: metoclopramide, phenytoin, penicillamine, theophylline, gabapentin, clonidine, pregabalin
- Hypogonadism
- Infectious: breast abscess
- Tumors: testicular (including Sertoli cell and germ cell), adrenal, ectopic tumors that produce human chorionic gonadotropin
- Chronic disease: renal failure, liver cirrhosis, malnutrition with refeeding, HIV infection
- Congenital disorders causing gonadal hypofunction, androgen receptor issues, or increased aromatization: Klinefelter syndrome, vanishing testes syndrome, androgen resistance syndromes, true hermaphroditism, excessive peripheral tissue aromatase
- Acquired testicular failure (viral, torsion, other)
- Late-onset congenital adrenal hyperplasia—elevated androgens converted to estrogen
- Spinal cord injury leading to testicular failure over the long term
- Neoplasms: breast carcinoma, neurofibroma, lymphangioma, lipoma, neuroblastoma metastasis
- Trauma: hematoma
- Miscellaneous masses: dermoid cyst

DIAGNOSIS

ALERT

- Do not mistake pseudogynecomastia (i.e., fatty enlargement of the breasts) for true gynecomastia.

- Do not overlook drug-related causes. Drug-related gynecomastia is usually reversible if diagnosed during year of onset.

HISTORY

- Family history: 1/2 of adolescents with gynecomastia have positive family history.
- Time of onset relative to puberty: Onset usually at testicular size 5–10 mL and Tanner stage III or IV pubic hair.
- Prepubertal more concerning than pubertal.
- Unilateral more concerning than bilateral.
- Rate of progression
 - Rapidly enlarging, painful gynecomastia with acute onset is of more concern than long-standing enlargement.
- Drug exposures, including alcohol, marijuana, and heroin, along with exposure to exogenous estrogen and commercial products containing estrogens, lavender, tea tree oil, phthalates, ginseng, and others
- Symptoms suggestive of hyperthyroidism
- Symptoms suggestive of liver disease, such as cirrhosis
- Symptoms suggestive of renal failure
- Symptoms suggestive of neoplastic disease
- Symptoms suggestive of hypogonadism, such as decreased libido, erectile dysfunction, or infertility, may indicate an abnormal estrogen-to-androgen ratio.

PHYSICAL EXAM

- Assess for malnourishment: may result in hepatic dysfunction causing higher estrogen-to-androgen ratio
- Perform a complete breast exam:
 - With patient supine, grasp breast between thumb and forefinger and move digits toward the nipple: Look for a firm, rubbery, mobile, discoid mound of glandular tissue arising concentrically below the nipple and areola. Measure diameter of the disc. Asymmetry and tenderness are common.
 - Check for galactorrhea, which is a sign of drug ingestion or hyperprolactinemia.
 - Masses not concentric around the areola, that are hard, firm, fixed,

that are unilateral, or have any skin dimpling, nipple retraction, nipple bleeding, or discharge, are concerning for carcinoma. This is very rare in male adolescents.

- Check for pseudogynecomastia: (fatty enlargement): If present, no glandular disc will be palpable under areola.
- If disc diameter is >5 cm, regression is very unlikely.
- Thyroid exam: Goiter may indicate hypothyroidism.
- Testicular exam: Consider testicular tumors with masses or significant asymmetry of testes. Consider gonadal failure for small, firm testes. Gynecomastia more likely to be pathologic if testes <5 mL (in this case, not defined as pubertal gynecomastia).

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Benign presentations do not need extensive workup. Neonatal gynecomastia can be monitored without workup for regression by 1 year of age. Bilateral pubertal gynecomastia arising after pubertal onset, <5 cm in diameter can be monitored as well for further growth.
- In other cases, direct workup to suspected causes based on history and exam:
 - LH for pituitary function
 - FSH to rule out testicular failure
 - Prolactin for hyperprolactinemia
 - TSH for hyperthyroidism
 - Testosterone for gonadal function
 - Estrogen for aromatization excess, estrogen excess, or estrogen-secreting tumors (Although in some cases, local aromatase activity can cause gynecomastia without high circulating estrogen.)
 - DHEA-S for adrenal tumors
 - hCG for germ cell tumors (Note that this specific lab is to be ordered, not a qualitative pregnancy test.)
 - Karyotype to rule out Klinefelter syndrome (only indicated in suspicious cases via history or exam, or those with proven testicular failure via high FSH)
 - Most of these labs are best done in the morning if possible.

Imaging

- None indicated for benign presentations.
- Testicular ultrasound in cases with concerns of testicular tumor via asymmetric exam, elevated estradiol or hCG, or pubertal level testosterone with suppressed LH
- Abdominal/adrenal CT or MRI
 - To rule out adrenal neoplasm, if estradiol elevated, DHEA-S elevated, or in cases concerning for testicular tumor that turn out to have negative testicular ultrasound
 - Consider chest CT in such cases as well.
- Brain MRI or CT, with and without contrast: if pituitary tumor is suspected
- Bone age can be an adjunct evaluation in cases with concerns for estrogen excess; estrogen results in bone age advance.

DIFFERENTIAL DIAGNOSIS

See “[Etiology](#).”

TREATMENT

MEDICATION

- Generally, drug therapy should proceed under the guidance of an endocrinologist.
- Tamoxifen and aromatase inhibitors in off-label use have shown some benefit in benign pubertal gynecomastia if started within 1 year of onset.
- If hypogonadal, replace testosterone.
- If gynecomastia has been present for >1 year, pharmacologic therapy is of little benefit because of an increase in fibrosis.

ADDITIONAL TREATMENT

Additional Therapies

- Reassurance for patients with pubertal gynecomastia measuring <5 cm
- Discontinue drugs or commercial products known or suspected to induce gynecomastia, and follow up in 1–2 months.
- Reexamine at 3–6-month intervals for size change.

- For gynecomastia >5 cm, consider surgical consultation once history, exam, and lab evaluation for pathology (along with imaging in indicated cases) have been conducted.

ISSUES FOR REFERRAL

Consider surgical consultation in patients with >5-cm diameter glandular tissue near the end of puberty. Surgery prior to completion of puberty may increase risk of recurrence.

SURGERY/OTHER PROCEDURES

- Surgery is therapy of choice for macrogynecomastia or persistent gynecomastia refractory to medical therapy, although obtaining insurance coverage may be difficult.
- Obesity should not preclude surgical intervention.
- Surgical options include periareolar incision with adjunctive liposuction or glandular tissue removal through 2 incisions in the anterior axillary regions.
- Ultrasound-assisted liposuction has emerged as a new alternative surgical option.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Reexamine every 3–6 months for size and characteristics.
- Watch for signs of psychological stress.
 - Significant issue in some male adolescents and should not be dismissed
 - Reassure that eventually, they shall be referred for treatment.
 - In those with significant psychological stress, referral before completion of puberty may result in repeat surgery later, but this can be considered after discussion with patient and family.

PROGNOSIS

- In benign cases, prognosis is good.
- Neonatal gynecomastia usually resolves within the 1st year of life.
- Pubertal gynecomastia <5 cm: 50–75% disappear spontaneously within

- 2 years, 90% within 3 years. If size >5 cm, regression unlikely
- Medical therapy effective only if treatment initiated within a year of onset.

COMPLICATIONS

- In benign cases
 - Pain (may interfere with sports)
 - Psychological stress
 - Embarrassment
 - Skin erosion of the nipple owing to rubbing against clothing

CODES

ICD10

- N62 Hypertrophy of breast
- P83.4 Breast engorgement of newborn

FAQ

- Q: When should a neonate with gynecomastia be referred to a

specialist?

- A: For male neonates, if galactorrhea persists at 3 months of age, or the gynecomastia not resolved by 1 year of age.
- Q: When should a nonneonatal, but prepubertal, male with gynecomastia be referred to a specialist?
- A: Gynecomastia in a prepubertal boy is rare and concerning. Urgent referral should be made to a pediatric endocrinologist.
- Q: When should a pubertal adolescent with gynecomastia be referred to a specialist?
- A: If gynecomastia is unilateral; if size is >5 cm; if size is <5 cm but with visible enlargement ongoing within 1 year of onset of problem; if started before onset of puberty; if nipple bleeding, discharge or retraction. Also, if testes are <5 mL or testicular mass present; if abnormal hormonal workup or imaging study.
- Q: How can gynecomastia be distinguished from breast cancer?
- A: Breast cancer usually presents as a unilateral, eccentric hard or firm mass fixed to underlying tissues. Location usually outside the nipple–areolar complex. Associated findings can include dimpling of the skin, retraction of the nipple, nipple discharge, and/or axillary lymphadenopathy. Breast cancer in the pediatric population is extremely rare: $<0.1\%$ of all breast cancers occur in patients <20 years of age. Benign tumors, such as fibroadenomas, much more common than malignant tumors. If differentiation between gynecomastia and breast carcinoma cannot be made by physical exam alone, patient should undergo diagnostic mammography.
- Q: Has the incidence of gynecomastia increased?
- A: As the prevalence of childhood and adolescent obesity has increased, the presence of pseudo gynecomastia has also increased. Pseudogynecomastia is best treated with diet and exercise.

HAND, FOOT, AND MOUTH DISEASE

Ross Newman • Jason Newland

BASICS

DESCRIPTION

Hand, foot, and mouth disease is a viral illness with the characteristic clinical features of the following:

- Vesiculoulcerative stomatitis
- Papular or vesicular exanthem on the hands and/or the feet
- Mild constitutional symptoms such as fever and malaise

GENERAL PREVENTION

- Frequent hand washing, especially after changing diapers, and good personal hygiene are the most useful means to prevent spread of enteroviral illnesses.
- Contact precautions should be maintained with all hospitalized patients.
- The prodromal and enanthem periods appear to be the most contagious; however, some may shed virus in the stool 3 months after infection.

EPIDEMIOLOGY

- In temperate climates, hand, foot, and mouth disease is most common in the summer and fall (a pattern common to many of the enterovirus infections).
- In tropical climates, disease is present year-round.
- Transmitted by oral–fecal route. Respiratory secretions may also transmit the virus.
- Incubation period is 3–6 days.
- Highly contagious, afflicting up to 50% of those exposed
- Close household contacts are particularly susceptible.
- Most common in children younger than 5 years but may affect adults
- May occur as an isolated case or in an epidemic distribution

PATHOPHYSIOLOGY

- Enteroviruses are acquired primarily from oral–fecal contamination.
- Lymphatic invasion leads to viremia and spread to secondary sites.
- Viremia ceases with antibody production.
- Direct inoculation of the extremities from oral lesions has been hypothesized with regard to hand, foot, and mouth disease.

ETIOLOGY

Coxsackie A16 virus is the most common causative agent. Other serotypes include the following:

- Coxsackieviruses A5, A7, A9, A10, A16, B1, and B3
- Enterovirus 71
- Echoviruses
- Other enteroviruses

DIAGNOSIS

HISTORY

- History of ill contacts
 - Family members or close contacts are often similarly affected.
 - Incubation period 3–6 days
- Any fever, pain, or other symptoms
 - A mild prodrome occasionally precedes the characteristic enanthem and exanthem by 1 or 2 days
 - Low-grade fever (usually near 101°F [38.3°C])
 - Malaise, sore mouth, anorexia, coryza, diarrhea, abdominal pain
- Lesions in mouth
 - Oral lesions typically occur shortly before the hand and foot manifestations.
- Hydration status
 - Determine quality and amount of oral intake, quality and amount of urine output, recent weight loss, duration of symptoms.

PHYSICAL EXAM

- Enanthem
 - Oral lesions begin as small, red papules.
 - Papules quickly evolve to small vesicles on an erythematous base.

- Lesions progress to ulcerations.
- Tongue, buccal mucosa, palate, gingiva, uvula, and/or tonsillar pillars may be involved.
- Typically 2–10 lesions that may persist up to 1 week
- Exanthem
 - Less consistently present than oral lesions occurring in 1/4–2/3 of patients
 - Maculopapular eruptions progress to vesicles.
 - Rarely tender or pruritic
 - Most frequent on the dorsal aspects of fingers and toes
 - May also occur on the palms, soles, arms, legs, buttocks, and face
- Adenopathy
 - Enlarged anterior cervical or submandibular nodes are present in 1/4 of cases.
- Other
 - Attention should be given to the patient's vital signs; general appearance; and respiratory, cardiac, and neurologic functioning to help identify the rare patient with a threatening complication of hand, foot, and mouth disease.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Hand, foot, and mouth disease has unique clinical features and a relatively benign course. Laboratory confirmation of the diagnosis is seldom needed or indicated.
- Culture
 - Causative viruses may be cultured from many sites:
 - Oral ulcers
 - Cutaneous vesicles
 - Nasopharyngeal swabs
 - Stool (Isolation of an enterovirus from the stool does not confirm it to be the cause of disease because the virus can be shed for many weeks after infection.)
 - Cerebrospinal fluid (CSF) (in cases where meningoencephalitis is suspected). Reverse transcription-polymerase chain reaction (RT-PCR) can be used and is more sensitive than culture in the CSF.

DIFFERENTIAL DIAGNOSIS

Few infectious diseases have such characteristic clinical findings. Oral ulcerations followed by lesions on the distal extremities are virtually pathognomonic. The most difficult diagnostic dilemmas may occur early in the disease course when isolated oral lesions predominate:

- Herpangina
 - Also caused by coxsackie A viruses
 - Associated with higher fever
 - Usually limited to the posterior oropharynx
- Herpetic gingivostomatitis
 - Most common cause of stomatitis in children
 - Associated with higher fever
 - More frequently associated with lymphadenopathy
 - Gingival involvement severe
 - Aphthous ulcers
 - Can occur without fever or upper respiratory symptoms
 - Does not occur in outbreaks
 - No seasonal predilection
- Stevens-Johnson syndrome
 - Ulcerations frequently coalesce.
 - Usually affects other mucous membranes
 - Often appears with separate cutaneous manifestations
- The Boston exanthem
 - Caused by echovirus 16
 - Mild febrile illness with a macular rash on the palms and soles occurring at time of or after defervescence
 - Oral lesions absent

TREATMENT

SUPPORTIVE CARE

No specific therapy is indicated or usually necessary. Most cases are mild and self-limiting and only require parental reassurance.

SPECIAL THERAPY

- Symptomatic relief from particularly painful oral ulcers may be accomplished by application of a topical antihistamine or anesthetic directly to the sores.
- Dehydration should be treated when present. IV fluids may be required in the more severe cases, especially in infants and young children.
- Good supportive care is generally sufficient to treat most complications.

MEDICATION

Acetaminophen may relieve malaise and minor discomfort associated with the oral ulcers. It also may be used as an antipyretic in those children with fever.

INPATIENT CONSIDERATIONS

Admission Criteria

Dehydration and inability to maintain adequate oral hydration

Discharge Criteria

Rehydration and good oral intake

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Small children must be followed closely for signs of dehydration.

DIET

Dietary adjustments often improve oral intake from painful oral lesions and prevent or relieve dehydration:

- Avoid spicy or acidic foods.
- Provide cool or iced liquids in small quantities frequently.

PROGNOSIS

- In nearly all instances, hand, foot, and mouth disease will resolve quickly, usually within 1 week after diagnosis, requiring only supportive care.
- Careful history and examination should distinguish those patients with the rare aforementioned complications.

- Rare cases may recur at intervals for up to 1 year.

COMPLICATIONS

- Hand, foot, and mouth disease is usually self-limited and uncomplicated, resolving within 7–10 days.
- Dehydration is the most frequent morbid complication:
 - Oral ulcerations are painful and interfere with feeding.
 - Infants and children are at highest risk.
- Rare complications include the following:
 - Neurologic complications such as aseptic meningitis, encephalitis, and acute flaccid paralysis
 - Pneumonia
 - Myocarditis
 - A possible association with 1st-trimester spontaneous abortions in previously infected women

CODES

ICD10

- B08.4 Enteroviral vesicular stomatitis with exanthem
- B34.1 Enterovirus infection, unspecified

FAQ

- Q: What is in the “magic mouthwash” often used to relieve the pain of stomatitis?
- A: Many health care providers will prescribe a magic mouthwash for symptomatic relief of oral ulcers, pharyngitis, and teething pain. The most common such treatment consists of an aluminum hydroxide/magnesium hydroxide gel suspension and diphenhydramine elixir (12.5 mg/5 mL) in a 1:1 formulation. It can be applied directly to the sores with a cotton swab or a small syringe before meals. Note: Some people will have a reaction to topical diphenhydramine.
- Q: Should lidocaine be used topically or in suspension with magic mouthwash for symptomatic relief of oral ulcers?
- A: The routine use of lidocaine in this situation is not recommended. Lidocaine is an effective topical anesthetic and comes in a 2% viscous suspension. In practice, the pain relief is short lived, which encourages frequent administration. Lidocaine is absorbed from the mucous membranes (bypassing 1st-pass liver metabolism) and has been frequently reported to cause poisoning of the cardiovascular and central nervous systems. Both pediatric and adult fatalities have occurred. Topical viscous lidocaine should be reserved for use by physicians knowledgeable about its proper dosage and potential side effects and by educated, compliant parents or caregivers.
- Q: When may children with hand, foot, and mouth disease return to school?
- A: Good hygiene will greatly reduce viral transmission. Isolation from school or day care contacts should occur while fever remains and/or while the enanthem persists. As mentioned, some patients may shed the virus in their stool for weeks after symptoms have resolved (again stressing the need for good personal hygiene).

HEAD BANGING

Ana Catarina Garnecho • Yvette E. Yatchmink

BASICS

DESCRIPTION

- Head banging (HB) is defined as the hitting of head on solid object such as a wall, side of crib, mattress, or floor.
- Tend to hit the front or side of the head
- Usually last for 15 minutes but can go on for >1 hour
- Regular rhythm of 60–80 bpm
- Can be seen along with body rocking or head rolling

EPIDEMIOLOGY

- Average age of onset is 9 months; usually extinguished by 3 years of age. Older patients with head banging are more likely to have a developmental delay or other medical problems
- More common in boys than girls (3:1)
- Occurs in 3–15% of typically developing children
- Estimated that 2–3% of kids with intellectual disability have stereotypic movement disorder (SMD) (HB) and 5% of kids with Tourette syndrome have SMD (HB)

ETIOLOGY

- Can be comforting and be a part of other self-soothing activities such as body rocking or head rolling
- Can be seen during a temper tantrum secondary to frustration or anger
- Can be seen with typically developing children as an expression of happiness or as a method of self-stimulation (sometimes secondary to sensory deprivation)
- Need to rule out medical causes specifically if head banging occurs suddenly and is associated with other symptoms
- Can be part of a sleep rhythmic disorder called Jactatio capitis nocturna (partial arousal during light, non-REM sleep); head banging occurs when drowsy or falling asleep.

- Can be described as SMD, which is a repeated, rhythmic, purposeless movement or activity; these usually cause self-injury or severely interfere with normal activities. These are most prevalent in adolescence and tend to occur in clusters of symptoms. Diagnosis requires 4 weeks of duration.

COMMONLY ASSOCIATED CONDITIONS

- Medical causes: teething (pain), ear infection, seizures, meningitis, headaches, drug use (cocaine, amphetamines)
- SMD associated with cerebral palsy, intellectual disability, schizophrenia, autism spectrum disorders, Down syndrome, Lesch-Nyhan syndrome, blindness, deafness
- Tic disorder or Tourette syndrome
- Rule out child abuse if significant scalp laceration, skull fracture, or intracerebral or subdural hemorrhage

DIAGNOSIS

- Dependent on multiple factors
- Determine factors associated with behavior, including age of child, degree of parental concern, location of behavior, associated behaviors, motivations of the child, benefits to the child, etc.
- Determine if a medical cause exists, particularly if sudden onset.
- Determine if psychological factors are involved.

DIAGNOSTIC TESTS & INTERPRETATION

- Usually, no laboratory testing is needed for diagnosis.
- Physical examination to look for bruising, swelling, scratches, or minor lacerations.
- If swelling or blood loss is involved, brain imaging may be necessary to rule out damage.
- If severe and persistent head banging is reported, an ophthalmology exam is warranted to rule out complications.
- Developmental screening to rule out possible developmental delay
- If developmental delay is suspected, formal psychoeducational testing can be recommended.

TREATMENT

- Typically, developing children will outgrow the habit by age 3 years.
- Older children may need psychological/developmental follow-up to determine delay/cognition status and to determine if behavioral modification therapy could be beneficial in decreasing symptomatology.
- If severe, head banging can lead to ophthalmologic complications, including cataracts, glaucoma, or retinal detachment. Referral to ophthalmologist is recommended.
- For patients with particularly violent movements of Jactatio capitis nocturna, trials with clonazepam and citalopram have shown some success.
- For patients with stereotypic movement disorder, medications may help, including antipsychotics, tricyclic antidepressants, SSRIs, and benzodiazepines. These should be closely monitored.

ONGOING CARE

PROGNOSIS

- Normally disappears by age 3–4 years
- Jactatio capitis nocturna is usually benign and resolves by age 5 years.
- Stereotypic movement disorder usually peaks in adolescence and then declines.

CODES

ICD10

- F98.4 Stereotyped movement disorders
- G47.69 Other sleep related movement disorders

FAQ

- Q: Can head banging lead to serious head injury or neurologic damage?
- A: Typically, developing children rarely bang their heads hard enough to cause bleeding or fracture.
- Q: What can a parent do to prevent injury or diminish head banging behavior?
- A: Remove sharp or breakable objects from child's environment to avoid accidental injury.
 - Place a rubber pad on the floor or a thick rug.
 - Secure the crib to the wall to decrease noise and vestibular input to the child.
 - Pad crib with bumpers.
 - If behavior occurs during temper tantrums, ignore the behavior once safety is established. Reward the child for appropriate behaviors.

HEADACHE AND MIGRAINE

Christopher B. Oakley

BASICS

DESCRIPTION

- Primary headache: headache without an identifiable underlying etiology; includes but not limited to migraine, tension headache, cluster headache, and other trigeminal autonomic cephalgias; may be episodic or chronic in nature
- Secondary headache: headache attributed to an identifiable underlying etiology
- Other: unusual headaches, especially in children, that include various cranial neuralgias and central and primary facial pain

EPIDEMIOLOGY

- Headache prevalence can approach 30–50% by school age, 60–80% by early adolescence, and as high as 85% by adulthood.
- Tension-type headache is most common type of headache, with migraine second.
- Mean age of onset for migraine is 7 years for boys and 11 years for girls. Migraine precursors such as abdominal migraine, cyclic vomiting syndrome, and benign paroxysmal vertigo of childhood can be seen even younger. These may transform into migraines by puberty.
- Overall migraine reported prevalence ranges between 8 and 23%. Suspicion is that migraine prevalence may be as high as 30–35% due to underreporting. Prevalence of chronic daily headache in younger children is 2–4% and 4–5% in adolescence/adulthood.
- Until puberty, migraines more common in males (55–60%), post puberty in females (75%)
- Genetics plays a role with some reports of 90% family history noted. Genes have been identified for some migraine subtypes including familial hemiplegic migraine.
- Ethnicity plays a role, with majority of reported chronic migraine sufferers being Caucasian.

DIAGNOSIS

Migraine in children is classified into the following groups:

- Migraine without aura: “Common” migraine represents most cases
- Migraine with aura: “Classic” migraine must include aura, a reversible focal neurologic symptom that gradually develop over 5–20 minutes and typically resolve within 1 hour.
- Basilar-type migraine (up to 20% of childhood migraines): often seen migraine with aura with occipital pain often and must include two of the following: dysarthria, vertigo, tinnitus, hyperacusis, diplopia, ataxia, visual symptoms, bilateral paresthesias, and decreased consciousness
- Childhood periodic syndromes that are precursors to migraine: benign paroxysmal vertigo of childhood, cyclic vomiting, abdominal migraine, benign paroxysmal torticollis
- Hemiplegic migraine: type of migraine with aura, with symptoms that must include motor weakness along with one of the following: sensory symptoms, visual symptoms, dysphasic speech
- Others: “Alice in Wonderland syndrome” has distortions of vision, space, and/or time; confusional migraine has impaired sensorium, agitation, and lethargy.

General migraine diagnostic criteria set by the International Classification of Headache Disorders 3rd edition, beta (ICHD III, beta) in children/adolescents

- 5 attacks not attributed to another condition
 - Lasting 2–72 hours
 - 2 of the following:
 - unilateral or bilateral pain
 - moderate to severe pain
 - pulsating quality
 - aggravated by routine activity
 - 1 of the following:
 - photophobia and phonophobia (may be inferred)
 - nausea or vomiting
- Aura has separate criteria.

Tension-type headache differs from migraine as follows: more episodes typically seen, lasts 30 minutes to 7 days, typically describes as bilateral pain, pressing/tightening quality, mild to moderate intensity, not worse with activity, not associated with sensitivity to light or sound, nausea, or vomiting

HISTORY

The history should help clarify the diagnosis of which type of headache is present and help guide workup and treatment.

- The following questions should be asked:
 - Is there more than 1 type of headache?
 - Have headaches gotten worse?
 - How often do they occur?
 - Where is the pain located?
 - What is the quality of the pain?
 - Do the headaches occur at any special time of day?
 - What associated symptoms are present?
 - Is there a warning sign or aura noted?
 - What triggers a headache?
 - What helps the headache feel better?
 - Any symptoms present between episodes?
 - What treatments have been tried? (include dose, duration, and outcome)
 - Any migraine precursors noted or other common comorbidities such as motion sickness or psychiatric concerns?
- “Red flags”: age of onset younger than 3 years of age; first or worst headache; occipital location; recent headache onset; increasing severity or frequency; headache in the morning associated with vomiting; headache causing awakening from sleep; worse with straining; change in mood, mental status, or school performance; or underlying neurocutaneous syndrome or other neurologic concern
- Lifestyle considerations that affect headaches: amount and quality of sleep, hydration status, consistent diet/meals, caffeine consumption, level of fitness and amount of cardiovascular exercise, stress, and anxiety

PHYSICAL EXAM

- Vital signs: blood pressure, heart rate, and weight. Consider orthostatic blood pressure and pulse for dizziness or syncope; if obese, consider pseudotumor or sleep apnea syndrome.
- Skin changes consistent with neurocutaneous syndrome
- Sinus tenderness, limitation of jaw excursion, or occipital trigger points
- Complete neurologic exam including vision screen and funduscopic exam: should be normal in primary headaches. Exception is during aura: Exam may show temporary deficit.
- Basic depression and psychiatric screen
- Any abnormality on exam warrants further investigation, as it may suggest secondary headache with possible underlying etiology.

DIAGNOSTIC TESTS & INTERPRETATION

Practice parameters are established in 2002 for the evaluation of children and adolescents with recurrent headaches. The guidelines address laboratory evaluation, ancillary testing, and imaging.

Imaging

- Neuroimaging studies (CT or MRI): generally not recommended if neurologic exam is normal and no red flags. If exam is abnormal or red flags are present, imaging should be obtained with determining which study to obtain based on clinical concern and situation.
 - CT if there is any suspicion for any acute process such as hemorrhage, but otherwise MRI is preferred.
 - Consider risk of imaging (e.g., younger children require anesthesia for MRI; radiation exposure with CT).
 - Consider MRA/MRV if vascular cause/etiology in differential diagnosis.
- Neuroimaging guidelines are based on multiple studies with more than 600 images reviewed. Only 3% of those images obtained led to specific treatments geared toward imaging findings, and in all those who had abnormal imaging that required treatment, their neurologic exams were found to be abnormal.

Diagnostic Procedures/Other

- EEG: no role for EEG in routine testing of patients with headache

- Laboratory investigation: generally not recommended in primary headaches
- Lumbar puncture (LP): not recommended unless concern for secondary headache or underlying etiology such as infection, hemorrhage, sinus thrombosis, pseudotumor cerebri, and low-pressure headache. Imaging should be done first to ensure it is safe to perform LP.

DIFFERENTIAL DIAGNOSIS

The pattern of headache can help clarify the differential. There are 5 patterns.

- Acute, 1st severe headache
 - CNS infection, cocaine or other substance abuse, medication (methylphenidate, steroids, psychotropic drugs, analgesics, cardiovascular agents), hypertension (usually secondary), hydrocephalus, pseudotumor cerebri (idiopathic intracranial hypertension), post-LP, CNS hemorrhage, ventriculoperitoneal shunt malfunction, sinus thrombosis, migraine, other infection including upper respiratory, somatization
- Acute recurrent headache
 - Much of what is listed above in acute, 1st severe headache can be recurrent as well. Additional consideration would include migraine and variants, cluster, and tension.
- Chronic progressive headache
 - Brain tumor, chronic CNS infection including abscess, hydrocephalus, vascular malformation, hematoma, sinus thrombosis, idiopathic intracranial hypertension, depression or other psychiatric condition, anemia, rheumatologic diseases
- Chronic nonprogressive or daily headache
 - Much of what is listed above in chronic progressive headache can be nonprogressive as well. Additional consideration would include medication overuse, substance abuse including caffeine, chronic infection such as sinusitis, occipital neuralgia, temporomandibular joint syndrome, orthostatic headache, post-LP, other systemic disease, posttraumatic, sleep disorder, tension headache, fibromyalgia.
- Mixed headache: migraine-superimposed tension headache with broad

differential including much of what is listed above

TREATMENT

MEDICATION

Practice parameters are established in 2004 for the pharmacologic treatment of migraine in children and adolescents. The guidelines addressed acute and prophylactic medical management.

- Acute treatment: generally most effective if given early in the acute headache/migraine
 - 1st line is ibuprofen (10 mg/kg PO) – level A.
 - Acetaminophen (10–15 mg/kg PO) – level B
 - Naproxen sodium 5.5–7.7 mg/kg PO per dose: longer acting NSAID than ibuprofen
 - Sumatriptan nasal spray can be 1st line in adolescent migraine – level A.
 - Many options noted to be level U (not enough data).
- Additional acute treatments often used especially in refractory patients
 - Antiemetics (prochlorperazine, metoclopramide, ondansetron) also enhance effectiveness of analgesics and may abort migraines. Prochlorperazine has best evidence of this class, with up to 95% improvement noted in some studies.
 - Triptans: generally safe, but only almotriptan is currently FDA approved for use in children or adolescents. Rizatriptan and zolmitriptan have been shown effective in children and adolescents. Seven triptans are available in various forms, including tablet, nasal spray, dissolvable, and injection.
 - Any agent that may lead to vasoconstriction such as triptans and ergotamines are not recommended in basilar, hemiplegic, or any migraine with vascular risk factors.
 - Most over-the-counter or prescription pain/headache/migraine medications may cause rebound headaches.
- Status migrainosus
 - Migraine lasting >72 hours
 - General treatment involved a combination of

medications/treatments.

- Not well studied, but some evidence that the following combinations are successful:
 - Fluids, triptan if used successfully prior, NSAID (ibuprofen/naproxen/ketorolac), antidopaminergic (prochlorperazine [Compazine] with best evidence), and Benadryl
 - Valproic acid can be used as second tier.
 - No definitive evidence for steroids or magnesium despite often being used
- Dihydroergotamine (DHE-45) noted to be highly effective in small studies; can be IV, IM, or intranasal; given with combination of treatments including antiemetic
- Narcotics are not recommended.
- Prophylaxis
 - When to start is controversial, but generally if there is more than 1 day per week with disability or dysfunction, daily medication is recommended.
 - Goal is reduction in headache frequency or severity by $\geq 50\%$. There is no cure for headaches/migraines. Keeping realistic expectations is key to treatment.
 - Start at a low dose and titrate as needed while being mindful of adverse effects.
 - Can take 4–6 months for effects to be seen
 - Choose a drug that may address comorbidities as well. Be careful to avoid drug classes that may exacerbate other medical conditions (e.g., beta-blockers in asthma patients).
 - Practice parameters from 2004 very limited: Flunarizine (not available in United States) only prophylactic medication with any recommendation other than level U
 - Amitriptyline (TCA) and topiramate (anticonvulsant) most commonly used and studied options in children
 - Cyproheptadine (antihistamine) frequently used 1st line in younger children as well as for migraine precursors and GI symptoms
 - Other options would include the following:

- Calcium channel blockers: verapamil
- Beta-blockers: propranolol, nadolol
- Tricyclic agents: nortriptyline, imipramine
- SNRI: venlafaxine, duloxetine
- Anticonvulsants: valproic acid, gabapentin, carbamazepine (neuralgias), and oxcarbazepine (neuralgias)

COMPLEMENTARY & ALTERNATIVE THERAPIES

- Physical therapy, exercise (aerobic, yoga, Pilates), massage therapy, relaxation techniques (meditation, progressive muscle relaxation, self-hypnosis), stress management, cognitive behavioral therapy, biofeedback
- Some evidence for vitamins, supplements, and herbs such as butterbur (50–75 mg b.i.d.), riboflavin (50–400 mg daily), magnesium oxide (50–200 mg b.i.d.). Of note, supplements and vitamins are not regulated by the FDA. Melatonin as low as 3 mg nightly is reported to be as effective as low-dose amitriptyline.

- G44.209 Tension-type headache, unspecified, not intractable

HEAT STROKE AND RELATED ILLNESS

Patrick B. Solari • George Anthony Woodward

BASICS

DESCRIPTION

- Heat stroke occurs during imbalance in heat production, absorption, and dissipation. It can result from excessive body heat generation and storage without appropriate dissipation, high ambient temperature, low radiation or convective heat loss, decreased evaporation, or inadequate fluid/electrolyte replacement in response to losses through sweat or GI disturbance.
- 2 forms of heat stroke exist.
 - Exertional heat stroke, which occurs during periods of intense exertion
 - Nonexertional heat stroke, in which the body is unable to compensate for an increase in ambient temperature; more common in very young and elderly and during heat waves

RISK FACTORS

- Environmental predisposition
 - Hot and humid without wind, heat wave, overheated indoor environment, lack of air conditioning; social isolation, inability to care for self, or entrapment in closed space (e.g., car, trunk; internal automobile temperature in sunlight with poor ventilation can reach 131–172°F; the sharpest temperature increase occurs within the first 15 minutes)
- Medical
 - Obesity, low fitness level, cardiac disease, diabetes mellitus and insipidus, diarrhea, hyperthyroidism, dehydration, vascular disease, sweat gland dysfunction, sunburn, viral illness
- Drugs/medications
 - Anticholinergics
 - Antihistamines
 - Stimulants

- Beta-blockers
- Diuretics
- Psychiatric medications
- Recreational drugs and alcohol
- Behaviors
 - Lack of recognition of risk factors or warning signs
 - Overexertion or inadequate fluid intake
 - Inappropriate clothing; heavy, dark, tight-fitting, overbundling
 - Lack of acclimatization and conditioning
 - Children in enclosed space within vehicle

GENERAL PREVENTION

- Avoid enclosed spaces (e.g., children in closed cars).
- Reduce activity levels, keep cool, and use shaded areas. Adaptation to warmer climates may take 8–10 exposures of 30–45 minutes each daily or every other day.
- Air conditioning or fans during hot weather
- Cool or tepid baths
- Fluid intake
 - Increase fluid intake before, during, and after scheduled exercise or strenuous activity.
 - Up to 200–300 mL q10–20 min
 - Do not wait until there is a sensation of thirst.
- Precooling using external (cold water immersion, cooling vests) or internal (drinking cold liquid/ice slurry) methods may improve performance before endurance events in heat.
- Appropriate clothing
 - Loose, light-colored clothing
 - Protective hat
- Acclimatization via gradual conditioning over 10–14 days in hotter environment
- Liberal dietary sodium
 - Avoid NaCl tablets (possible hyponatremia, potassium depletion, gastric irritation, delayed gastric emptying).
- Frequently flex leg muscles when standing.
- Avoid prolonged standing in hot environments.

- Avoid caffeine and alcohol.

PATHOPHYSIOLOGY

- Heat production increases 10–20 times by strenuous exercise.
- When environmental temperature is greater than body temperature, body gains heat by conduction and radiation and can lose heat by evaporation and convection.
- Children have greater body surface-to-mass ratio, higher metabolic rate, inability to increase cardiac output, decreased sweat production, and inability to independently change environments compared to adults.
 - Dehydration results in loss of sweating, hence decreased evaporation.
 - Above 40°C, cell volume, membrane integrity, metabolism, and acid–base balance is affected.
 - Extreme core temperatures >42°C can uncouple oxidative phosphorylation and allow enzyme systems to cease functioning.

COMMONLY ASSOCIATED CONDITIONS

- Miliaria rubra (prickly heat)
 - Heat rash, usually caused by obstruction of sweat glands by clothes or lotions
 - Erythematous papular rash; usually self-limited
- Heat cramps/spasms
 - Related to physical exercise in people who have not trained or are poorly acclimatized with mild dehydration
 - Related to water and sodium depletion
- Heat tetany
 - Paresthesias and carpopedal spasm help distinguish tetany from heat cramps.
- Heat syncope
 - Alteration of consciousness (i.e., dizziness, syncope) at end of strenuous or upright event
- Heat edema
 - Swollen feet and ankles (i.e., vascular leak, orthostatic pooling)
- Heat exhaustion

- Relatively slow onset
- Water and/or salt depletion
- Copious perspiration with headache, nausea, vomiting, malaise, myalgias, pallor, light-headedness, visual disturbances, syncope, temperature 38–40°C, dehydration, electrolyte imbalance, hemoconcentration
- Can evolve into heat stroke
- Heat stroke
 - Core body temperature exceeding 40°C with altered mental status ranging from confusion, disorientation, and incoherent speech to delirium, decerebrate posturing, seizure, and coma
 - May have acute, sudden onset (80%) or slower onset (minutes to hours, 20%)
 - Classic heat stroke is associated with dry skin and prolonged exposure to elevated temperatures at rest.
 - Exertional heat stroke may present with anhidrosis or profuse sweating.

DIAGNOSIS

HISTORY

- Heat exhaustion
 - Weakness, lethargy, thirst, malaise, diminished ability to work or play, headache, nausea, vomiting, myalgias, pale skin, dizziness
- Heat stroke
 - History of CNS dysfunction in environment consistent with, or predisposing conditions conducive to, development of heat-related illness should suggest heat stroke.

PHYSICAL EXAM

- Heat exhaustion
 - Visual disturbances, syncope, mild CNS dysfunction, impaired judgment, cramps, vertigo, hypotension, tachycardia, hyperventilation, paresthesias, agitation, ataxia, psychosis, temperature <40°C, sweating, environmental exposure, and activity;

no coma or seizures

- Heat stroke
 - Temperature $>40^{\circ}\text{C}$ (may be cooler after prehospital interventions and maneuvers)
 - Altered level of consciousness (confusion, drowsiness, irritability, neurologic deficits, euphoria, combativeness, obtundation), ataxia, posturing, incontinence, seizures, coma, purpura, or petechiae
 - 2/3 with constricted pupils
 - May have muscle rigidity with tonic contractions and dystonia that mimic seizures
 - Shock: tachycardia, hypotension, widened pulse pressure, tachypnea
 - Hot, dry (classic), or clammy (exercise-induced) skin; pink or ashen color
 - Weakness, nausea, vomiting, anorexia, headache, dizziness
- Temperature measurement (continuous best)
 - Esophageal thermometry is probably the best.
 - Deep rectal thermometry is a good approximation of core temperature.
 - Tympanic, oral, axillary, and temporal artery temperatures are less accurate measures of core temperature.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

Tests are only to confirm diagnosis, evaluate extent of injury, or rule out other processes because treatment should be empiric.

- Heat cramps: decreased levels of serum and urine sodium and chloride; BUN level normal or slightly increased
- Heat exhaustion: may see hyponatremia or hypernatremia (free water loss), hypochloremia, low urine sodium, and chloride hemoconcentration; normal LFTs
- Heat stroke
 - Electrolyte abnormalities: sodium, chloride level normal or high, hypokalemia, elevated BUN/creatinine; hypoglycemia
 - Hematologic: hemoconcentration, leukocytosis, thrombocytopenia
 - Prerenal azotemia

- Elevated AST/ALT
- Metabolic acidosis: lactate high, especially with exertional heat stroke
- Coagulopathy
- Arterial blood gases (classic heat stroke: respiratory alkalosis and hypokalemia early; lactic acidosis later; exertional heat stroke; lactic acidosis)
- Others: creatine phosphokinase (rhabdomyolysis), urinalysis (casts, brownish color proteinuria, microscopic hematuria, myoglobinuria), CSF, EKG, chest radiograph

DIFFERENTIAL DIAGNOSIS

- Heat cramps: rhabdomyolysis, tetany
- Heat edema: thrombophlebitis, lymphedema, congestive heart failure
- Heat stroke: CNS process with fever (cerebrovascular stroke, meningitis, encephalitis), other infections, anticholinergic poisoning (dilated pupils), drug/medication induced, temperature rise, severe dehydration. Chills suggest febrile illness, not heat stroke.
- Neuroleptic malignant syndrome
- Serotonin syndrome
- Malignant hyperthermia

TREATMENT

MEDICATION

- Antipyretics are not useful because an intact hypothalamus is required for action.
- Avoid anticholinergic drugs, which inhibit sweating.
- May require inotropic support
- Chlorpromazine may improve peripheral vasodilatation and prevent shivering.
- Benzodiazepine for sedation and/or seizures
- Dantrolene not shown to be effective

ADDITIONAL TREATMENT

General Measures

- Heat stroke: Treat empirically, and then rule out other causes of presentation. Maintain airway, breathing, and circulation including securing airway as indicated and supplemental oxygen delivery.
 - Cooling is mainstay of treatment, external, internal, or both.
 - Fluid replacement: IV 0.9% NS or LR solution. Rule out hypoglycemia.
 - Miscellaneous therapies
 - ▢ Foley catheter to monitor urine output
 - ▢ Nasogastric tube
 - ▢ Myoglobinuria therapy (mannitol, bicarbonate, dialysis if necessary)
 - ▢ Electrolyte replacement if symptomatic from hypokalemia or hypocalcemia
 - ▢ Fresh frozen plasma for disseminated intravascular coagulation (DIC)

INPATIENT CONSIDERATIONS

Initial Stabilization

- Rapid recognition and cooling imperative
- Specific therapy
 - Heat cramps: rest, salt and water replacement
 - Heat syncope: self-limited, as return to horizontal position is treatment; rest and fluids, salted liquids
 - Heat exhaustion: Clinical findings (heart rate, BP, orthostatic changes, urine output) should direct therapy. Most treated as outpatient with rapid rehydration, cooling; mild case: oral electrolyte solution; if with nausea, vomiting, inability to drink: IV (0.45 [similar to sweat losses]–0.9% NS); avoid rapid overcorrection of hypernatremia (treat as with hypernatremic dehydration); if with hyponatremic seizures, treat with 3% saline at ~5 mL/kg.
 - Heat stroke: immediate cooling and support of cardiovascular system. Remove clothing, remove patient from hot environment; use air conditioning, open vehicle for transport if possible; esophageal or rectal temperature probe (continuous temperature measurements); cooling should exceed 0.1°–0.2°C/min; slow cooling down at 38.5°–

39°C to avoid overshoot.

- Cooling options: Cold water immersion (15°–16°C) has lowest morbidity and mortality for exertional heat stroke and is as effective as ice bath without discomfort, shivering, or vasoconstriction.
 - Also: ice packs to neck, groin, axillae; wet sheet over patient; moisten skin with water spray, convection increase (fan) to increase evaporative cooling; cooling blankets; cool/ice water lavage (peritoneum, rectum, gastric); cold to room temperature IV fluids; massage with ice (decreases shivering response).

Admission Criteria

- Patients with symptoms suggestive of heat stroke require immediate cooling and should be closely observed.
- Patients with evidence of multisystem disease (altered mental status, electrolyte imbalances, hematologic abnormalities) should be admitted until such issues are resolved.
- Patients with respiratory or hemodynamic instability may require intensive care.

ONGOING CARE

PROGNOSIS

- Heat-related illness (e.g., heat rash, edema, cramps, tetany, syncope, exhaustion): rapid recovery with supportive care
- Heat stroke: poor prognosis if not recognized and aggressively managed; morbidity and mortality directly proportional to how rapidly core temperature is reduced

FAQ

- Q: How can one distinguish between heat exhaustion and heat stroke?
- A: Heat stroke involves temperature $>40^{\circ}\text{C}$ with CNS and LFT abnormalities, whereas heat exhaustion refers to inability to continue exercise.
- Q: When should heat stroke be suspected?
- A: Suspect heat stroke in a patient with or without sweating and who demonstrates alterations of CNS function.
- Q: Does the presence or absence of sweating help with the diagnosis of heat exhaustion versus heat stroke?
- A: No. Sweating will be present with heat exhaustion and may or may not be present with heat stroke.
- Q: Are children at increased risk of heat illness?
- A: Yes. They have a number of predisposing factors: greater surface area-to-body mass ratio than adults, higher metabolic rate, slower rate of sweating than adults, temperature when sweating starts is higher, lower cardiac output at a given metabolic rate than adults, rate of acclimatization is slower, thirst response is blunted, and access to fluids may be limited.

HEMANGIOMAS AND OTHER VASCULAR LESIONS

Katherine B. Püttgen

BASICS

DESCRIPTION

- Vascular tumors: neoplasms of the vasculature
 - Infantile hemangioma (IH)
 - Congenital hemangiomas: noninvoluting congenital hemangioma (NICH) and rapidly involuting congenital hemangioma (RICH)
 - Tufted angioma (TA)
 - Kaposiform hemangioendothelioma (KHE)
 - Pyogenic granuloma
 - Hemangiopericytoma
- Vascular malformations (VaM): anomalous blood vessels without endothelial proliferation
 - Capillary malformations (CM) (e.g., salmon patch, port-wine stain, nevus flammeus)
 - Venous malformations (VM)
 - Arterial malformations: arteriovenous malformations (AVM) or arteriovenous fistula (AVF)
- Lymphatic malformations (LM) (macrocytic and microcytic)
- Combined malformations (e.g., capillary-venous-lymphatic)
- Other types of VaM may occur in any part of the body and may be associated with soft tissue overgrowth of the involved part.

EPIDEMIOLOGY

Incidence

Infantile hemangiomas

- 4–5% of infants
- ~10% of Caucasian infants by age 12 months
- Increased incidence in low-birth-weight and premature infants
- Other demographic risk factors include white non-Hispanic race,

female sex, multiple gestation pregnancy, advanced maternal age, chorionic villus sampling during pregnancy, and positive family history.

COMMONLY ASSOCIATED CONDITIONS

- Infantile hemangiomas
 - PHACES
 - Segmental hemangioma (usually facial) associated with other developmental anomalies (Posterior fossa malformations; hemangiomas; arterial anomalies; cardiac anomalies, including aortic coarctation; eye abnormalities; sternal defects/supraumbilical raphe)
 - Cerebral malformations occur in >50% and cerebrovascular anomalies in 33%.
 - Lumbosacral
 - An underlying spinal dysraphism may be present.
 - PHACE-like syndromes of the lower body with associated GI and GU anomalies have been described.
 - Segmental
 - Commonly located on the face and involving a developmental unit (segment) and frequently associated with complications, even without meeting full PHACES criteria
 - Segmental IHs are much more likely to have complications and to receive treatment than focal IHs.
- Kaposiform hemangioendothelioma
 - Kasabach-Merritt phenomenon (consumptive coagulopathy, severe thrombocytopenia)
- VaM
 - CM may be present as part of syndromes (e.g., Sturge-Weber, RASA-1 mutations associated with fast-flow VaM, von Hippel-Lindau, Rubinstein-Taybi, Beckwith-Wiedemann, Cobb syndrome).
 - VM can be inherited autosomal dominantly due to TIE2/TEK gene mutations.
 - CM-AVM: due to RASA-1 gene mutation and associated with fast-flow VaM
 - Generalized LM and lymphedema have been associated with

VEGFR3 mutations.

DIAGNOSIS

HISTORY

- Onset of lesions and timing of changes
- IHs are often inapparent at birth or present with nascent telangiectatic patches followed by a rapid growth phase.
 - Proliferative phase: During the first 2 months of life, nearly all IHs double in size.
 - Most rapid period of growth occurs between 5.5 and 7.5 weeks of age; majority of rapid growth phase is in the first 8 weeks of life.
 - Most IHs reach 80% of their maximum size by 3–5 months of age.
- Segmental and deep IH grow longer.
- Congenital hemangiomas (RICH and NICH) are present fully formed at birth.
- VaM are present (although may not be noticed) at birth. Most slowly enlarge over time.
- Past medical history for IH
 - Low birth weight, twin or other multiple gestation, prematurity
- Family history
 - Present in up to 15% of IH
 - CM-AVM is autosomal dominantly inherited.

PHYSICAL EXAM

- Infantile hemangiomas
 - Neonate: flat pale patch, superficial telangiectasia with halo border
 - Superficial IH: raised red, partially compressible, nontender plaque or nodule with well-demarcated borders. Overlying skin is usually intact, although sometimes ulceration may be present.
 - Deep IH: raised soft mass with bluish-purplish discoloration with smooth, intact, overlying skin
 - Mixed IH: Lesions will have both superficial and deep components.
 - Morphology may be localized (most common), segmental, indeterminate (looks “sub”-segmental), or multifocal (>5 IH).

- Ulceration occurs in up to 25% in a referral setting; risk of ulceration peaks by age 4 months.
- Involuting lesion: flat, atrophic pale or gray center with surrounding raised reddish border with stippled texture
- The presence of large numbers of small- to moderate-sized IH may indicate a rare condition called diffuse neonatal hemangiomatosis. Internal organ involvement (liver, lungs, GI tract, CNS) may be present.
- VaM
 - Salmon patches (nevus simplex)
 - Most notable at birth as pinkish-red macules that often blanch and are most commonly found at the nape of the neck, glabella, and upper eyelids
 - Frequently, all three locations are involved in an individual newborn.
 - Port-wine stains (nevus flammeus)
 - Easily seen at birth and are deep pink to red-purplish, nonblanching macules with well-demarcated borders
 - Most commonly located on the face and often cover a large area
 - Matured port-wine stains are deeper in color and frequently develop raised nodules and vascular blebs.
 - If an extremity is heavily involved, there may be underlying bony and soft tissue overgrowth with limb hypertrophy.
 - AVMs
 - Raised pulsating lesions with bruits audible by stethoscope if large in size
 - Smaller lesions may vary in appearance from macular erythema to thin vascular plaques.
 - Signs of cardiac compromise (i.e., tachycardia, gallop rhythm, shortness of breath, hepatomegaly) may be associated with very large AVMs.
 - VMs
 - Deep blue to purplish, soft, fleshy compressible nodules in the skin; may be surrounded by superficial venules
 - The drainage pattern is generally obvious upon inspection.

- Mature lesions may include small calcifications (phleboliths).
- LM
 - Present differently depending on size
 - Large lesions are rubbery, skin-colored, massive nodules with ill-defined borders, most often located in the head, neck, axilla, or chest (cystic hygromas in older, less preferred nomenclature).
 - Lesions in the neck area may be associated with respiratory compromise if the airway is constricted.
 - Microcystic LM present as nodules or plaques, sometimes in clusters, with overlying skin changes such as discoloration. Complicated lesions may be hemorrhagic or leak translucent lymph fluid.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnosis is usually made by recognition of the typical physical exam findings.

Imaging

- Occasionally helpful in distinguishing vascular tumors like IH from VaM but primarily useful in determining subtype and extent of VaM for treatment planning
- For multifocal IH, abdominal ultrasound to rule out hepatic involvement should be ordered.
- Preoperative MRI/MRA, CT angiography, or venography aids in treatment planning of VaM.

Diagnostic Procedures/Other

- Biopsy: rarely required but may be helpful to differentiate lesions suspicious for malignancy; should be avoided if lesion is highly suspected to be vascular, as significant bleeding may ensue
- Other diagnostic tests should be considered if concerns for syndromes or other complications (e.g., cardiac or respiratory compromise) exist.

TREATMENT

GENERAL MEASURES

- Infantile hemangiomas

- Most patients will not need treatment, as lesions will spontaneously involute without complications.
- Consider treatment of lesions interfering with critical organ functions, such as vision or breathing, or lesions significantly affecting appearance, such as on the face.
- Timing of surgical treatment of IH should be carefully determined to minimize the risk of undesirable cosmetic outcome. Surgery during the proliferative phase in infancy is rare. Most surgery is performed between 3 and 6 years of age.
- Propranolol, given orally at 2 mg/kg/24 h in divided doses (range 1–3 mg/kg/24 h) is now accepted as 1st-line therapy for IH.
- Oral corticosteroids (generally given as prednisolone at 2–3 mg/kg/24 h) are now 2nd-line treatment.
- Topical timolol maleate 0.5% gel-forming solution or solution (ophthalmic dosage forms used topically) may be used for small, superficial IH.
- Interferon may be useful in refractory or severe lesions. The development of spastic diplegia in up to 20% of treated infants (highest risk group is <12 months of age) is a known complication and has drastically limited modern use of this therapy.
- Vincristine is another 3rd-line therapy and is rarely used.
- For ulcerated IH, petrolatum, zinc oxide paste, and topical dressings are used; pulsed dye laser may be used. Propranolol has been shown to speed ulcer healing.
- VaM
 - Pulsed dye laser
 - ▢ The treatment of choice for port-wine stains and other superficial VaM
 - ▢ Serial treatments over several years may be necessary. Large lesions may not completely respond.
 - ▢ Better outcomes are noted in children treated in infancy and early childhood.
 - Sclerotherapy or surgery may be appropriate for complicated, symptomatic VaM.

ISSUES FOR REFERRAL

Consider referral to specialty services if the following conditions are present:

- Lesions in locations where function may be impacted such as periorbital, ear canal, tip of nose, lips, or anogenital areas
- Lesions distributed in a “beard-like” distribution, which may be associated with airway IH
- Presence of numerous cutaneous lesions increasing the likelihood of visceral involvement (including the GI tract, liver, CNS, lungs)
- Lesions causing or likely to cause significant disfigurement
- Lesions located over the lumbosacral spine, which may be associated with spinal dysraphism
- Lesions located in a segmental distribution about the head and face
- Large AVMs impacting circulation and cardiac function (e.g., resulting in high-output heart failure)
- Presence of dysmorphic features along with vascular lesions
- Lesions that are ulcerating or bleeding
- Suspected VaM of unknown type or extent

ONGOING CARE

PATIENT EDUCATION

Vascular Birthmarks Foundation (www.birthmark.org)

PROGNOSIS

- Infantile hemangiomas
 - All IHs undergo spontaneous involution. By 9–10 years of age, 90% will have completed involution. Greater than 85% will resolve without need for treatment.
 - Residual areas of skin atrophy and/or discoloration occur in up to 50%.
 - Complicated lesions marked by ulceration result in scarring.
- VaM
 - VaM do not generally involute or resolve.
 - Salmon patches fade over time and generally are not a cosmetic problem.

- Port-wine stains may darken and become nodular with age; bleeding can occur.
- Larger lesions can be associated with excessive growth of the involved body area resulting in hypertrophy.
- Malignant transformation is rare.

COMPLICATIONS

- Infantile hemangiomas
 - Bleeding, ulceration, superinfection
 - Interference with function of important organs (including vision, airway, GI tract, CNS)
 - Disfigurement
 - Hypothyroidism may occur with large hemangiomas that stimulate increased breakdown of thyroid hormone.
 - KHE and TA may be associated with Kasabach-Merritt phenomenon with severe thrombocytopenia (due to platelet trapping, consumptive coagulopathy, and microangiopathic hemolytic anemia).
- VaM
 - High-output cardiac failure due to circulatory “steal” associated with AVMs
 - Skeletal overgrowth of the involved limb can occur with disfigurement and orthopedic complications.
 - Limitation of movement and pain from localized ischemia
 - Problems associated with lymphedema
 - Airway compromise from constriction by large neck lesions

- Q27.9 Congenital malformation of peripheral vascular system, unsp
- Q27.30 Arteriovenous malformation, site unspecified

FAQ

- Q. When will the IH go away?
- A. Growth in nearly all IH stops by 12 months of age. Regression occurs over a period of years, with most involution occurring in the first 3 years of life; further regression will occur until about age 10 years.
- Q. Is the risk of bleeding in IH significant?
- A. No. Risk of significant bleeding is less than 1%. Even with ulceration, bleeding is more of an “ooze.”

HEMATURIA

Stephanie Nguyen • Jennifer Yang

BASICS

DESCRIPTION

- Hematuria is defined as ≥ 3 –5 RBCs per high-power field (hpf) using a standard urinalysis technique on a centrifuged sample.
- Persistent hematuria: hematuria on >2 separate examinations
- Macroscopic or gross hematuria: hematuria visible to the naked eye
- Microscopic hematuria: hematuria detected by urinalysis or microscopy only

EPIDEMIOLOGY

- Asymptomatic microscopic hematuria (on >1 sample): 0.5–2% of school-aged children
- Gross hematuria: 0.13% children in walk-in clinic
- Gross hematuria is more common in boys.

RISK FACTORS

Hematuria, hypercalciuria, nephrolithiasis, and nephritis can be inherited.

PATHOPHYSIOLOGY

Bleeding can occur from anywhere along the urinary tract or kidney. In glomerular hematuria, RBCs cross the glomerular basement membrane (GBM) into the urinary space.

DIAGNOSIS

No identifiable cause is found in the majority (up to 80%) of children with asymptomatic microscopic hematuria and in up to 30% of children with a single episode of gross hematuria.

DIFFERENTIAL DIAGNOSIS

Hematuria may originate at any site along the urinary tract. Nonglomerular

causes are more common than glomerular causes.

- Factitious causes: Urine appears bloody, but no RBCs are present.
 - Endogenous pigments
 - Myoglobin (rhabdomyolysis)
 - Hemoglobin (hemolysis)
 - Porphyrin
 - Bile pigments
 - Urate crystals (pink diaper syndrome)
 - Beets, blackberries
 - Exogenous pigments
 - Food and beverage dyes
 - Drugs that cause urinary discoloration:
 - Phenazopyridine (Pyridium)
 - Senna (Ex-Lax)
 - Rifampin
 - Sulfa
 - Others
 - *Serratia marcescens*
- Glomerular causes
 - Common:
 - Strenuous exercise
 - Acute postinfectious glomerulonephritis (GN)
 - IgA nephropathy
 - Thin basement membrane disease (benign familial hematuria)
 - Uncommon:
 - Alport syndrome, hereditary nephritis
 - Membranoproliferative GN
 - Nephritis of systemic disease (Henoch-Schönlein purpura [HSP], systemic lupus, or other vasculitis)
- Nonglomerular causes
- Upper urinary tract
 - Common:
 - Pyelonephritis
 - Hypercalciuria/nephrolithiasis/nephrocalcinosis
 - Renal trauma (contusion), particularly in hydronephrotic or cystic

- kidneys
 - Ureteropelvic junction obstruction
 - Hemoglobinopathies (sickle cell disease, sickle cell trait)
- Uncommon:
 - Drug-induced interstitial nephritis (penicillins, cephalosporins, NSAIDs, phenytoin, cimetidine, omeprazole)
 - Cystic disease (simple cyst, polycystic kidney disease)
 - Neoplasm: Wilms tumor
 - Coagulopathy
 - Renal venous thrombosis, renal arterial thrombosis
 - “Nutcracker” phenomenon
- Lower urinary tract
 - Common:
 - Bladder catheterization, Foley catheter
 - Cystitis (bacterial, viral, occasionally chemical)
 - Perineal trauma or irritation
 - Urethrorrhagia
 - Meatal stenosis
 - Urethritis
 - “Terminal hematuria” syndrome (trigonitis)
 - Epididymitis
 - Uncommon:
 - Bladder tumor
 - Arteriovenous malformation
 - Polyp
 - Urethral or bladder trauma
 - Foreign body or calculus in bladder or urethra
 - Schistosomiasis
- External causes of “hematuria”
 - Menstrual contamination
 - Diaper rash, perineal irritation

APPROACH TO THE PATIENT

Evaluate all children with gross hematuria and those children with microscopic hematuria confirmed on 2 of 3 consecutive samples over several weeks:

- Phase 1: Determine if the pigment in urine is from blood or another source. Are RBCs present on microscopy?
- Phase 2: Determine the source of bleeding: glomerular or nonglomerular, kidney or urinary tract?
- Phase 3: Select those who will require referral versus those who will simply require follow-up.

HISTORY

- **Question:** Blood on voiding?
- Significance: Glomerular or renal source will be constantly bloody; urethral bleeding is more likely at initiation or end of stream.
- **Question:** Prior episodes of gross hematuria or abnormal urinalyses?
- Significance: Chronic versus acute process
- **Question:** Antecedent infection, streptococcal pharyngitis, or impetigo?
- Significance: Suggests postinfectious GN
- **Question:** Concurrent upper respiratory infection (URI) or gastroenteritis?
- Significance: Suggests IgA nephropathy
- **Question:** Any precipitating factors (trauma, exercise)?
- Significance: Renal contusion, exercise hematuria, or myoglobinuria
- **Question:** Voiding symptoms, dysuria, urgency, frequency?
- Significance: Suggests bacterial or viral (adenovirus) hemorrhagic cystitis
- **Question:** Renal colic or other pain?
- Significance: Suggests stones or other obstructive process
- **Question:** Drops of blood or spotting in underwear after or between voiding in prepubertal boys?
- Significance: Suggests urethrorrhagia
- **Question:** Fever, rash, arthritis?
- Significance: Signs or symptoms of systemic illness or immune-mediated process
- **Question:** Bleeding from any other source (i.e., gums, GI tract)?
- Significance: Suggests coagulopathy
- **Question:** Symptom-less “terminal” hematuria?
- Significance: Suggests trigonitis, hemorrhagic cystitis

- **Question:** Medications and diet?
- Significance: Food or drug pigment, drug nephrotoxicity
- **Question:** Sexually active? STD?
- Significance: Urethritis, epididymitis
- **Question:** Family history?
- Significance:
 - Hematuria in family members: Familial hematuria, kidney failure, or premature deafness suggests Alport syndrome.
 - Sickle cell disease or trait in child or family members: Suggests sickle nephropathy, papillary necrosis, or hemoglobinuria
 - Renal stone disease in family members: Suggests renal stones, hypercalciuria, or metabolic disease
 - Cystic kidney disease in family members: Autosomal recessive or autosomal dominant polycystic kidney disease

PHYSICAL EXAM

- **Finding:** Head, ears, eyes, nose, throat (HEENT) exam (periorbital edema)?
- Significance: GN, renal failure, volume overload
- **Finding:** Cardiovascular exam (hypertension, tachycardia, murmur, gallop)?
- Significance: GN, renal failure, volume overload
- **Finding:** Abdominal exam (ascites, organomegaly, tenderness, or masses)?
- Significance: Volume overload, tumor, polycystic or hydronephrotic kidneys, venous thrombosis
- **Finding:** Back exam (flank tenderness)?
- Significance: Pyelonephritis, renal calculi, large cysts
- **Finding:** Genital exam (blood at urethral meatus, normal urethral opening)?
- Significance: Urethral trauma, meatal stenosis
- **Finding:** Perineal exam (skin breakdown, irritation)?
- Significance: External source of bleeding or infection
- **Finding:** Extremities (pretibial edema, arthritis)?
- Significance: GN, volume overload, systemic illness
- **Finding:** Skin and mucosal exam (petechial, vasculitic rash,

ulcerations)?

- **Significance:** Systemic illness (lupus, HSP)

DIAGNOSTIC TESTS & INTERPRETATION

Positive test for blood on urine dipstick may be myoglobin or hemoglobin. If the urinary sediment does not show RBCs, investigate for problems such as rhabdomyolysis (elevated creatinine phosphokinase [CPK]) or hemolysis.

- **Test:** Repeated urinalysis to confirm persistent microscopic hematuria
- **Significance:**
 - Patient should be told not to exercise before the urine collection.
 - 2 of 3 positive specimens over several weeks should be documented in an otherwise well child before diagnostic testing is initiated.
- **Test:** Gross and microscopic analyses of fresh urine specimen
- **Significance:**
 - Absence of RBCs suggests factitious hematuria.
 - Dysmorphic RBCs suggest glomerular source.
 - Eumorphic RBCs suggest nonglomerular source/collecting system etiology.
 - RBC casts: Diagnostic for GN
 - WBCs suggest cystitis.
 - WBC casts suggest pyelonephritis.
- **Test:** Screening of the family members for occult hematuria
- **Significance:** Familial benign hematuria or Alport syndrome
- **Test:** Testing for hypercalciuria (random urine calcium/creatinine ratio >0.2 mg/mg in children >6 years; >0.6 in children 6–12 months; >0.8 in children <6 months)
- **Significance:** If elevated, 24-hour urine calcium collection >4 mg/kg/day in children >2 years of age: Hypercalciuria
- **Test:** Culture
- **Significance:** Bacterial, viral—cystitis, *S. marcescens*, adenovirus
- **Test:** Serum electrolytes, BUN, and creatinine levels
- **Significance:** Impaired renal function suggests inflammation, infection, or obstruction.
- **Test:** Evaluation for GN
- **Significance:**

- Hematuria with RBC casts in combination with proteinuria, edema, hypertension, and/or impaired renal function
- Streptococcal serology (ASO titer, streptozyme): Acute postinfectious GN
- Complement studies (C3,C4): Hypocomplementemic GN—immune complex-mediated (lupus nephritis, postinfectious GN, membranoproliferative GN)
- Antinuclear antibody (ANA) titer or anti-double-stranded DNA if hypocomplementemic or signs of systemic vasculitis: Vasculitis (lupus)
- Quantitation of proteinuria and serum albumin concentration
 - 3–4+ proteinuria, urine protein/creatinine ratio >2 mg/mg, and hypoalbuminemia suggest glomerular disease/nephrosis.
 - 24-hour urine protein \geq 1 g/day
- **Test:** CBC with platelets, coagulation times
- **Significance:** May suggest hemolysis, clotting disorder, or systemic illness
- **Test:** Hemoglobin electrophoresis should be considered in black patients.
- **Significance:** Sickle cell disease or sickle trait may cause hematuria.
- Rarely, additional studies, such as voiding cystourethrogram, renal angiography, cystoscopy, and renal biopsy, will be required with an appropriate referral to urology or nephrology.
- Audiometry and ophthalmologic exam may be indicated if hereditary (Alport) nephritis is suspected; should be performed on boys with familial hematuria

Imaging

Every child with gross hematuria should have imaging of the kidneys and urinary tract. It may or may not be indicated in children with microscopic hematuria.

- Ultrasound of kidneys and bladder: urinary tract obstruction, congenital malformation, cysts, stones, nephrocalcinosis, malignancy
- Abdominal CT scan: after trauma if there are >50 RBCs/hpf; if mechanism (deceleration injury, multiple organ injury) or signs or symptoms (flank pain or ecchymosis) are significant, even if <50

RBC/hpf

- Helical CT without contrast: study of choice for the visualization of stones; however, must consider radiation exposure risk. Ultrasound is reasonable first test for stones.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- For children with microscopic hematuria, in the absence of other clinical, laboratory, or imaging findings, no specific treatment is indicated besides routine follow-up.
- For children with glomerular hematuria, treatment depends on the histopathologic diagnosis, clinical features, renal function, and degree of proteinuria.
- For children with an anatomic/structural etiology, treatment is specific to abnormality.

ISSUES FOR REFERRAL

- Nephrology: recurrent gross hematuria, proteinuria, RBC casts, nephrosis, edema, hypocomplementemia, hypertension, azotemia, cysts, hypercalciuria, family history of renal failure, hereditary nephritis, deafness, or cystic kidney disease
- Urology: congenital anomaly of urinary tract, uncontrollable bleeding after trauma, recurrent, painful or large stones, recurrent urinary infections
- Hematology: bleeding secondary to coagulopathy or sickle cell disease papillary necrosis

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

A healthy child with asymptomatic isolated hematuria and a negative

workup should be reassessed annually with a complete physical exam, measurement of BP, and urinalysis. If hematuria is persistent, periodic assessment of renal function should also be performed. The development of significant proteinuria, hypertension, elevated creatinine, family history of renal failure, or other concerns should prompt evaluation by a pediatric nephrologist.

PROGNOSIS

- Most children with asymptomatic isolated microscopic hematuria detected on a well-child examination, without proteinuria, hypertension, or azotemia, will NOT be found to have serious underlying pathology and will simply require longitudinal follow-up.
- Many children with hematuria will not have an identifiable cause; however, long-term prognosis is still generally good.
- Children with asymptomatic microscopic or gross hematuria combined with proteinuria have a higher likelihood of glomerular disease.
- Children with a history of stones or hypercalciuria are at increased risk of developing renal stones in the future.
- Familial hematuria secondary to thin GBM disease is a diagnosis of exclusion. Although it often has a benign prognosis, in some families, it can progress to chronic kidney disease. Children should be examined yearly for the development of proteinuria or hypertension.

BASICS

DESCRIPTION

Premature destruction of RBCs, either intravascularly or extravascularly, leading to a shortened red cell survival time. The premature destruction can be caused by intrinsic factors (defects within the RBC itself) or extrinsic factors (factors outside the RBC leads to premature destruction).

EPIDEMIOLOGY

Incidence depends on the cause of hemolysis.

ETIOLOGY

Table 1. Common mechanisms of hemolysis

Acquired (extrinsic) disorders	Hereditary (intrinsic) disorders
Infectious	Hemoglobinopathies
Drug induced	RBC membrane defects
Immune mediated	RBC enzyme defects
Microangiopathic	

RISK FACTORS

- Acquired (extrinsic): ABO and/or Rh incompatibility is a risk factor in the newborn period.
- Hereditary (intrinsic): Although many hereditary disorders are autosomal dominant, 20% of these patients represent new spontaneous mutations and have no affected family members.

GENERAL PREVENTION

- Acquired (extrinsic): Most causes of acquired, non–transfusion-related hemolytic disease are not preventable.
- Hereditary (intrinsic): Although there is no way to prevent hereditary forms of hemolysis, newborn screening can help identify and allow

proper management of some of these conditions. Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency should be counseled to avoid triggers such as fava beans, broad beans, and mothballs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Acquired (Extrinsic)

- Allergic/inflammatory/immune
 - Autoimmune hemolytic anemia
 - Warm antibody mediated
 - Cold antibody mediated
 - Hemolytic transfusion reaction
- Congenital/anatomic
 - ABO blood type incompatibility and Rh incompatibility between infant and mother
 - Cardiac lesions with turbulent flow; left-sided more common than right-sided
 - Prosthetic heart valve (especially aortic)
 - Kasabach-Merritt syndrome
 - Hypersplenism
- Infectious
 - Congenital infections with syphilis, rubella, cytomegalovirus, and toxoplasmosis
 - Malaria
 - Bartonellosis
 - Clostridium perfringens (via a toxin)
 - Mycoplasma pneumoniae
 - HIV
 - Hemolytic uremic syndrome
- Toxic, environmental, drugs
 - Immune complex “innocent bystander” mechanism
 - Quinidine
 - Acetaminophen
 - Amoxicillin

- Cephalosporins
 - Isoniazid
 - Rifampin
- Immune complex drug adsorption mechanism
 - Penicillin
 - Cephalosporins
 - Erythromycin
 - Tetracycline
 - Isoniazid
- Drug-induced autoimmune hemolytic anemia: alpha-methyldopa
- Toxic drug-induced hemolysis: ribavirin (generally mild and not clinically significant)
- Snake and spider venoms
- Extensive burns
- Mechanical hemolysis
 - Cardiac hemolysis
 - Abnormal microcirculation
 - Thrombotic thrombocytopenic purpura (TTP)
 - Disseminated intravascular coagulation (DIC)
 - Malignant hypertension
 - Eclampsia
 - Hemangiomas
 - Renal graft rejection
 - March hemoglobinuria (prolonged physical activity)
- Tumor
 - Lymphomas
 - Thymoma
 - Lymphoproliferative disorders

Hereditary (Intrinsic)

- Genetic/metabolic
 - RBC membrane defects
 - Hereditary spherocytosis (HS)
 - Hereditary elliptocytosis
 - Pyropoikilocytosis
 - Paroxysmal nocturnal hemoglobinuria (can be acquired)

- Enzyme defects
 - PK deficiency
 - G6PD deficiency
- Thalassemias (β -thalassemia major is the most severe)
- Hemoglobinopathies
 - Sickle cell anemia (Hgb SS and SC variants)
 - Unstable hemoglobins

ALERT

Factors that constitute an emergency:

- Hemoglobin <5 g/dL, especially with signs of cardiovascular compromise
 - Attempts to stabilize cardiovascular compromise with volume should be undertaken with care because hemodilution may occur.
 - Transfusion may be riskier in autoimmune hemolysis because of potential problems with cross-matching.
- Renal failure may accompany severe hemolysis in TTP or hemolytic uremic syndrome.
- Hemolysis in the neonatal period secondary to ABO or Rh incompatibility may require exchange transfusion either for anemia or for hyperbilirubinemia.

APPROACH TO THE PATIENT

General goal is to establish existence of hemolysis rather than other causes of anemia, such as blood loss and hypoproduction.

- **Phase 1:** Determine acuity and severity of the anemia and hemolysis:
 - With acute onset, there will be evidence of unstable vital signs and possibly heart failure.
 - Parents may give a history of a rapid deterioration of the child's physical and/or mental state.
 - Patients with chronic anemia that has progressed slowly may have a low hemoglobin yet be well compensated with fairly normal vital signs (except for tachycardia).
 - CBC with a corrected reticulocyte count will help determine if there is an appropriate bone marrow response to the level of anemia and, therefore, whether the process is hypoproduative or hemolytic.

- **Phase 2:** Determine the cause of hemolysis. Treatment approaches will vary depending on the underlying etiology.

HISTORY

- Hemoglobinuria is a sign of intravascular hemolysis, whereas pallor, fatigue, and jaundice may occur with either intravascular or extravascular hemolysis.
- **Question:** History of anemia, splenectomy, or early cholecystectomy in multiple family members?
 - While many hereditary membrane defects and enzyme deficiencies are autosomal dominant, some are autosomal recessive or X-linked. Thus, a negative familial history does not always rule out these diagnoses.
 - In some cases, the diagnosis of HS has not been made, yet multiple family members have had their gallbladders removed at an early age, which may indicate the presence of this defect.
 - Thalassemia (especially β -thalassemia) and sickle cell anemia may present in early childhood with chronic hemolysis with or without a familial history.
- **Question:** History of travel?
 - Malaria is endemic to Africa, India, and parts of Central America.
- **Question:** Drugs and diet history?
 - Specifically ask about exposure to fava beans, mothballs, and antibiotics. Drugs can themselves cause hemolysis or can induce hemolysis if there is an underlying disorder such as G6PD deficiency.
- **Question:** Age at first signs and symptoms of hemolysis (pallor or jaundice)?
 - Hereditary causes of hemolysis are most often chronic or recurrent, although the diagnosis may be delayed until the child is older if the process is mild.
 - Acute, acquired hemolytic disorders may also recur.

PHYSICAL EXAM

Hemolysis that is a secondary problem (e.g., related to infection, tumors) may be found incidentally during evaluation of the primary process.

- **Finding:** Acute processes such as autoimmune hemolytic anemia (both warm and cold antibody mediated) may present with a child in extremis.
 - Tachycardia is a common finding in nearly all cases of acute hemolysis.
 - BP instability is a late finding.
- **Finding:** More chronic processes, such as HS, G6PD, PK deficiencies, thalassemia intermedia, and sickle cell disease, may be picked up at well visits or by laboratory examination.
 - These children often appear well (except for jaundice) but may become more anemic with an acute illness.
- **Finding:** Splenomegaly (often impressive) and hepatomegaly are common findings in extravascular hemolysis.
 - Hepatomegaly may be more pronounced if the child is in heart failure due to acute, severe anemia.
 - Splenomegaly may be either the cause of or, more frequently, a result of a hemolytic process.
 - If significant lymphadenopathy is present, look for an underlying cause such as lymphoproliferative disorders or malignancy.
- **Finding:** Skin changes
 - Pallor is nearly a universal finding in acute hemolysis and in exacerbations of chronic hemolysis.
 - Jaundice is more common in intravascular hemolysis.
 - Presence of ecchymoses or petechiae suggests DIC or thrombocytopenia.

DIAGNOSTIC TESTS & INTERPRETATION

- CBC with differential and reticulocyte count
 - Interpret level of anemia and the reticulocyte count together. Chronic hemolysis in HS, for example, may have a nearly normal hemoglobin count but usually has an increased reticulocyte count.
 - With a rapid fall in hemoglobin, as in acute autoimmune hemolytic anemia, the reticulocyte count may be low at the start, rise in response to anemia, and fall during recovery.
 - Thrombocytopenia should raise suspicions about TTP or hemolytic uremic syndrome.

- Peripheral blood smear
 - Fragmented RBCs, schistocytes, and helmet cells are seen in DIC, TTP, hemolytic uremic syndrome, and cardiac valve hemolysis.
 - Helmet or bite cells are nearly pathognomonic for G6PD deficiency.
 - Other findings on the smear that may be helpful are spherocytes (HS and warm autoimmune hemolytic anemia), target cells (hemoglobin C and thalassemias), and acanthocytes (anorexia nervosa).
- Bilirubin
 - Total and unconjugated bilirubins are elevated in most cases.
- Urinalysis
 - Hemoglobinuria is present in intravascular hemolysis; established by a urine dipstick positive for heme with no intact red cells microscopically
 - Myoglobinuria can also give this picture.
- Coombs test
 - Direct Coombs test (direct antiglobulin test) detects antibodies or complement fragments present on the patient's RBCs.
 - Indirect antiglobulin test detects antibodies in the patient's serum that can bind normal RBCs.
 - Direct antiglobulin test provides direct evidence of immune-mediated hemolysis.
 - Warm antibody autoimmune hemolytic anemia is caused by an IgG antibody that coats RBCs, which are subsequently removed by the spleen.
 - Cold antibody autoimmune hemolytic anemia is caused by an IgM antibody that binds RBCs, fixes complement, and can cause both extravascular and intravascular hemolysis.
- Haptoglobin, hemopexin, and lactate dehydrogenase (LDH)
 - In intravascular hemolysis, haptoglobin levels may be undetectable, hemopexin is reduced, and LDH increased.
 - In extravascular hemolysis, haptoglobin is decreased (but detectable) and LDH may be increased but not to the level seen in intravascular hemolysis.
- Bone marrow aspiration

- Rarely indicated, but if done, erythroid hyperplasia may be seen.
- Blood for diagnostic RBC enzyme or hemoglobinopathy studies must be drawn prior to transfusion.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Red cell transfusion may be indicated for symptomatic anemia regardless of cause: Rate and volume of blood to be transfused will depend on severity of anemia and speed of onset (generally slower transfusion rate needed in chronic anemia).
- Plasmapheresis for TTP
- Withdrawal of inducing drug/agent (G6PD)

ISSUES FOR REFERRAL

- Most patients with severe, acute hemolysis or an underlying chronic hemolytic disorder will need to be evaluated by a hematologist.
- Suspected RBC membrane and enzyme defects, as well as hemoglobinopathies, should be referred for initial evaluation.

Admission Criteria

Unstable vital signs with acute hemolysis, significant exacerbation of chronic hemolysis

CODES

ICD10

- D58.2 Other hemoglobinopathies
- D59.1 Other autoimmune hemolytic anemias
- P58.9 Neonatal jaundice due to excessive hemolysis, unspecified

FAQ

- Q: When are blood transfusions indicated in patients with active hemolysis?
- A: Patients with severe, acute hemolysis that is causing cardiovascular compromise may require a transfusion if the process cannot be stopped with standard therapy (e.g., steroids for warm autoimmune hemolytic anemia, plasmapheresis for TTP). Transfusions must be given slowly if the hemolytic process has been chronic and the patient's blood volume is expanded.
- Q: Can hemolysis always be identified on a peripheral blood smear?
- A: No. Schistocytes, fragments, spherocytes, targets, and other morphology may provide clues to specific diagnoses but are not always present. The presence of a hemolytic process is inferred from a fall in hemoglobin, rise in the reticulocyte count, and elevation of the bilirubin and LDH levels.

HEMOLYTIC DISEASE OF THE NEWBORN

Janice E. Hobbs • Maureen M. Gilmore

BASICS

DESCRIPTION

A hemolytic anemia in newborns due to the destruction of fetal and newborn RBCs by maternal antibodies passively transferred across the placenta; primarily related to ABO blood group or RhD incompatibility

EPIDEMIOLOGY

- ABO incompatibility
 - Occurs in 12% of first pregnancies
 - Only 10–20% become significantly jaundiced, requiring phototherapy.
- Rh incompatibility
 - Incidence of Rh hemolytic disease: 6–7/1,000 live births
 - Prevalence of RhD positive (RhD+) fetus in RhD negative (Rh–) mother: 15%
 - RhD(–) status in 15% of white, 7–8% of black and Hispanic, and 2% of Asian persons
 - 48–55% are heterozygous (Dd)
 - 35–45% are homozygous (DD)
 - Of all Rh-sensitized pregnancies:
 - 9% require intrauterine transfusion.
 - 10% are delivered early and require newborn exchange transfusion.
 - 31% require treatment after a full-term delivery.
 - 50% require no treatment.

RISK FACTORS

- Type O mother pregnant with either type A, B, or AB fetus
- RhD(–) mother becomes pregnant with an RhD(+) fetus; D-antigen is inherited from the father.
- Omitted or failed RhIG (anti-D) prophylaxis

- Only a fraction of women at risk develop antibodies.

GENERAL PREVENTION

- Rh incompatibility: RhIG is given to an RhD(–) woman after any exposure to RhD(+) blood.
 - RhIG is also known by trade names RhoGAM and HyperRHO.
 - Given at 28 weeks, 34 weeks (prophylaxis), and within 72 hours of birth, or following, for example, amniocentesis, abortion, antepartum bleeds
- No prophylaxis for HDN caused by other blood group incompatibilities.

PATHOPHYSIOLOGY

- Isoimmunization—general principles:
 - Passage of fetal RBCs into maternal circulation occurs as a result of asymptomatic transplacental hemorrhage.
 - Initial sensitization of mother from fetomaternal hemorrhage can occur with placental abruption, abortion, ectopic pregnancy, or procedures (CVS, amniocentesis, or cordocentesis).
 - Exposure triggers maternal immune response (anti-D antibodies).
 - Maternal IgG antibodies (Ab) cross the placenta and bind to fetal RBCs. Coated RBCs are then destroyed in the reticuloendothelial system, primarily the spleen.
 - Isoimmunization may lead to hyperbilirubinemia, severe anemia, and potentially hydrops.
 - Extramedullary hematopoiesis in the fetal liver and spleen is a response to severe fetal anemia, leading to hepatosplenomegaly.
- ABO isoimmunization
 - Occurs in type O mothers with a type A or B fetus; clinically a milder hemolysis compared to Rh incompatibility and rarely requires intervention
 - 1% of type O mothers have high titers of IgG Ab against both A and B that cross the placenta and cause HDN.
 - Hemolysis due to anti-A is more common.
 - Hemolysis due to anti-B can be more severe and may require exchange transfusion in the newborn.

- Rh isoimmunization
 - Passage of RhD(+) fetal RBCs which cross the placenta into the circulation of an Rh(–) mother
 - RhD(–) state is the absence of D antigens on RBCs.
 - Decreased risk of RhD sensitization of mother if fetus is also ABO incompatible
 - Rh isoimmunization rarely occurs in first pregnancy.

ETIOLOGY

- Fetomaternal hemorrhage, usually asymptomatic, with maternal immune response to foreign fetal RBC antigens
- Most common systems involved: ABO blood group antigens, with mild HDN, and RhD antigens, with more severe HDN
- 1% of cases involve other RBC antigens, such as Kell, Kidd, Duffy, or MNS blood groups.

DIAGNOSIS

HISTORY

- Maternal exposure to incompatible blood products
- Previous stillbirths and/or abortions
- Neonatal hyperbilirubinemia requiring exchange transfusion in previous pregnancy
- RhIG not given after previous pregnancy or abortion

PHYSICAL EXAM

- Milder cases—hyperbilirubinemia only
- Minimal jaundice at birth but rapidly develops within 24 hours
- Pallor, tachycardia, tachypnea due to CHF secondary to severe anemia
- Generalized edema and massive hepatosplenomegaly in cases with severe anemia and hydrops

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Antenatal
 - ABO and Rh blood typing of all mothers at first prenatal visit

- Indirect Coombs test: detects anti-D Ab in maternal serum
- Father's ABO and Rh type and zygosity (D/D or D/d)
- Fetal blood group typing from amniotic fluid or fetal cord blood
- Fetal blood sample to assess degree of anemia in severe cases
- Neonatal
 - Cord blood or neonate red blood cells for ABO and Rh types
 - Hemoglobin (Hgb), hematocrit (Hct), bilirubin (direct and indirect), reticulocyte count
 - Direct Coombs test: detects maternal anti-D Ab already bound to fetal/newborn RBCs
 - Kleihauer-Betke test or flow cytometry: estimates proportion of fetal RBCs in maternal circulation
 - Peripheral smear: nucleated RBCs (spherocytes in ABO disease)

Imaging

- Fetal ultrasound (estimate fetal size, weight, and organomegaly)
- Doppler ultrasonography of fetal middle cerebral artery: peak systolic velocity

Diagnostic Procedures/Other

- Fetal cordocentesis (for fetal anemia)
- Amniocentesis

Pathologic Findings

- Kernicterus
- Extramedullary hematopoiesis
- Hepatosplenomegaly

DIFFERENTIAL DIAGNOSIS

- Hydrops fetalis
 - Hematologic: α -thalassemia, severe G6PD deficiency, twin-to-twin transfusion
 - Cardiac: hypoplastic left heart syndrome, myocarditis, endocardial fibroelastosis, heart block
 - Congenital infections: parvovirus, syphilis, cytomegalovirus (CMV), rubella
 - Renal: renal vein thrombosis, urinary tract obstruction, nephrosis
 - Placental: umbilical vein thrombosis, true knot of umbilical cord

- Genetic: trisomy 13, 18, 21; triploidy; aneuploidy
- Other: diaphragmatic hernia

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Antenatal
 - Serial fetal monitoring
 - Intrauterine RBC transfusion: for severely affected fetuses (fetal Hct <25–30%) where early delivery is not possible; usually performed after 20 weeks gestation
 - Early delivery and neonatal resuscitation may be required if with severe HDN.
 - For high-risk fetus after amniocentesis or history of a prior stillbirth or hydrops
- Neonatal
 - Phototherapy, IV hydration, and serial bilirubin monitoring begins immediately.
 - Exchange transfusion: removes sensitized fetal RBCs and circulating bilirubin and also
 - Corrects anemia in severely anemic infants
 - Removes circulating antibodies
- Indications for early exchange transfusion:
 - Cord blood bilirubin >3 mg/dL and Hgb <13 g/dL
 - Bilirubin rising at rate >1 mg/dL/h despite optimal phototherapy
 - Indirect bilirubin ≥20–25 mg/dL or rising to reach that level
 - Hgb of 11–13 g/dL and bilirubin rising at rate >0.5 mg/dL/h despite optimal phototherapy
 - Lower indirect bilirubin triggers are used in preterm or high-risk infants.
- In hydropic infants, immediate partial exchange may be needed to correct anemia and CHF.
- Double-volume exchanges may be needed for hyperbilirubinemia.
- Selection of blood for exchange transfusion:

- Fresh, washed, CMV-safe, and irradiated, hemoglobin S negative
- For Rh disease: type O, Rh(–) cross-matched against mother's blood
- For ABO disease: type O, Rh(–) or Rh compatible cross-matched against mother or infant's serum
- For other antibodies: antigen-negative RBCs selected to avoid the clinically significant antibody. ABO type-specific blood can be used if baby's type confirmed.
- Risks of exchange transfusion include prolonged neutropenia, thrombocytopenia, late anemia, metabolic abnormalities, arrhythmias, thrombosis, and death.
- Most infants with ABO incompatibility require no treatment or phototherapy only.
- Some infants with milder Rh isoimmunization may have only exaggerated physiologic anemia at 8–12 weeks.
- Avoid drugs that interfere with bilirubin metabolism or its binding to albumin (e.g., sulfonamides, caffeine, and sodium benzoate).

ISSUES FOR REFERRAL

Late anemia: Infants who had HDN are at risk due to reticulocytopenia related to persistent high titers of circulating maternal antibody. Small-volume RBC transfusion may be required.

ADDITIONAL THERAPIES

- Intravenous immunoglobulin (IVIG): in some studies shown to diminish hemolysis and may prevent the need for exchange transfusion
- Oral iron supplementation
- Erythropoietin, with iron, may be used to support infants at high risk for late anemia.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Hct and reticulocyte count every 1–2 weeks for first 2–3 months, especially for infants who had exchange transfusion, due to risk of late

anemia at 8–12 weeks

- Assess for neurodevelopmental delays or neurologic injury.

PROGNOSIS

- ~50% of affected infants have minimal anemia and hyperbilirubinemia and require either no treatment or phototherapy only.
- ~25% with severe HDN will require exchange transfusions.
- Hydropic infants have an ~30% mortality rate.

COMPLICATIONS

- Hydrops fetalis
- Stillbirths
- Kernicterus

CODES

ICD-10

- P55.1 ABO isoimmunization of newborn
- P55.0 Rh isoimmunization of newborn
- P55.8 Other hemolytic diseases of newborn

FAQ

- Q: Why does the Rh isoimmunization become worse with each

pregnancy?

- A: Most sensitizing fetomaternal hemorrhages occur at delivery. In the first exposure, mother produces IgM Ab, which does not cross the placenta; IgG Ab slowly develops. In second or subsequent pregnancies, repeat exposure to even small amounts of fetal RhD causes rapid production of IgG anti-D, which crosses the placenta and attacks fetal RBCs. Other antibodies, such as Kell, may result in severe HDN even in a first pregnancy.
- Q: Can maternal blood be used to transfuse the affected baby?
- A: Washed maternal blood may be used, but donor infectious disease testing protocols would need to be followed so it would not be routinely available in an emergency situation.
- Q: How does IVIG work, and does it decrease the need of an exchange transfusion?
- A: HDN occurs by destruction of RBCs via an antibody-dependent cytotoxic mechanism mediated by Fc receptors of the neonatal reticuloendothelial system. IVIG nonspecifically blocks these Fc receptors, decreasing hemolysis. In a 2009 Cochrane analysis of IVIG in HDN, results showed a significant decrease in the need for exchange transfusion in those treated with IVIG.

HEMOLYTIC UREMIC SYNDROME

Erica Winnicki • Marsha Lee

BASICS

DESCRIPTION

- HUS is characterized by the triad of acute kidney injury, thrombocytopenia, and hemolytic anemia with fragmentation of erythrocytes (schistocytes noted on peripheral smear).
- Kidney dysfunction may manifest as hematuria and/or proteinuria and/or azotemia.
- HUS is one of the leading causes of acute kidney injury in infants and young children.
- ~90% of childhood cases are associated with Shiga toxin, primarily Shiga toxin–producing *Escherichia coli* (STEC-HUS, or typical HUS), and follow a diarrheal prodrome. *Shigella dysenteriae* is also a well-recognized infectious cause.
- The term “atypical HUS” is used for non-STEC HUS and primarily refers to familial, complement-mediated HUS but encompasses a variety of sporadic causes of HUS including malignancies, *Streptococcus pneumoniae* infection, organ transplantation, pregnancy, collagen vascular disorder, or drugs such as calcineurin inhibitors and antiplatelet agents.
- Atypical forms of HUS have a worse outcome than STEC-HUS.

EPIDEMIOLOGY

- STEC-HUS
 - Tends to occur in the summer months and may be sporadic or occur in epidemic outbreaks
 - Occurs mainly in older infants and young children, between 6 months and 5 years of age
- Atypical HUS
 - Has no seasonal variation and can occur at any age (including early infancy); may be sporadic or familial

GENERAL PREVENTION

- STEC is primarily found in the intestine of ruminants, particularly cattle, and can be transmitted by undercooked beef, unpasteurized milk, or by contamination of water and produce.
- For adequate prevention, practice good hand hygiene, wash food well, and cook food, especially meat, thoroughly.

PATHOPHYSIOLOGY

- Vascular endothelial cell injury is central to the pathogenesis of all forms of HUS.
- STEC colonize colonic mucosa, adhere to mucosal villi, and release Shiga toxin (Stx).
- Stx enters the systemic circulation, where it causes endothelial cell injury via inflammation, upregulation of chemokine and cytokine production, and by binding to endothelial cell surface receptors (Gb₃) and interrupting protein synthesis.
- Endothelial cell injury exposes the thrombogenic basement membrane, causing platelet activation and local intravascular thrombosis.
- In vitro studies show that glomerular endothelial cells and proximal tubular epithelial cells have receptors with very high affinity for the Stx.
- Atypical HUS is caused by dysregulation of the alternate complement pathway.

ETIOLOGY

- STEC-HUS: Most cases are caused by the O157:H7 strain of E. coli.
 - STEC most commonly infects children from 6 months to 5 years of age in the summer and the fall. The primary reservoir is cattle.
 - A negative stool culture in a patient who has HUS does not rule out STEC.
- Atypical HUS: Mutations of complement regulatory proteins are identifiable in ~60% of cases, with either an autosomal dominant or recessive inheritance. Reported mutations include complement factor H (most frequent), I, and B; membrane cofactor protein; and C3. Autoantibodies to complement factor H have also been reported.
- One of the common causes of sporadic non–STEC-HUS is

Streptococcus pneumoniae infection.

DIAGNOSIS

HISTORY

- GI prodrome: STEC-HUS typically develops 5–13 days after the onset of diarrhea (usually bloody). There can be associated vomiting and fever.
- Symptoms of pneumonia or meningitis: *S. pneumoniae*–associated HUS is associated with severe disease.
- Consumption of undercooked meat, particularly hamburger; consumption of unpasteurized milk, cheese, or juice; consumption of raw seed sprouts
- Direct animal contact (petting zoos)
- Family history of HUS (reported in up to 20% of patients with atypical HUS)
- Note that atypical HUS may be triggered by mild infections; presence of diarrhea does not exclude the diagnosis of atypical HUS.

PHYSICAL EXAM

- Pallor and petechiae
- Dehydration secondary to the gastroenteritis
- Edema
- Pulmonary edema (volume overload)
- Hypertension
- Irritability
- Behavioral changes

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
 - Anemia (Coombs negative), thrombocytopenia ($<150,000/\text{mm}^3$), leukocytosis (often seen in typical HUS)
- Blood smear: schistocytes
- Markers of hemolysis:

- Elevated LDH, circulating free hemoglobin, decreased haptoglobin, elevated unconjugated bilirubin, increased reticulocyte count
- Renal function: elevated BUN and serum creatinine
- Serum electrolytes
 - Hyperkalemia (hypokalemia can be observed with severe GI involvement), metabolic acidosis, hyponatremia, hypocalcemia, hyperphosphatemia
- Serum albumin: usually low due to enteral losses and/or hypercatabolic state
- Amylase/lipase: elevated with pancreatic involvement
- Stool culture
 - Should be screened for *E. coli* O157:H7
 - Preferably <6 days after the onset of diarrhea
 - The local health department should be notified of any isolates.
- Identification of Stx from stool

Imaging

- Plain film of the abdomen often demonstrates colonic distension and may show evidence of bowel perforation.
- Barium enema may show “thumb-printing” secondary to bowel wall edema and submucosal bleeding.

Pathologic Findings

Renal biopsy shows thrombotic microangiopathy: hyaline thrombi involving the glomerular capillaries and afferent arterioles with swelling of endothelial cells.

DIFFERENTIAL DIAGNOSIS

- Sepsis
- Diffuse intravascular coagulation
- Vasculitis
- Thrombotic thrombocytopenic purpura (TTP)
- Severe hemolytic anemia
- Malaria

TREATMENT

GENERAL MEASURES

- Treatment of HUS is generally supportive. The mainstay of therapy involves the following:
 - Strict fluid balance
 - Nutritional support
 - Control of hypertension
 - Treatment of seizures

MEDICATION

- Antihypertensives
 - Vasodilators, such as calcium-channel blockers or hydralazine, are useful in the acute phase.
 - After recovery, if a patient persists with hypertension and/or proteinuria, then ACE inhibitors are indicated.
- In patients with seizures, diazepam or lorazepam is preferred. In patients with recurrent seizures or cerebral infarcts, long-term anticonvulsant therapy is indicated.
- Treatment with insulin may be needed in patients with pancreatic necrosis.
- Antibiotics are not indicated for treatment of STEC but would be indicated for patients with invasive bacterial infections or abscesses.
- Avoid antiperistaltic agents for treatment of colitis.

ADDITIONAL TREATMENT

- Renal replacement therapy
 - Intermittent or continuous hemodialysis or peritoneal dialysis
 - For severe acidosis, fluid overload, electrolyte imbalance, or uremia (required in ~2/3 of patients with STEC-HUS).
- Treatment of severe anemia
 - Packed RBCs are transfused slowly if the hemoglobin decreases below 6 g/dL (BP can increase during transfusion).
- Platelet transfusion
 - Indicated only if there is active bleeding and severe thrombocytopenia or the patient needs surgery or invasive procedure (as platelet transfusion can contribute to microthrombi formation).

ADDITIONAL THERAPIES

- Plasma exchange should be initiated in atypical (complement mediated) forms of HUS.
- Eculizumab, a humanized anti-C5 monoclonal antibody that inhibits complement activation, is approved for treatment of atypical HUS. Patients on this medication are at increased risk of serious bacterial infections, including meningococcal infection.
- Patients with typical or atypical forms of HUS who progress to end-stage renal disease should be considered for kidney transplant. Depending on the genotype, patients with atypical HUS should also be considered for liver transplant.

SURGERY/OTHER PROCEDURES

Some patients can have extensive bowel necrosis requiring resection.

INPATIENT CONSIDERATIONS

IV Fluids

Any fluid deficit should be corrected, and additional fluids should be limited to ongoing losses (insensible water loss plus urine and/or GI losses).

Monitoring

Patients generally require ICU-level care. Along with frequent laboratory monitoring and assessment of fluid balance, frequent neurologic assessments should be performed.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Resolution is usually heralded by a rise in platelet count and a gradual decrease in the frequency of blood transfusions.
- Pancreatic insufficiency may persist, requiring long-term insulin therapy beyond resolution of acute illness.

DIET

- Adequate nutritional support is important due to the hypercatabolic state of these patients.
- Enteral feeding should be trialed if GI symptoms are not severe, and

total parenteral nutrition is used in patients with severe GI involvement.

- Close attention should be paid to fluid, sodium, potassium, and phosphorus intake.
- Some patients can have pancreatic involvement with subsequent exocrine or endocrine pancreatic insufficiency.

PROGNOSIS

- Patients with STEC-HUS can be mildly or severely affected. ~25% of survivors demonstrate long-term renal sequelae such as proteinuria, hypertension, and chronic kidney disease.
 - Mildly affected patients do not develop anuria, almost never have seizures, are rarely hypertensive, do not require dialysis, and have an excellent outcome.
 - Severely affected patients develop anuria and require dialysis, develop hypertension, and may have seizures.
 - They can also progress to end-stage renal disease.
 - Recurrence after kidney transplantation is very uncommon.
- Atypical HUS is associated with a poor prognosis, with mortality in up to 25% of patients and end-stage renal disease in 50% of patients.

COMPLICATIONS

- GI
 - Acute colitis is usually transient.
 - Rectal prolapse, toxic megacolon, bowel wall necrosis, intussusception, perforation, and stricture
 - Pancreatic involvement may result in pancreatitis or insulin-dependent diabetes mellitus.
- CNS
 - CNS involvement occurs in 20–25% of patients and may be acutely life threatening.
 - Most patients have mild CNS symptoms that include irritability, lethargy, and behavioral changes.
 - Major symptoms such as stupor, coma, seizures, cortical blindness, posturing, and hallucinations may also occur. Thrombotic or hemorrhagic stroke may occur.

- Cardiac: Cardiomyopathy may occur.
- Musculoskeletal: rarely, rhabdomyolysis

CODES

ICD10

D59.3 Hemolytic-uremic syndrome

FAQ

- Q: What factors should raise concern for atypical HUS?
- A: Age <6 months at presentation, insidious onset, relapsing disease, or failure to identify STEC or Stx in the stool
- Q: How many patients with gastroenteritis from E. coli O157:H7 will develop HUS?
- A: 10–15%
- Q: What should the family tell the day care staff and neighbors?
- A: If the patient has enteropathic HUS, contacts should be informed that any episodes of gastroenteritis merit close follow-up for evidence of anemia, thrombocytopenia, and kidney injury. No prophylaxis is indicated. Exclusion of infected children from day care centers until 2

consecutive stool cultures are negative for *E. coli* O157:H7 has been shown to prevent additional transmission.

HEMOPHILIA

Char Witmer

BASICS

DESCRIPTION

- Hemophilia A is factor VIII deficiency, and hemophilia B is factor IX deficiency.
- Deficiency or absence of factor VIII or factor IX leads to a delay and disruption of blood clotting that results in prolonged bleeding.
- The severity of bleeding depends on the baseline percentage of clotting activity.

EPIDEMIOLOGY

- Most common severe inherited bleeding disorder
- Distribution
 - Hemophilia A: 80–85%
 - Hemophilia B: 10–15%
- No geographic or ethnic associations

Incidence

- Hemophilia A: 1 per 5,000 male births
- Hemophilia B: 1 per 30,000 male births

RISK FACTORS

Genetics

- X-linked recessive disorder
- Daughters of fathers with hemophilia are obligate carriers for the hemophilia gene mutation. An obligate carrier has a 50% chance of passing the hemophilia gene mutations to her offspring.
- Carrier status and prenatal testing available
- Hemophilia A
 - The intron 22 inversion mutation in the factor VIII gene is found in ~40–50% of patients with severe hemophilia A.
- Hemophilia B
 - Most factor IX gene defects are single base pair changes that result

in missense, frameshift, or nonsense mutations. Mutations have been detected in all regions of the factor IX gene.

GENERAL PREVENTION

- Prophylaxis: the regularly scheduled infusion of clotting factor concentrate with the goal of preventing bleeding episodes; primarily used in patients with severe disease
- Anticipatory guidance and prevention
 - Good dental hygiene
 - Immunizations: no intramuscular injections; give subcutaneously with a small-gauge needle and apply direct pressure.
 - Rapid treatment of hemarthrosis to avoid chronic joint damage
 - Avoidance of contact sports (e.g., football, hockey, rugby)
 - Encourage physical fitness to ensure strong muscles to maintain joint health and prevent joint bleeding.
 - Head trauma precautions

PATHOPHYSIOLOGY

- Both factors VIII and IX are crucial for normal thrombin generation via the intrinsic pathway. The absence or decrease in activity of either protein severely impairs the ability to generate thrombin and fibrin.
- Hemophilia patients do not bleed more rapidly; rather, there is delayed formation of an abnormal clot resulting in prolonged bleeding.

DIAGNOSIS

HISTORY

- Family history
 - Familial history of hemophilia in male offspring of female blood relatives is present in only 70% of cases.
- Excessive bleeding in a male neonate
 - Excessive bleeding with circumcision may be an initial presentation of hemophilia, although only 50% of patients with hemophilia will bleed with circumcision.
 - Muscle bleeding from intramuscular injections (e.g., vitamin K or immunizations); presents as increasing swelling at the site of

injection

- Prolonged bleeding from a torn frenulum, venipuncture, or heel puncture can be seen.
- 3.5–4% of neonates with hemophilia may present with an intracranial hemorrhage.
- Pattern of bleeding in severe hemophilia
 - Characterized by easy, excessive, and palpable bruising with normal activity, spontaneous joint and muscle hemorrhages, and prolonged hemorrhage after trauma or surgery
- Age of onset of bleeding
 - Bleeding events occur frequently when the child begins to crawl and walk or with the eruption of teeth.
 - Patients with mild hemophilia may not present until they are older.
- Location of hemarthroses
 - Large weight-bearing joints are most often involved: knees, ankles, and hips.
 - Other non-weight-bearing joints can be involved including elbows and shoulders.
- Early symptoms of a hemarthroses:
 - Aura of tingling or warmth, visible swelling
 - Followed by increasing pain and decreasing range of motion (ROM) and inability to bear weight

PHYSICAL EXAM

Joint exam

- Acute hemarthrosis: limitation and pain with ROM, warmth, swelling, tenderness
- Chronic joint changes: crepitus, decreased ROM, synovial hypertrophy, bony abnormalities, and proximal muscle weakness
- Intramuscular hemorrhage: may not have external bruising; pain with motion and swelling; discrepancy in limb circumference
- Distal extremity neurovascular compromise can be a sign of compartment syndrome from bleeding into the forearm.

DIAGNOSTIC TESTS & INTERPRETATION

ALERT

- Neonates have a normal physiologic reduction in the vitamin K–dependent factors, including factor IX, making a determination of the degree of factor IX deficiency difficult in the neonatal period. The factor IX level must be confirmed after 6 months of age.
- When interpreting coagulation testing in a neonate, neonatal normal values for the PT and aPTT are different from those in adults.

Lab

Patients with hemophilia either A or B will have a normal PT and a prolonged aPTT. Assay for factor VIII and factor IX levels:

- <1%: severe hemophilia, characterized by spontaneous bleeding, hemarthroses, and deep tissue hemorrhages
- 1–5%: moderate hemophilia; bleeding following mild to moderate trauma; seldom spontaneous hemorrhage
- 5–30%: mild hemophilia; bleeding only from trauma

DIFFERENTIAL DIAGNOSIS

- Isolated prolonged aPTT associated with increased bleeding tendency:
 - von Willebrand disease
 - “Acquired hemophilia” owing to an inhibitory antibody to factor VIII or IX (extremely rare in children)
 - Hereditary factor deficiency of either VIII, IX, or XI
- Prolonged aPTT without increased bleeding tendency:
 - Factor XII deficiency
 - High-molecular-weight kininogen deficiency
 - Prekallikrein deficiency
 - Antiphospholipid antibody
 - Heparin artifact
 - Underfilling of the specimen tube

TREATMENT

MEDICATION

Acute bleeding episodes:

- Factor replacement
 - Factor VIII replacement products

- Recombinant, non-plasma-derived factor VIII
 - Plasma-derived, monoclonal antibody-purified factor VIII concentrate; heat or solvent detergent treated for viral inactivation
 - Cryoprecipitate (rarely used)
- Factor IX replacement products
 - Recombinant, non-plasma-derived factor IX
 - Plasma-derived, immunoaffinity-purified factor IX concentrate; heat or solvent detergent treated for viral inactivation
 - Fresh frozen plasma (rarely used)
- Calculation of dose for pediatrics:
 - Recombinant factor VIII dosing (units) = % desired rise in plasma factor VIII \times body weight (kg) \times 0.5
 - Recombinant factor IX dosing (units) = % desired rise in plasma factor IX level \times body weight (kg) \times 1.4
- Target factor levels:
 - Joint bleed: 30–50% for 24–48 hours
 - Large muscle bleed: 70–100% for 24–48 hours
- CNS bleeding: 80–100% maintained for 10–14 days
- Desmopressin (DDAVP)
 - Synthetic vasopressin analog that stimulates release of endogenous factor VIII and von Willebrand factor
 - Only suitable for patients with mild or moderate factor VIII deficiency who have shown a response to DDAVP in a trial
 - Tachyphylaxis (unresponsiveness) may occur with repeated dosing.
 - Hyponatremia may also occur. Fluid restriction is recommended after each dose. Should not be used in neonates.
- Antifibrinolytic therapy (aminocaproic acid or tranexamic acid)
 - Antifibrinolytic therapy is used to stabilize a clot by inhibiting the normal process of clot lysis by the fibrinolytic system.
 - Used for the treatment of oral hemorrhages and to minimize bleeding from dental and some surgical procedures

ADDITIONAL TREATMENT

General Measures

- Joint hemorrhage

- Factor replacement
- Immobilization: splints, casts, crutches, and/or bed rest (24–48 hours)
- Prolonged immobilization may reduce recovery of joint ROM.
- Initiation of physical therapy with factor coverage may be recommended, particularly after joint surgery.
- Special bleeding situations
 - Intracranial hemorrhage
 - Significant bleeding can occur despite a minor mechanism of head injury and the absence of external bruising.
 - In severe hemophilia, spontaneous intracranial bleeding can occur.
 - Factor replacement to 100% should be administered immediately followed by the diagnostic evaluation.
 - Major surgery
 - Factor replacement to 100% preoperatively and postoperatively
 - Regular dosing of factor for a minimum of 1 week postoperatively, even in mild hemophilia
 - Compartment syndrome
 - Bleeding within the fascial compartments of muscles
 - Most often occurs in the forearm
 - Neurovascular compromise can lead to shortening of the forearm muscles and clawlike deformity of the hand (Volkmann contracture).
 - Iliopsoas bleed
 - Lower abdominal or upper thigh pain may be the first symptom.
 - Exam is notable for inability to extend hip with preservation of internal and external rotation (allows distinction from hemarthrosis of hip joint).
 - Diagnosis confirmed by ultrasound or CT scan
 - Treat with factor replacement and bed rest.
 - Oral bleeding/epistaxis
 - Constant pressure for 15–20 minutes
 - Aminocaproic acid or tranexamic acid
 - Topical thrombin directly to the site of bleeding

- Factor replacement if these measures don't work.
- Dental care
 - Factor replacement is required for significant dental procedures like tooth extraction or procedures that require a mandibular block.
 - Factor replacement is not required for routine teeth cleaning.
- Lacerations
 - Factor replacement is necessary at time of placement and removal of the sutures.
- Hematuria
 - Increased fluid intake and bed rest as initial treatment
 - If hematuria persists 24–48 hours, 30–40% factor replacement
 - Antifibrinolytics are contraindicated in the setting of hematuria because of the concern of obstructive uropathy from excessive clot formation.
- Patients should be followed regularly at a comprehensive hemophilia treatment center.

INPATIENT CONSIDERATIONS

Initial Stabilization

Life-threatening hemorrhages

- Prompt therapy with clotting factor concentrate should start immediately and prior to any diagnostic procedures.
 - CNS bleeding
 - Bleeding into and around the airway
 - Exsanguinating hemorrhage

ONGOING CARE

COMPLICATIONS

- Complications of disease:
 - Hemophilic arthropathy: Repeated joint hemorrhages lead to synovial thickening and joint cartilage erosion. Joint space becomes narrowed and eventually fuses. Patients can develop joint contractures, limited ROM, and chronic pain.

- Complications of therapy:
 - Inhibitors: antibodies against factor VIII or IX, which can inactivate infused factor. This is currently the most significant complication in hemophilia and is associated with significant morbidity and decreased quality of life. Bleeding episodes are treated with less effective bypassing agents (activated prothrombin complex concentrates or activated recombinant factor VIIa).
 - Anaphylaxis: seen primarily with infusions of factor IX

CODES

ICD10

- D66 Hereditary factor VIII deficiency
- D67 Hereditary factor IX deficiency
- D68.1 Hereditary factor XI deficiency

FAQ

- Q: Are there any medications contraindicated in a child with hemophilia?
- A: Aspirin should not be given as it interferes with platelet function. NSAIDs cause a milder effect on platelets and should also be avoided when possible. Patients with hemophilia should use acetaminophen for

fever or pain.

- Q: Can immunizations be given to a child with hemophilia?
- A: To prevent bleeding from immunizations, they can be given SQ (instead of IM) with the smallest gauge needle available. Ice or cold packs should be applied to the area to minimize hematoma formation.

HEMOPTYSIS

Stamatia Alexiou • Suzanne E. Beck

BASICS

DESCRIPTION

- Hemoptysis is the expectoration of blood from the respiratory tract. The term comes from the Greek words haima, meaning blood, and ptysis, meaning spitting.
- Bleeding from the respiratory tract can range from blood-streaked sputum to massive hemoptysis from the lung. The amount and nature of bleeding should be characterized by taking a careful history.
- The source of bleeding can be anywhere in the respiratory tract, from the nose to the alveolus.
- Consequences of hemoptysis may include exsanguination, hypoxemia, and anemia, or there may be none.

EPIDEMIOLOGY

Large series of pediatric patients with massive hemoptysis have not been described. Most instances of massive hemoptysis take place in older children, usually with an underlying cardiac abnormality.

PATHOPHYSIOLOGY

- Related to the underlying pulmonary or cardiac disease
- Vascular origin of hemoptysis is from 2 locations:
 - Pulmonary arteries: higher volume, lower pressure
 - Bronchial arteries: lower volume, higher pressure

ETIOLOGY

- More common causes:
 - Infection (pneumonia, bronchitis, viral illnesses)
 - Bronchiectasis
 - Cavitary infections (e.g., tuberculosis, abscess, histoplasmosis)
 - Cystic fibrosis
 - Congenital heart disease with collateral vessels or pulmonary

- hypertension
- Foreign body aspiration
- Tracheostomy-related complications
- Trauma (pulmonary contusion, bronchoscopy, airway manipulation)
- Aspiration
- Less common causes:
 - Factitious hemoptysis
 - Congenital vascular or airway lesions (pulmonary arteriovenous malformation, hemangioma, bronchogenic cyst, pulmonary sequestration)
 - Hemorrhagic diathesis, including anticoagulant therapy
 - H-type tracheoesophageal fistula
 - Pulmonary embolism
 - Pulmonary hemosiderosis
 - Tumors (teratomas, lymphomas)
 - Immune mediated: Henoch-Schönlein purpura, Goodpasture syndrome, Wegener granulomatosis, polyarteritis nodosa, systemic lupus erythematosus, Heiner syndrome
 - Sarcoidosis

DIAGNOSIS

HISTORY

- Associated symptoms vary and may include cough, chest pain, rhinorrhea, or dyspnea, or there may be none.
- Distinguish the source of bleeding: nose, mouth, gastrointestinal (GI) tract versus lungs:
 - Bleeding from the nose and mouth may be associated with recurrent episodes, recent trauma, or pain at the site and is usually self-limited.
 - Bleeding from the GI tract may be associated with vomiting, history of gastritis, or abdominal pain.
 - Bleeding from the lungs may be associated with chest discomfort or sensations, shortness of breath, or coughing.
 - Blood from the GI tract is often darker and acidic, whereas blood

from the airway tends to be bright red and alkaline or pink and frothy.

- Determine amount of bleeding:
 - Massive: >240 cc in 24 hours or >100 cc per day for several days
 - Minor: smaller volumes
 - Life-threatening hemoptysis is typically defined as greater than 8 cc/kg/day
- Determine associated symptoms/conditions:
 - Familial history of pulmonary disease or bleeding disorder
 - Systemic symptoms (weight loss, may indicate tumor)
 - Exposure to environmental toxins (mold or flood-damaged homes)
 - Exposure to tuberculosis
 - Medication/drug use: cocaine, marijuana, propylthiouracil
 - Recurrent episodes of cough associated with blood-tinged sputum or hemoptysis suggests underlying bronchiectasis or chronic pulmonary infection.
 - Acute pleuritic chest pain raises the possibility of pulmonary embolism with infarction or other pleural lesion.

PHYSICAL EXAM

- Respiratory distress or hypoxemia: indicates significant ventilation–perfusion mismatch due to airspace disease, shunt due to pulmonary embolism, or acidosis due to hypovolemia from blood loss
- Pallor: indicates anemia or poor perfusion
- Pleural friction rub: may be associated with pulmonary embolism
- Loud 2nd heart sound: suggests primary pulmonary hypertension, mitral stenosis, or Eisenmenger syndrome
- Localized wheeze over a major lobar airway: suggests an intramural lesion such as hemangioma, foreign body, or carcinoma
- Presence of a murmur over the lung fields: may suggest pulmonary arteriovenous malformation
- Clubbing: indicates the presence of underlying pulmonary disease such as cystic fibrosis, congenital cardiovascular disease, bronchiectasis, or liver disease

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Complete blood count, reticulocyte count, and coagulation profile: may indicate the degree of blood loss or evidence of a bleeding diathesis
- Comprehensive metabolic panel: to determine hepatic and renal function, acid–base status
- Sputum for bacterial culture, Gram stain, and acid-fast bacilli
- Purified protein derivative (PPD) testing
- Drug screen: if appropriate
- Electrocardiogram: to determine presence of right ventricular hypertrophy
- Erythrocyte sedimentation rate and C-reactive protein can help identify the chronicity of the bleed.
- Antinuclear antibodies (ANA), antineutrophil cytoplasmic antibody (ANCA), and antibodies to double-stranded DNA (anti-dsDNA) can help identify an immune-mediated etiology.

Imaging

- Chest radiograph, both anteroposterior and lateral
 - May reveal pleural effusion, bronchiectasis, foreign bodies, or consolidation
 - Fleeting alveolar infiltrates suggest pulmonary hemorrhage.
- Computed tomography (CT)
 - Useful when chest radiographs and fiberoptic bronchoscopy are normal
 - High-resolution CT may identify an area of bleeding, especially if bronchiectasis and arteriovenous malformation are suspected.
 - A CT angiography is helpful to directly visualize the vessel during interventional treatment.
- Ventilation–perfusion scans: helpful if a pulmonary embolism or infarct is suspected

Diagnostic Procedures/Other

- Flexible fiberoptic bronchoscopy
 - Usually performed to localize the site of bleeding; preferred over rigid bronchoscopy to identify a distal or alveolar bleed
 - If a bronchoalveolar lavage is performed, the presence of hemosiderin-laden macrophages can help identify the time of onset

because they usually appear 48 hours after the onset of bleeding and can remain present for up to several weeks following the event.

- Rigid bronchoscopy is preferred for removal of foreign objects or masses in the proximal airway. The wide lumen provides airway stabilization and a means to ventilate the patient during the procedure.

DIFFERENTIAL DIAGNOSIS

- Infections
 - Pneumonia
 - Pulmonary abscess
 - Tuberculosis
 - Bronchitis
- Pulmonary disease
 - Cystic fibrosis
 - Bronchiectasis
 - Foreign body aspiration
 - Arteriovenous malformation
 - Congenital lung malformation
 - Pulmonary emboli
 - Pulmonary hemosiderosis
 - Alveolar capillaritis
 - Aspiration
 - Isolated unilateral pulmonary agenesis
 - Bronchogenic cysts
- Cardiovascular disease
 - Congenital heart malformations
 - Pulmonary hypertension
- Collagen vascular disease
 - Systemic lupus erythematosus
 - Vasculitis
 - Goodpasture disease
 - Wegener granulomatosis
 - Heiner syndrome
- Trauma
- Coagulation disorder
- Other

- Munchausen syndrome
- Pseudohemoptysis (red-colored sputum secondary to *Serratia marcescens* production of red pigment)
- Neoplasms
- Hemangiomas

TREATMENT

GENERAL MEASURES

- Initial management is supportive and should be aimed at identifying the underlying cause.
- Blood loss should be replaced using colloidal solutions (i.e., normal saline, Ringer lactate) until red blood cells become available.
- Methods used to stop localized bleeding:
 - Tamponade with balloon-tipped catheter
 - Ice water lavage
 - Local instillation of epinephrine
 - Catheter-directed umbilication
 - IV vasopressin
 - Bronchial artery embolization
 - Surgical resection is usually reserved for the most difficult cases such as extensive collateralization of bronchial arteries or arteriovenous malformations unresponsive to embolization.
 - Other techniques include endoscopic instillation of fibrinogen/thrombin and endobronchial argon plasma coagulation.

ONGOING CARE

PROGNOSIS

- Depends on the etiology and severity of hemoptysis
- Immediate airway management reduces morbidity and mortality.

COMPLICATIONS

- Respiratory insufficiency
- Acute airway obstruction

- Hypovolemic shock
- Anemia
- Pneumonia
- Death

- P26.9 Unsp pulmonary hemorrhage origin in the perinatal period

HENOCCH-SCHÖNLEIN PURPURA

Blaze Robert Gusic

BASICS

DESCRIPTION

- Henoch-Schönlein purpura (HSP) is an immunologically mediated, purpuric, nonthrombocytopenic, and systemic vasculitis involving the small blood vessels of the skin, gastrointestinal (GI) tract, joints, and kidneys.
- Defined by the presence of 2 of the following:
 - Palpable purpura (without thrombocytopenia)
 - Age of onset <20 years
 - Abdominal pain
 - Granulocytic infiltration of vessel walls
 - In children, only palpable purpura with normal platelet count needs be documented.
 - Although most children do have purpura, colicky abdominal pain, and arthritis, up to 1/2 may present with symptoms other than purpura.

EPIDEMIOLOGY

Incidence

- Incidence of 13.5 cases per 100,000 school-aged children per year (90% of patients are <10 years)
- Most common acute vasculitis in childhood
- Slight male predominance

RISK FACTORS

Genetics

Familial history of IgA-related disorders or inherited defects in complement (C2, C4 deficiency) may predispose to HSP.

PATHOPHYSIOLOGY

- Considered to be an immune-mediated vasculitic disorder involving

primarily IgA, specifically subclass IgA1

- IgA from mucosal B cells interacts with IgG to form immune complexes that activate the alternate pathway of the complement system.
- Circulating IgA is deposited in the affected organs, causing the inflammatory process.
- Capillaries, arterioles, and venules are affected in HSP as opposed to polyarteritis nodosa, granulomatosis with polyangiitis (Wegener granulomatosis), and systemic lupus erythematosus (SLE), where small arteries are affected.
- Biopsy of the involved kidneys shows endocapillary proliferative glomerulonephritis involving endothelial and mesangial cells. Crescent formation may also be present. IgA, IgG, C3, and fibrin are commonly found in the mesangial regions.

ETIOLOGY

- No single etiologic agent has been identified.
- Most cases are associated with preceding upper respiratory tract infections (URIs), usually group A β -hemolytic streptococci. A recent study shows a significant association with *Bartonella henselae*. Also reported following infections with parvovirus, adenovirus, hepatitis A virus, *Helicobacter pylori*, and *Mycoplasma pneumoniae*; parvovirus B19 previously proposed, but evidence is inconclusive
- Also reported after drug ingestion (e.g., thiazides) and insect bites

DIAGNOSIS

HISTORY

- Previous illness: especially infections such as hepatitis, URI, and streptococcal infections
- Abdominal pain
 - Pain is the most common GI tract symptom and may precede the rash by up to 2 weeks.
 - 2/3 of children have GI tract symptoms. Emesis and melena are also reported.

- Transient, nondeforming, nonmigratory arthritis of knees, ankles, wrists, elbows, and digits is a frequent problem and most common in knees and ankles.
- Presence of testicular pain or scrotal swelling, headache, cough, and hematuria suggests vasculitic lesions in the associated system.

PHYSICAL EXAM

- Pay particular attention to blood pressure: Hypertension is common.
- Low-grade fever is present in 50% of the cases.
- Rash that is petechial or purpuric in a pressure-dependent symmetric distribution, usually around the lateral malleoli of the ankles, on the ventral surfaces of the feet, and on the buttocks
- Purpura may be briefly preceded by maculopapular or urticarial lesions.
- Lesions may ulcerate or present as hemorrhagic bullae.
- Joints should be examined for swelling and limitation of motion: Redness and warmth are not common. Symptoms precede the rash by up to 2 weeks in 25% of patients.
- Nonpitting subcutaneous edema of the scalp, periorbital region, hands, and feet is often noted.
- Generalized edema is more common in children <3 years of age. The edema may lead to acute hemorrhagic edema, now considered to be a variant of HSP.
- Abdomen is often tender to palpation but without rebound tenderness. Hepatosplenomegaly may be found. Because intussusception and appendicitis are possible complications, serial examinations may be necessary to determine if radiographic studies are indicated.
- Symptoms of pancreatitis may appear after the onset of the rash but may be a rare presenting symptom.
- Orchitis, where affected testicle may be tender and swollen
 - Swelling and bruising may be noted on the scrotum.
 - Testicular torsion has also been reported in HSP and may mimic orchitis.
- Neurologic changes
 - CNS involvement may present with headaches, seizures, or behavioral changes.

- Guillain-Barré syndrome has been reported.

DIAGNOSTIC TESTS & INTERPRETATION

There are no definitive diagnostic tests.

Lab

- CBC
 - Normal platelet count differentiates from thrombocytopenic purpura.
 - Hemoglobin is usually normal.
 - Leukocytosis (especially eosinophilia), may be present.
- ESR: elevated in about 60% of cases
- Prothrombin (PT) and partial thromboplastin time (PTT): normal
- IgA: often elevated in the acute phase of illness, with normal or increased IgG and IgM
- C3: normal (decreased in poststreptococcal glomerulonephritis and SLE)
- Antinuclear antibody: negative (elevated in SLE)
- Von Willebrand factor antigen elevated with active HSP due to endothelial damage
- Throat swab for group A β -hemolytic streptococci: positive in up to 75% of cases
- Serum chemistries: Elevated BUN and creatinine levels and decreased protein and albumin are seen with renal involvement.
- Urinalysis
 - Gross hematuria and proteinuria are present in many patients.
 - Proteinuria alone is rare.
 - Microscopic blood, RBCs, WBCs, and casts suggest glomerulonephritis.
- Stool guaiac: GI tract involvement may present as guaiac-positive stools, bloody stools, or melena.

Imaging

- Chest radiograph: may show interstitial lung disease
- Abdominal ultrasound: may be helpful if intussusception or appendicitis suspected
- Barium enemas are not indicated for suspected intussusception.

- They will not reduce the ileoileal intussusception common to HSP (idiopathic intussusception is usually ileocolic in location).
- Barium enema may damage or perforate the inflamed bowel.
- Testicular ultrasound if torsion of the testes or appendix testes, known complications of HSP, suspected on clinical exam

Diagnostic Procedures/Other

- Renal biopsy: With severe renal failure, a biopsy should be performed to determine the extent of disease.
- Skin biopsy: Direct immunofluorescence for IgA can be helpful in confirming the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Petechial and purpuric rashes seen in thrombocytopenia from the following:
 - Idiopathic thrombocytopenic purpura (ITP)
 - Meningococcemia
 - Rocky Mountain spotted fever
 - Leukemia
 - Hemolytic uremic syndrome (HUS)
 - Coagulopathies
- Vasculitic rashes may result from primary and secondary vasculitides.
 - Polyarteritis nodosa
 - Granulomatosis with polyangiitis (Wegener granulomatosis)
 - Infection related
 - Connective tissue diseases (e.g., SLE), Berger disease (IgA nephropathy)
 - Glomerulonephritis similar to HSP both clinically and immunologically but not associated with the skin, GI tract, or joint manifestations of HSP streptococcal glomerulonephritis
 - Infantile acute hemorrhagic edema
 - Vasculitis that presents with urticarial or maculopapular rash, which then becomes purpuric
 - It is differentiated from HSP in that it usually affects children from 4 months to 2 years of age and is not associated with systemic symptoms.

- On biopsy, IgA deposits are not as consistent a finding as with HSP.
- Juvenile idiopathic arthritis
- Rheumatic fever

TREATMENT

MEDICATIONS

- HSP usually resolves spontaneously without specific therapy.
- Analgesics and NSAIDs may be used for control of joint pain and inflammation, but salicylates and other agents that affect platelet function should be avoided if GI tract bleeding is present.
- Steroids are used for painful cutaneous edema, arthritis, and abdominal pain (2 mg/kg/24 h of prednisone until clinical resolution); however, steroids have not been shown to affect purpura or to decrease duration of disease or frequency of recurrences.
 - No consensus on management of GI and renal involvement. Oral prednisone at 2 mg/kg/24 h has shown faster resolution of abdominal pain, whereas other studies indicate that the symptoms will resolve similarly without intervention.
 - Steroids may mask associated problems such as intussusception and bowel perforation.
 - In nephritis, immediate treatment with steroids may prevent more serious renal disease; however, most will improve spontaneously. Treatment should be considered for children at high risk for chronic renal insufficiency or failure (those presenting with nephrotic syndrome or renal insufficiency).
- >50% crescentic glomerulonephritis on renal biopsy has a greater risk of future renal failure. Such cases should be considered for aggressive therapy with pulse or oral steroids and/or immunosuppressants (azathioprine, cyclophosphamide, cyclosporine) or plasmapheresis and intravenous immunoglobulin (IVIG). There are rare reports of treatment with danazol and fish oil.
- Treatment of hypertension may delay or prevent progression of renal disease in patients with glomerulonephritis.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Patients should be seen weekly during the acute illness. Visits should include history and physical exam, along with BP measurement and urinalysis. Urine spot protein-to-creatinine ratio should be followed when proteinuria is present.
- All patients, even those who did not present with renal involvement, should have urine monitored for 6 months; however, there is no consensus on frequency. Previous evidence recommended weekly for 6 months. Recent studies recommend weekly studies only for the first 2 months. This recommendation is based on findings that the risk for developing nephritis is less than 2% after 2 months. Others suggest less frequent urinalysis (day 7; day 14; then 1,3, and 6 months) may be sufficient, with more intense follow-up if renal involvement is noted.
- Women with a history of HSP should be monitored during pregnancy.

PROGNOSIS

- Generally excellent: Most (>60%) children are better within 4 weeks of the onset.
- Better prognosis associated with younger age
- Recurrence within the first 6 weeks in up to 40%, usually as rash and abdominal pain
- No laboratory or clinical findings have been found to be predictive of recurrence.
- Most have only 1–3 episodes of purpura; however, a few will continue to experience symptoms for months or years. These patients have a poor prognosis and are more likely to develop severe nephritis.
- GI tract disease accounts for the most significant morbidity in the short term.
- Renal involvement is the cause of the most serious long-term morbidity. Microscopic hematuria alone or with mild proteinuria generally has a good outcome. A nephritic and nephrotic combination is more guarded, and those patients with a high percentage of crescent

formation have worse outcomes.

COMPLICATIONS

- Persistent hypertension
- End-stage kidney disease (acute or as a late sequela)
- Intussusception (most common GI tract complication; affecting 1–5% of patients)
- Protein-losing enteropathy
- Hemorrhagic pancreatitis
- Hydrops of the gallbladder
- Strictures of the esophagus and ileus
- Bowel perforations, ischemia, and infarctions
- Pseudomembranous colitis
- Appendicitis
- Skin necrosis
- Subarachnoid, subdural, and cortical hemorrhage and infarction
- Peripheral mononeuropathies and polyneuropathies (Guillain-Barré syndrome)
- Pulmonary hemorrhage (uncommon, but may result in death)
- Torsion of the testis and appendix testes and priapism, scrotal swelling, and pain

D69.0 Allergic purpura

FAQ

- Q: When should I consider hospitalization for HSP?
- A: Often it is not necessary. Severe complications require admission. These include GI hemorrhage, orchitis, protein-losing enteropathy requiring total parenteral nutrition (TPN), decreased glomerular filtration rate (GFR) or hypertension, and pulmonary hemorrhage.
- Q: Is there a role for prophylactic penicillin?
- A: In patients with frequent relapses in whom group A β -hemolytic streptococci is often the inciting agent, administration of penicillin may be helpful.
- Q: Who are Henoch and Schönlein?
- A: The clinical finding of joint pain associated with purpura was named “purpura rheumatica” in 1837 by Schönlein. Henoch, a student of Schönlein’s, later described the association of GI tract and renal involvement. However, the 1st report was by Heberden in 1801. Of note, it has been speculated that Mozart—whose symptoms included fever, vomiting, exanthem, arthritis, anasarca, and coma—died of HSP.

HEPATOMEGALY

Sivan Kinberg • Sarah S. Lusman

BASICS

DESCRIPTION

Hepatomegaly is enlargement of the liver beyond age-adjusted normal values. It can be due to intrinsic liver disease or associated with systemic diseases seen in infants and children.

- Normal liver size
 - Depends on age, gender, and body size
 - Average liver span is 4.5–5 cm (neonates), 6–6.5 cm (12-year-old girls), 7–8 cm (12-year-old boys), and up to 16 cm (adults).

PATHOPHYSIOLOGY

- Inflammation (hepatitis)
- Excessive storage
- Infiltration
- Vascular congestion
- Biliary obstruction

DIAGNOSIS

HISTORY

Obtain a detailed history to identify potential risk factors for liver disease and to evaluate for underlying systemic disease.

- **Question:** Prenatal history suggesting possible TORCH infection or HIV infection?
 - Infections may cause hepatomegaly.
- **Question:** Prolonged hyperbilirubinemia after 2 weeks of age?
 - Could suggest biliary atresia, cystic fibrosis, alpha-1 antitrypsin deficiency
- **Question:** Developmental delay or poor growth?
 - Could suggest a metabolic disorder

- **Question:** Family history of early infant death or hepatic, neurodegenerative, or psychiatric disease?
 - Could suggest a metabolic disorder
- **Question:** Sexual activity, intravenous (IV) drug use, tattoo?
 - Risk factors for hepatitis B and C infections and HIV; also consider gonococcal perihepatitis (Fitz-Hugh–Curtis syndrome) and syphilis
- **Question:** Foreign travel?
 - Parasitic infection or liver abscess
- **Question:** Pruritus?
 - Can be a subtle sign of cholestasis
- **Question:** Contaminated shellfish?
 - Source of large outbreaks of hepatitis A
- **Question:** Previous total parenteral nutrition (TPN)?
 - Can lead to cholestasis, bile duct proliferation, fatty infiltration, and early cirrhosis
- **Question:** Medications, supplements, and recreational drug use?
 - Many commonly used medications can be hepatotoxic; ask about vitamin A, alcohol, and certain mushroom species.
- **Question:** Other chronic illnesses?
 - Heart disease: liver enlargement from CHF
 - Cystic fibrosis: related liver disease
 - Diabetes mellitus: increased glycogen secretion
 - Severe anemia: extramedullary hematopoiesis
 - Inflammatory bowel disease: increased likelihood of primary sclerosing cholangitis
 - Obesity: nonalcoholic fatty liver disease

PHYSICAL EXAM

Perform a careful physical exam to look for clues to etiology and for signs of chronic liver disease.

- **Finding:** Liver edge?
 - Children <2 years: can be normal up to 3.5 cm below costal margin; however, if >2 cm, further workup or referral may be indicated.
 - Children >2 years: normal up to 2 cm
 - Verify all suspected cases of hepatomegaly by checking the liver span.

- **Finding:** Signs of chronic liver disease?
 - Liver is usually firm and enlarged; can decrease in size with advanced disease
 - Splenomegaly, ascites, caput medusae, spider angiomas, esophageal varices, and hemorrhoids suggest portal hypertension.
 - Also look for signs of occult bleeding or bruising due to vitamin K deficiency.
- **Finding:** Tender liver?
 - May indicate hepatitis or acutely congested liver secondary to right-sided heart failure or Budd-Chiari syndrome
- **Finding:** Splenomegaly?
 - In the context of chronic liver disease, implies portal hypertension
 - In the context of other signs of viral illness, suggests acute viral hepatitis
 - In the absence of these signs, suggests storage disease or malignancy
- **Finding:** Coarse facial features?
 - Suggests mucopolysaccharidoses
- **Finding:** Kayser-Fleischer rings or cataracts?
 - Suspect Wilson disease

DIAGNOSTIC TESTS & INTERPRETATION

All patients with hepatomegaly should have a laboratory evaluation. History and physical exam should direct laboratory and further testing.

Lab

- CBC with differential
 - Thrombocytopenia may suggest portal hypertension.
- Comprehensive metabolic panel
 - Elevated aspartate aminotransferase (AST) and alanine aminotransferase (ALT) can reflect the amount of damage to hepatocytes. Elevations >1,000 IU/L indicate severe damage. ALT is more liver-specific.
 - Albumin assesses synthetic function.
 - Hyperbilirubinemia suggests cholestasis (direct hyperbilirubinemia) or hemolytic disease (indirect hyperbilirubinemia).

- Prothrombin time (PT)
 - Assesses synthetic function
 - Prolongation can occur with an acute injury or illness.
 - Can also be prolonged due to vitamin K deficiency
- Gamma-glutamyl transferase (GGT) and alkaline phosphatase
 - Elevation of GGT out of proportion to elevation in aminotransferases can indicate an obstructive or infiltrative process.
 - If an elevated GGT is associated with elevations in bilirubin, cholesterol, and alkaline phosphatase, an obstructive process is more likely.
- Ammonia level
 - Important to send on ice
 - Increasing ammonia levels, with prolonged PT, can suggest liver failure.
- Viral hepatitis serology
 - Hepatitis A IgM, hepatitis B surface antigen, hepatitis B surface antibody, hepatitis B core antibody, hepatitis C antibody
 - Should be obtained in patients with suggestive prodromal illness
- EBV and CMV IgM/IgG
- Monospot
 - Nonspecific heterophile antibody test for Epstein-Barr virus infection; can be predictive in association with an elevation of atypical lymphocytes
 - High false-negative rate in children <4
- α -Fetoprotein and carcinoembryonic antigen
 - Tumor markers for hepatoblastoma and hepatocellular carcinoma, respectively
- TORCH titers
 - Consider in newborns with hepatomegaly
- Autoimmune markers
 - Serum immunoglobulins, antinuclear antibody, anti-smooth muscle antibody, anti-liver/kidney microsomal antibody, soluble liver antigen
- Ceruloplasmin and urinary copper excretion
 - Wilson disease: decreased ceruloplasmin and increased urinary

- copper excretion
 - Consider for patients with unexplained liver disease and neurologic symptoms
- Iron, total-iron binding capacity (TIBC), ferritin
 - To assess for hemochromatosis
- Alpha-1 antitrypsin phenotype
 - To look for alpha-1 antitrypsin deficiency
 - Only send if no blood transfusion in last month

Imaging

- Abdominal ultrasound with Doppler
 - Most helpful initial study
 - Perform in all patients with acholic stools, asymmetric liver enlargement or mass
 - Can measure liver size and consistency, masses, cysts, abscesses, biliary tree abnormalities, and venous blood flow
- CT or MRI can be done for further evaluation.
- Echocardiogram to assess heart function

Pathologic Findings

Liver biopsy is often needed for definitive diagnosis.

ALERT

Refer to gastroenterologist or hepatologist if

- Unexplained or persistent elevation of liver enzymes
- Decreased synthetic function or signs of portal hypertension

DIFFERENTIAL DIAGNOSIS

Inflammation (hepatitis)

- Infections
 - Viral infections
 - Hepatitis types A–E
 - Epstein-Barr virus
 - Cytomegalovirus
 - Coxsackievirus
 - Congenital infections
 - TORCH

- ▣ HIV
- Bacterial infections
 - ▣ Hepatic abscess
 - ▣ Tuberculosis
 - ▣ Sepsis
- Parasitic infections
 - ▣ Amebiasis

- Fungal diseases
 - ▣ Candidiasis
 - ▣ Histoplasmosis
- STDs
 - ▣ Gonococcal perihepatitis
 - ▣ Syphilis
 - ▣ HIV
- Zoonotic diseases
 - ▣ Brucellosis
 - ▣ Leptospirosis
 - ▣ Bartonella henselae
 - ▣ Pasteurella multocida
- Toxic, metabolic, drugs
 - Acetaminophen
 - Alcohol
 - Corticosteroids
 - Erythromycin
 - Hypervitaminosis A
 - Iron
 - Isoniazid
 - Nitrofurantoin
 - Oral contraceptives
 - Phenobarbital
 - Valproate
- Autoimmune

- Autoimmune hepatitis
- Sarcoidosis
- Systemic lupus erythematosus

Storage disorders

- Glycogen
 - Glycogen storage disease
 - Diabetes mellitus
 - TPN
- Lipids
 - Wolman disease
 - Niemann-Pick disease
 - Gaucher disease
- Fat
 - Nonalcoholic fatty liver disease
 - Cystic fibrosis
 - Fatty acid oxidation defect
 - Mucopolysaccharidoses
 - Reye syndrome
- Iron
 - Hemochromatosis
- Copper
 - Wilson disease
- Abnormal proteins
 - Alpha-1 antitrypsin deficiency

Infiltration

- Tumors
 - Benign tumors
 - Hemangioma
 - Hemangioendothelioma
 - Mesenchymal hamartoma
 - Focal nodular hyperplasia
 - Adenoma
 - Malignant tumors
 - Hepatoblastoma
 - Hepatocellular carcinoma

- Metastatic tumors
 - Leukemia
 - Lymphoma
 - Neuroblastoma
 - Wilms tumor
 - Histiocytosis
- Cysts
 - Choledochal cysts
 - Parasitic cysts
 - Polycystic liver disease
- Amyloidosis
- Granulomatous disease
- Hemophagocytic syndromes
- Extramedullary hematopoiesis

Vascular congestion

- Intrahepatic
 - Veno-occlusive disease
 - Budd-Chiari syndrome (hepatic vein thrombosis)
- Suprahepatic
 - Congestive heart failure
 - Pericardial disease
 - Suprahepatic web

Biliary obstruction

- Biliary atresia
- Alagille syndrome
- Choledochal cyst
- Cholelithiasis
- Tumors
- Primary sclerosing cholangitis

ALERT

Indications for immediate hospitalization:

- Persistent anorexia and vomiting
- Mental status changes
- Worsening jaundice
- Relapse of symptoms after initial improvement

- Known exposure to a liver toxin
- Rising PT/INR
- Rising ammonia level
- Bilirubin >20 mg/dL
- AST >2,000
- Development of new ascites
- Hypoglycemia
- Leukocytosis and thrombocytopenia
- Hematemesis

TREATMENT

Depends on underlying etiology of hepatomegaly.

- B19.9 Unspecified viral hepatitis without hepatic coma
- K76.1 Chronic passive congestion of liver

FAQ

- Q: Why does cholestasis cause pruritus?
- A: This phenomenon probably reflects an abnormal accumulation of bile acids in the skin.

- Q: Do patients with chronic liver disease have any different nutritional needs?
- A: Yes. Patients may have impaired fat absorption and therefore may have deficiencies of fat-soluble vitamins A, D, E, and K, which can lead to visual disturbances, rickets, pathologic fractures, neuropathy, hemolytic anemia, or bleeding. Consider supplementing the diet with medium-chain triglycerides, which are more easily absorbed.
- Q: What causes TPN-associated cholestasis?
- A: It is likely multifactorial. TPN components act as toxins; bacterial endotoxins and lack of enteral feeding also play significant roles.
- Q: What conditions can mimic hepatomegaly?
- A: Riedel lobe is an extended, tongue-like, right lobe of the liver and is a normal variant. A normal liver can be displaced by pulmonary hyperinflation, subdiaphragmatic abscesses, retroperitoneal mass lesions, or rib cage anomalies.

HEREDITARY ANGIOEDEMA

Barry Pelz • Anna B. Fishbein

BASICS

DESCRIPTION

Hereditary angioedema (HAE) is an autosomal dominant condition characterized by recurrent, unpredictable, and potentially life-threatening swelling. Deficiency or dysfunction of C1 esterase inhibitor (C1-INH) leads to unregulated activation of complement and plasma kinin-forming pathways, leading to angioedema. There are 3 main classifications of HAE:

- Type I HAE: deficiency of C1-INH (~85% of patients)
- Type II HAE: dysfunction of C1-INH (~15%)
- HAE with normal C1-INH (previously called type III HAE): unclear mechanism (very rare)
- Acquired or ACE inhibitor-induced angioedema (are not HAE and will be minimally discussed here)

EPIDEMIOLOGY

- HAE type I or II
 - Prevalence between 1 in 10,000 and 150,000
 - All genders and races affected equally
 - Onset before puberty in ~50% of patients
 - Symptoms tend to worsen during puberty and persist into adulthood.
- HAE with normal C1-INH
 - Only a few families described, mostly women of childbearing age

ETIOLOGY

Genetics

- HAE type I or II
 - Autosomal dominant, high penetrance
 - 25% spontaneous mutations
 - Mutations on chromosome 11 in SERPING1 gene which codes for C1-INH

- HAE with normal C1-INH
 - Autosomal dominant, low penetrance
 - Some patients with mutation in coagulation factor XII gene

PATHOPHYSIOLOGY

- Deficiency/dysfunction of C1-INH leads to unopposed activation of the classical complement pathway, and conversion of prekallikrein to kallikrein.
- Kallikrein increases formation of bradykinin which produces angioedema.
- Histamine and other mast cell mediators are NOT involved.

COMMONLY ASSOCIATED CONDITIONS

Mildly increased risk of autoimmunity

DIAGNOSIS

Decide if symptoms consistent with HAE; if so, laboratory testing should be used to confirm the diagnosis (C4 + C1-INH antigen and function are confirmatory tests.).

SIGNS AND SYMPTOMS

Any of the following symptoms may be present:

- Recurrent “attacks” of angioedema worsening in first 24 hours, lasting 2–5 days
- Tingling sensation as prodrome to symptoms
- Abdominal pain (with possible nausea, vomiting, diarrhea) even without angioedema
- Laryngeal edema (tightness in throat, dyspnea is a late sign)

HISTORY

- Ask about potential triggers of attacks: minor trauma, emotional distress, surgery, infections, stress, menstruation, and/or pregnancy.
- Explore recurrent nature of symptoms can be intermittent or more chronic.
- Family history of angioedema

PHYSICAL EXAM

- Angioedema, nonpruritic, nonpitting
- 30% with transient serpiginous rash, erythema marginatum, on trunk/medial extremities
- Swelling of face, lips, larynx, gastrointestinal tract, genitals, and/or extremities
- Abdominal tenderness

ALERT

Be aware of laryngeal swelling in absence of facial swelling; can be severe enough to lead to asphyxiation

DIAGNOSTIC TESTS & INTERPRETATION

HAE type I or II

- C4 (natural substrate for C1-INH) and CH50 (general screen of complement) can be used as screening tests.
 - Will be very low or absent
 - CH50 needs to be sent on ice, as it will otherwise degrade, causing falsely low levels.
- C1-INH antigen (protein) level
 - Type 1 = <50% of normal value
 - Type 2 = normal
- C1-INH function
 - Type 1 = <50% of normal value
 - Type 2 = <50% of normal value
- Genetic testing available, not required to confirm diagnosis, helpful in children <1 year of age
- Lab testing should be repeated (ideally at least 1 month later) to confirm results.
- Labs preferably drawn during attacks but usually abnormal in-between episodes as well.

HAE with normal C1-INH

- Positive family history of angioedema
- Normal C4, C1-INH level and function (when drawn during an attack)
- Consider factor XII gene mutation analysis.

Acquired angioedema

- No family history of angioedema
- Low C4, C1-INH level and function usually low
- Low C1q (<50% normal)

Imaging

- Imaging rarely necessary
- Abdominal CT scan or ultrasound might demonstrate bowel wall edema in abdominal attacks.

DIFFERENTIAL DIAGNOSIS

- Allergic reactions and anaphylaxis:
 - IgE-mediated allergic reactions: drug, food, and insect allergies
 - Transfusion reactions
 - Idiopathic anaphylaxis
 - Exercise-induced anaphylaxis
- Drug-induced angioedema (particularly to ACE inhibitors or NSAIDs)
- Idiopathic angioedema—typically involves urticaria and not posterior oropharynx
- Allergic contact dermatitis
- Rheumatologic diseases (low C3 + low C4)
- Superior vena cava syndrome
- Oncologic diseases such as head and neck tumors or lymphomas
- Physical urticarias such as cold-induced urticaria, cholinergic urticaria, aquagenic urticaria, solar urticaria, pressure urticaria (or angioedema), or vibratory angioedema
- Psychological
 - Panic attacks
 - Globus sensation
 - Vocal cord dysfunction
- Presence of C4 null alleles can cause low C4 levels.

TREATMENT

MEDICATION

First Line

- C1-INH replacement protein (C1INHRP) from pooled human plasma,

rare risk of thrombosis

- Berinert
 - FDA-approved for acute attacks
 - IV dose for ≥ 6 years: 20 mg/kg or ≤ 50 kg = 1,000 U, >50 –100 kg = 1,500 U, >100 kg = 2,000 U up to 3 doses per attack
- Cinryze for prophylaxis
 - ≥ 6 years: 1,000 U IV q3–4d
- Bradykinin receptor antagonist
 - Icatibant (Firazyr)
 - ≥ 18 years: 30 mg SQ q6h up to 3 doses per 24 hours
- Recombinant plasma kallikrein inhibitor
 - Ecallantide (Kalbitor)
 - Rare risk of anaphylaxis
 - ≥ 16 years (new study used in children as young as 9 years): 30 mg SQ $\times 1$; if attack persists, an additional dose may be administered within a 24-hour period.

Second Line

- Plasma: Solvent/detergent-treated plasma or fresh frozen plasma (FFP) may be used in the setting of an acute attack if the above medications are not available.
- Attenuated androgens (danazol or stanozolol)
 - Increase production of C1-INH significantly
 - Androgenic side effects
 - No longer preferred in pediatric patients
- Plasmin inhibitors (β -aminocaproic acid or tranexamic acid)
- Recombinant C1-INH: Ruconest (Rhucin)
 - A rabbit-derived protein currently approved in Europe only
 - It may become approved for use in the United States in the near future.
- HAE symptoms do not respond to epinephrine, corticosteroids, or antihistamines.

Short-term prophylaxis

- Medications may be given prior to dental procedures, intubations, or other anticipated traumas or stressors.
- None of the therapies confer complete protection from HAE attacks, so

procedures should be performed in a setting where emergency intubation can be performed.

Long-term prophylaxis

- May be indicated for patients who have
 - Frequent and severe attacks
 - Rapid progression of attacks
 - Poor access or response to on-demand therapy for acute attacks
 - History of intubation(s) due to HAE
 - Excessive absences from work or school
 - Significant decrease in quality of life due to HAE

ISSUES FOR REFERRAL

- Any patient with angioedema should be referred to a physician with experience managing HAE.
- An allergist/immunologist can help with the evaluation, treatment, and management of these patients.

ONGOING CARE

FOLLOW-UP

- Patients should be seen at least annually.
- Education should be provided to the patient and patient's family regarding the disease.
- Testing family members should be considered.
- Care should include identification and avoidance of triggers when possible and plan in the event of an acute attack.
 - Medical identification band or wallet card
 - A written emergency action plan should outline treatment during an acute attack.
- Follow-up should include the following:
 - Review of triggers
 - Prospective genetic counseling
 - Review of attacks during the previous year
 - Reconsideration of the need for prophylaxis
 - Review of an emergency plan

- Regular follow-up with an endocrinologist is indicated for patients requiring androgen therapy.

PATIENT EDUCATION

- General education provided by physician
- Support groups, handouts, ID bands
- www.haea.org
- www.haei.org

PROGNOSIS

Variable. Once attacks begin, they generally persist throughout the patient's life, although the frequency and severity can be dramatically improved with available therapies.

COMPLICATIONS

- Upper airway obstruction may be life threatening or lead to asphyxiation.
- Severe abdominal pain may be mistaken for a surgical abdomen.
- Diagnosis may be delayed.
- Patients may be frustrated by the nature of the recurrent attacks and the significant impact on quality of life.

CODES

ICD10

D84.1 Defects in the complement system

FAQ

- Q: What is a good screening test for HAE?
- A: C4 is a good screening test. C1 inhibitor functional and quantitative assays are readily available from commercial labs and are the definitive tests of choice for HAE.
- Q: What is the mode of inheritance in HAE?
- A: Autosomal dominant
- Q: What are the side effects of prophylactic androgen therapy?
- A: Side effects include virilization, menstrual irregularities, enhanced epiphyseal growth plate closure, weight gain, water retention, hypertension, cholestatic hepatitis, hepatic carcinoma, decreased spermatogenesis, and gynecomastia.

HEREDITARY SPHEROCYTOSIS

Michele P. Lambert

BASICS

DESCRIPTION

- Hemolytic anemia with shortened RBC survival due to selective destruction of RBCs in the spleen secondary to an inherent defect of the RBC membrane.
- Pathophysiologically related to hereditary elliptocytosis and hereditary ovalocytosis
- Membrane loss is gradual; it results in spherocytosis, which results in increased osmotic fragility.
- Severity related to degree of membrane loss
 - Mild (20% of patients)
 - Hemoglobin near normal
 - Slight reticulocytosis (<6%)
 - Compensated hemolysis, mild splenomegaly
 - Often not diagnosed until adulthood due to gallstones
 - Moderate (60% of patients)
 - Hemoglobin 8–10 mg/dL
 - Reticulocytes generally >8%
 - >50% patients have splenomegaly.
 - Moderately severe (10%)
 - Hemoglobin 6–8 mg/dL
 - Reticulocytes >15%
 - Intermittent transfusions
 - Severe (3–5%)
 - Life-threatening anemia requiring regular transfusions
 - Almost always recessive

EPIDEMIOLOGY

Most common in people of Northern European extraction (~1:3,000)

RISK FACTORS

Genetics

- ~75% of cases are inherited in an autosomal dominant pattern.
- The other 25% are autosomal recessive forms, dominant disease with reduced penetrance, or new mutations.

PATHOPHYSIOLOGY

- The most common abnormality is a deficiency of ankyrin and subsequent decrease in spectrin, 2 major proteins of the erythrocyte membrane skeleton (50–60% Northern European decent; 5–10% Japan).
 - Spectrin deficiency alone accounts for 20% of HS.
 - Mutations in other erythrocyte surface proteins also occur, including the following:
 - Beta-spectrin (typically mild to moderately severe), alpha-spectrin (severe HS)
 - Band 3 (15–20% generally mild to moderately severe)
 - Protein 4.2 (<5% HS, recessive and results in almost complete absence)
 - Rh antigen (<10% mild to moderate hemolytic anemia)
- The membrane skeletal defect causes RBC membrane fragility, resulting in membrane loss.
- The sequelae are as follows:
 - Loss of cell surface area relative to volume (spherocytosis) causes a decrease in cellular deformability.
 - The spleen detains and “conditions” the nondeformable spherocytic RBC.
 - Conditioning of cells involves depletion of adenosine 5'-triphosphate (ATP), increased glycolysis, increased influx and efflux of sodium, and loss of membrane lipid.
- Ultimately, these events lead to premature RBC destruction.

DIAGNOSIS

HISTORY

- Fatigue (a sign of anemia)

- Jaundice, scleral icterus, dark urine (signs of hemolysis)
- Phototherapy required in newborn period (50% of cases): hyperbilirubinemia due to hemolysis
- Positive familial history (for disease, gallstones, or splenectomy) is significant because of autosomal dominant inheritance.

PHYSICAL EXAM

- Splenomegaly is present in most older patients and may worsen with intercurrent illness.
- Icterus/jaundice and pallor are present with increased hemolysis.
- Linear growth, weight gain, and sexual development may be delayed. Delayed growth is indication for splenectomy.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
 - Mild to moderate anemia
 - Mean corpuscular volume (MCV) usually normal
 - Mean corpuscular hemoglobin concentration (MCHC) elevated (useful screening test with high specificity)
 - Reticulocyte count: may be only slightly elevated
 - Often accompanied by elevated RBC distribution width (RDW)
 - Indirect hyperbilirubinemia: present in 50–60% of cases
 - Peripheral smear: microspherocytes, polychromasia
- Coombs test: negative
 - Important differential test in a patient with hemolytic anemia and spherocytes
- Urinalysis
 - Hemoglobinuria
 - Increased urobilinogen
- Special tests:
 - Osmotic fragility (most useful test in diagnosis but can be normal in 10–20% of patients)
 - Spherocytes are more fragile, less resistant to osmotic stress, and therefore lyse in higher concentrations of saline than normal RBCs.

- ▢ Test can result in a false-negative, especially in newborns whose RBCs may be more dehydrated and with high fetal hemoglobin.
 - ▢ Important to use an age-matched control if possible
 - ▢ Any anemia that results in spherocytes will give increased osmotic fragility (especially autoimmune hemolytic anemia) and must be excluded.
- Eosin-5-maleimide (EMA) binding
 - ▢ Flow cytometric analysis of RBCs with much higher sensitivity and specificity for HS
 - ▢ Is now the test of choice for diagnosis but not available at all centers

DIFFERENTIAL DIAGNOSIS

- Hemolysis secondary to intrinsic RBC defects
 - Membrane defects secondary to inherited disorders of membrane skeleton (HS and elliptocytosis) and RBC cation permeability and volume (stomatocytosis and xerocytosis)
 - Enzyme defects: Embden-Meyerhof pathway (i.e., pyruvate kinase deficiency) and hexose monophosphate pathway (i.e., glucose-6-phosphate dehydrogenase deficiency)
 - Hemoglobin defects
 - ▢ Congenital erythropoietic porphyria;
 - ▢ Qualitative hemoglobin S (sickle cell), Hgb C, Hgb H, Hgb M
 - ▢ Quantitative: thalassemias
 - Congenital dyserythropoietic anemias
- Hemolysis secondary to extracorporeal RBC defects
 - Immune-mediated (important in differential because spherocytes are present on smear and can give increased osmotic fragility if sent): isoimmune (e.g., hemolytic disease of the newborn, blood group incompatibility) and autoimmune (e.g., cold agglutinin disease, warm autoimmune hemolytic anemia)
 - Non-immune-mediated: idiopathic and secondary to underlying disorder (e.g., hemolytic uremic syndrome, thrombotic thrombocytopenic purpura)

ALERT

- A patient with HS may become extremely anemic during an aplastic crisis, hyperhemolysis episode, or folic acid deficiency, requiring transfusion.
- False-negative osmotic fragility tests can occur in several situations; therefore, index of suspicion must be high to follow the clinical course and repeat test (e.g., in neonatal period, during megaloblastic crisis, and recovery from aplastic crisis after transfusion when cells are youngest and least spherocytic).
- 20–25% of HS patients have normal unincubated osmotic fragility (incubated test almost always positive; therefore, it may be necessary to conduct both tests).
- Spherocytes are often present in immune-mediated hemolysis.

TREATMENT

GENERAL MEASURES

- Folic acid supplement
- Penicillin prophylaxis (if splenectomized)
- Pneumococcal, meningococcal, and Haemophilus influenza B vaccines (prior to splenectomy)

SURGERY/OTHER PROCEDURES

Splenectomy: high response rate (most patients normalize their blood counts):

- Indications: moderate to severe anemia with significant hemolysis resulting in transfusion dependence, decreased exercise tolerance, skeletal deformities, or delayed growth
- Complications: risk of postsplenectomy sepsis, emerging data on increased risk of later pulmonary hypertension, and increased risk of thrombosis

Cholecystectomy

- Indications: symptomatic gallbladder disease; sometimes done simultaneous with splenectomy if gallstones evident by ultrasound
- Complications: morbidity of surgical procedure and postoperative period

ONGOING CARE

- Physical exam
 - Check for splenomegaly.
 - Follow growth curves closely.
- CBC with reticulocyte count as needed: If patient develops fatigue, pallor, or increased jaundice especially in setting of viral illness
- Penicillin prophylaxis after splenectomy

PROGNOSIS

Severity of disease is extremely variable, ranging from an incidental diagnosis in adulthood to severe anemia requiring transfusions.

COMPLICATIONS

- Gallstones
 - Most common complication of HS
 - Pigment stones can lead to cholecystitis and/or biliary obstruction.
- Cholelithiasis in HS manifests in 2nd and 3rd decades of life.
- Aplastic crises
 - Can result in severe life-threatening anemia; often caused by parvovirus B19 infection
 - Epstein-Barr virus (EBV), influenza, and cytomegalovirus (CMV) can also cause worsening anemia and reticulocytopenia.
- Hyperhemolysis
 - Increased RBC destruction
 - Often precipitated by infection
- Postsplenectomy sepsis
 - Lower risk of infection if postponed until 4–5 years of age and immunized with pneumococcal vaccine
 - 50–70% of sepsis caused by *Streptococcus pneumoniae*
- Folate deficiency
 - Caused by insufficient dietary intake of folic acid for increased bone marrow requirement
 - Can result in megaloblastic crisis
- Pulmonary hypertension
 - Long-term complication of splenectomy due to recurrent small

vessel thrombosis in the lungs (either local clot or thromboembolic events)

- Long-term risk that weighs against splenectomy in patients with mild or well-compensated disease
- Other rare complications
 - Gout
 - Indolent leg ulcers
 - Chronic erythematous dermatitis on legs

FAQ

- Q: Will my child require blood transfusions?
- A: It depends on the clinical severity of your child's disease.

- Q: If a parent has HS, how should the newborn be followed?
- A: The infant has a 50% chance of having HS. In infants with HS, the CBC is usually normal in the first 72 hours of life but then drops because of an inability to mount an appropriate erythropoietic response to increased destruction. Therefore, infants at risk should have a CBC with reticulocyte count after 72 hours. These infants also need to be monitored closely for hyperbilirubinemia.
- Q: What are the risks and benefits of splenectomy?
- A: Splenectomy is almost always successful in ameliorating anemia but adds the risk of postsplenectomy infections and later risks for pulmonary hypertension and maybe increased risk of thrombosis and/or cardiovascular disease. The risks and benefits need to be carefully weighed and, in patients with mild, well-compensated hemolysis, splenectomy is not indicated.

HEROIN INTOXICATION

Jeannine Del Pizzo • Fran Balamuth

BASICS

DESCRIPTION

Heroin is a semisynthetic derivative of opium. The opioid family includes the following:

- Drugs that occur naturally in opium (from the poppy plant)
- Codeine
- Morphine
- Semisynthetic derivatives (e.g., hydromorphone, oxycodone)
- Synthetic compounds (e.g., meperidine, fentanyl, methadone)

EPIDEMIOLOGY

- General
 - 23 years of age: mean age of 1st use (2012)
 - ~50% of those who have used an opioid pain reliever for nonmedical uses state they obtained it for free from a friend or relative.
 - Nonmedical use of opioid pain relievers can lead to eventual injection heroin use.
- Neonatal
 - Fetal exposure commonly involves polysubstance abuse.
 - 60–80% of heroin-exposed infants develop withdrawal—dependent on maternal dosing and length of use.
- Adolescents
 - Most use experimentally or intermittently; few become addicted and use daily.
 - Use of opioid analgesics has increased dramatically over the last 10 years and has become more common than heroin use.
 - Most common substances were oxycodone, hydrocodone, and methadone
- Overdose
 - Up to 1/3 of heroin users experience nonfatal overdose.

- Most occur in the home and with other people present.
- Risk factors include length of injecting history, concurrent use of CNS depressants, recent completion of substance abuse program, and recent release from prison.
- Deaths
 - Most heroin deaths occur when drug is administered IV.
 - Most deaths in patients in their late 20s or 30s, with significant drug dependence
 - Males are 4 times more likely to die than females from heroin-related causes.
 - Multiple drug use common in heroin-related death
 - As of 2011, opioid pain relievers are responsible for more overdose fatalities than heroin and cocaine combined.

Prevalence

- Precise estimates of prevalence of use difficult
- ~2.9 million people used at least once.
- ~467,000 used in 2012 (double since 2001).
- Prevalence of fetal exposure <1–3.7%

PATHOPHYSIOLOGY

- Well-absorbed from gastrointestinal (GI) tract, nasal mucosa, pulmonary capillaries, and SC and IM injection sites
- Oral dose less potent than parenteral because of 1st-pass hepatic metabolism
- IV heroin peaks in <1 minute; intranasal and IM heroin peak in 3–5 minutes.
- Very lipid soluble; crosses blood–brain barrier within 15–20 seconds
- Extensive distribution into skeletal muscle, kidneys, liver, intestine, lungs, spleen, brain, and placenta
- Rapidly crosses the placenta, entering fetal tissues within 1 hour
- Crosses into breast milk in quantities sufficient to cause addiction
- Excreted in urine as morphine
- Receptor types
 - Mu (or OP3)
 - Located in CNS, GI tract, and sensory nerve endings

- Effect: analgesia, euphoria, respiratory depression, physical dependence, GI dysmotility, miosis, pruritus, bradycardia
- Kappa (or OP2)
 - Located in CNS
 - Effect: analgesia, miosis, diuresis, dysphoria
- Delta (or OP1)
 - Located in CNS
 - Effect: spinal analgesia, modulation of mu receptors/dopaminergic neurons

DIAGNOSIS

HISTORY

- Neonate
 - Maternal history of heroin or other drug use
 - Extent of prenatal care
 - Time from most recent use to delivery
 - Breastfeeding
- Older child/adolescent
 - History of heroin use
 - Observed overdose
 - Found in setting consistent with possible drug use

PHYSICAL EXAM

- Neonate with in utero exposure
 - Prematurity
 - Low birth weight
 - Perinatal depression with 5-minute Apgar <5
 - Hypotonia
- Intoxication/overdose
 - Classic toxidrome: depressed level of consciousness, very decreased respiratory effort, miotic pupils, with or without diminished bowel sounds
 - More severe overdose: bradycardia, hypotension, noncardiogenic pulmonary edema

- Withdrawal
 - Early signs (8–24 hours): anxiety, restlessness, insomnia, yawning, rhinorrhea, lacrimation, diaphoresis, stomach cramps, mydriasis
 - Late signs (up to 3 days): tremor, muscle spasms, vomiting, diarrhea, hypertension, tachycardia, fever, chills, piloerection, seizures
- Additional neonatal withdrawal signs and symptoms
 - Hyperirritability
 - Hypertonicity
 - Posturing
 - Exaggerated startle reflex
 - Tachypnea
 - Hyperpyrexia
 - Poor suck/swallow coordination
 - High-pitched cry
 - Poor weight gain
 - Timing of neonatal symptoms depends on maternal substance used: See withdrawal from heroin within 48 hours, can be longer for methadone; can see delayed withdrawal up to 4 weeks with both drugs

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Therapy should not be withheld pending laboratory results.
- Urine toxicology screen (heroin easily detected; synthetic opioids are not)
- Serum toxicology screen for acetaminophen level, etc., if suspect polydrug use
- Serum tests to rule out other causes, if needed (e.g., glucose)
- Urine testing in neonates and mothers. Meconium testing is also helpful but not readily available, and results can take days to weeks.

DIFFERENTIAL DIAGNOSIS

- Neonatal exposure
 - Sepsis
 - Hypoglycemia

- Hypocalcemia
- Hyperthyroidism
- CNS abnormality
- Metabolic disorder
- Withdrawal from other maternal drug use
- Intoxication/overdose
- Other pharmacologic agents
 - Clonidine, sedative hypnotics, barbiturates, antipsychotics, gamma hydroxy butyrate
- Hypoglycemia
- Hypothermia
- Hypoxia
- Heat stroke
- Pontine or subarachnoid hemorrhage

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Intoxication/overdose
 - ABCs (airway, breathing, circulation)
 - Antidote is naloxone (Narcan).
 - Assessment of respiratory status/adequacy of ventilation
 - If adequate respiratory effort, observe until normal level of consciousness.
 - ▢ Consider naloxone as diagnostic challenge.
 - If inadequate respiratory effort
 - ▢ Bag-valve-mask ventilation
 - ▢ Naloxone (IV preferred route, SC, IM)
 - ▢ If <20 kg, 0.1 mg/kg; 2 mg if ≥ 20 kg. Dose may be repeated.
 - ▢ ET route: optimal dose unknown but some recommend using 2–3 times the above IV dosage
 - ▢ Intranasal route: 2 mg (1 mg per nostril) has been used in adolescents ≥ 13 years and a slightly delayed onset of action compared to IV/IM route has been reported.

- If suspect dependence, start with lower dose (0.4-mg ampule)
- If no response to large dose, question diagnosis of heroin toxicity—heroin exquisitely sensitive to naloxone.
- Naloxone loses efficacy in 20–40 minutes.
 - May need repeat dosing
 - Can give as continuous infusion if necessary; dosing recommendations vary.
 - One method: 2/3 of effective bolus dose given on an hourly basis with gradual wean
- Consider low-dose naloxone (0.01 mg/kg) in apneic infants exposed to opiates in utero but caution, as naloxone can precipitate seizures in opioid-dependent neonates.
- Endotracheal intubation if no response to naloxone in 5–10 minutes, or other reason for invasive airway management
- Observe in emergency department for a minimum of 2–3 hours for respiratory status stabilization.
- Consider chest radiograph to evaluate for pulmonary edema.
- Consider glucose testing to evaluate for hypoglycemia.
- Consider whole bowel irrigation with GoLYTELY for symptomatic body packers and consult local poison control center.
- Withdrawal
 - Standard treatment methadone maintenance (adolescents/adults)
 - Blocks euphoria and prevents withdrawal symptoms
 - Patients generally treated in established methadone maintenance programs
 - Stabilize with 20–40 mg/24 h; wean by 2–5 mg/week over several months.
 - Adjust wean if signs of withdrawal appear.
 - Some programs use heroin maintenance when methadone fails; research ongoing
 - Buprenorphine is also an option.
 - Clonidine (0.2 mg q4–6h PRN for 5–7 days) can control acute withdrawal symptoms. Monitor blood pressure.
 - Rapid and ultrarapid detoxification (using opioid antagonist with or without general anesthesia) a possibility in selected patients; recent

review suggests high-rate adverse events.

- Should be used only by experienced team with appropriate resources
- Children receiving prescription opioids for pain likely will exhibit symptoms of withdrawal after 14 days of daily use and will need a weaning schedule. Use of daily opioids for less than 7 days usually does not result in withdrawal symptoms.
- In neonates
 - Nonmedical management of neonatal opioid withdrawal includes minimizing environmental stimulation (light, noise, cold), swaddling, and comfort measures.
 - Treatment
 - Paregoric (0.4 mg/mL) not recommended owing to high alcohol content (45%) and toxic compounds such as camphor, anise oil, benzoic acid, and glycerin
 - Oral tincture of opium (10 mg/mL) best diluted 25-fold to a concentration equal to paregoric (0.4 mg/mL)
 - 0.1 mL/kg q4h; increase 0.1 mL/kg q4h as needed to control symptoms.
 - After 3–5 days, wean dose by 0.1 mL/kg/24 h. Observe infant for 3–5 days after stopping therapy.
 - May need IV morphine in severe cases
 - Methadone and buprenorphine have also been shown to be effective.
 - Clonidine gaining favor for use in infants; pharmacokinetic data not available, although use is currently recommended only in the context of a randomized clinical trial.
 - Phenobarbital is not a 1st-choice agent owing to long half-life, CNS depression, induction of drug metabolism, and rapid tolerance to sedative effect; however, it has been shown to be effective in conjunction with diluted tincture of opium.
 - Infants with opioid withdrawal have elevated metabolic demands: Consider higher calorie (24 kcal/oz) feeds.
- Breastfeeding is not recommended in mothers using heroin but can be considered for mothers on methadone treatment.

FOLLOW-UP

DISPOSITION

Most patients with overdose warrant hospitalization.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Developmental follow-up for exposed neonates

ISSUES FOR REFERRAL

- Social services and referral to substance abuse program
- Consider referral for testing for HIV and hepatitis B and C.

PROGNOSIS

- Neonatal
 - Long-term morbidity from neonatal heroin dependence unclear owing to confounding variables (e.g., developmental environment)
- Intoxication/overdose
 - With adequate early treatment, patients with uncomplicated overdoses do well—key is to prevent respiratory arrest.
- Addiction
 - Dependent on involvement in other risky behaviors (polydrug use, high-risk sexual practices, school failure, delinquency, etc.)
 - Longer treatment likely produces a better outcome.
 - Most relapses require lifetime of therapy.

COMPLICATIONS

- Intoxication/overdose
 - Respiratory arrest
 - Noncardiogenic pulmonary edema
 - CNS depression/coma
 - Hypotension
 - Aspiration pneumonia
- Pregnancy
 - Poor prenatal care

- Preterm labor
- Premature rupture of membranes
- Breech presentation
- Antepartum hemorrhage
- Toxemia
- Anemia
- Uterine irritability
- Infection (e.g., HIV, hepatitis B)
- Infantile dependence
- Naloxone use
 - May precipitate withdrawal syndrome in opioid-dependent patients
 - Symptoms: agitation, hypertension, tachycardia, emesis
 - May cause acute severe withdrawal in infants born to addicted mothers

- F11.23 Opioid dependence with withdrawal
- P96.1 Neonatal w/drawal symp from matern use of drugs of addiction

FAQ

- Q: Is nalmefene an appropriate substitute for naloxone in a heroin overdose?
- A: Nalmefene, a long-acting specific narcotic antagonist, has not proved to be as effective as naloxone in a randomized, double-blind trial. It also may result in prolonged, dangerous withdrawal. It therefore has limited usefulness in this setting.

HERPES SIMPLEX VIRUS

Paul K. Sue • W. Christopher Golden

BASICS

DESCRIPTION

Herpes simplex virus (HSV) is an enveloped double-stranded DNA virus. It exists as two distinct subtypes, HSV-1 and HSV-2, and is responsible for a wide spectrum of illness ranging from fever blisters to genital ulcers and fatal encephalitis. It establishes lifelong latency and can lead to interval episodes of asymptomatic shedding and disease recurrence.

EPIDEMIOLOGY

- HSV-1 infects 40–80% of the U.S population by young adulthood, and 60–85% by age 60.
- HSV-2 incidence increases during adolescence and adulthood, and infects 20–35% of U.S. adults by age 40.
- In the United States, approximately 1,500 cases of neonatal HSV (1:3,200 live births) occur every year, primarily due to HSV-2.
- Following the neonatal period, HSV-1 infections predominate among children.
- Risk factors for HSV-1 and HSV-2 infection include older age and lower socioeconomic status. Additional risk factors for HSV-2 include number of lifetime sexual partners and female gender.

GENERAL PREVENTION

- Perinatal infection
 - The majority of neonatal HSV infections (85%) occur through contact with maternal HSV shed within the birth canal. A smaller proportion (5%) of infections occur in utero.
 - The majority (60–80%) of mothers of infected infants have no symptoms of HSV infection at the time of delivery.
 - Children born to mothers with primary genital HSV infection at time of delivery are at highest risk (~60%). In contrast, the risk of neonatal infection with recurrent maternal genital herpes is

significantly lower (2–5%).

- In the setting of active genital herpes (lesions or pain), cesarean delivery is recommended, preferably within 4 hours of rupture of membranes. However, infections may still occur despite cesarean delivery and intact amniotic membranes.
- Cesarean delivery is not recommended for mothers with a history of genital HSV in the absence of lesions or symptoms.
- Fetal scalp monitors should be avoided in women with suspected genital HSV.
- The use of antiviral therapy (acyclovir or valacyclovir) after 36 weeks' gestation decreases viral shedding and reactivation of genital lesions in mothers with a history of genital HSV, although breakthrough infections may still occur.
- Postnatal infection (neonates and children)
 - Secretions of active HSV lesions are highly infectious, and asymptomatic viral shedding is common. 10% of neonatal HSV infections are contracted postpartum through direct contact with infectious fluids.
 - Standard universal precautions are appropriate in caring for recurrent/localized lesions in immunocompetent persons.
 - Contact precautions should be considered in neonates, immunocompromised persons with active lesions, and in severe primary mucocutaneous HSV.
 - Contact with genital/cutaneous HSV lesions (e.g., sexual intercourse, wrestling) should be avoided until lesions resolve.

PATHOPHYSIOLOGY

- Spread occurs typically via contact with abraded skin or mucous membranes.
- The incubation period for primary infection is approximately 2–12 days.
- Viral replication begins at the portal of entry (epithelia) and commences within sensory ganglia. Migration occurs back to the site of inoculation, with subsequent destruction of epithelial cells.
- Following initial infection, the virus remains latent in sensory neural ganglia and can be reactivated by UV exposure, trauma, stress,

hormonal changes, or immunosuppression.

- Viral dissemination occurs most often in neonates, pregnant women, or immunosuppressed patients.
- HSV antibodies provide a degree of cross protection across serotypes; previous infection with one HSV serotype (e.g., HSV-1) can decrease the severity of infection with the alternate serotype (e.g., HSV-2).

COMMONLY ASSOCIATED CONDITIONS

- Gingivostomatitis
- Encephalitis
- Herpes gladiatorum
- Herpetic whitlow
- Eczema herpeticum
- Erythema multiforme

DIAGNOSIS

SIGNS AND SYMPTOMS

- The majority of primary HSV infections are asymptomatic in healthy individuals.
- Infections “above the waist” are classically due to HSV-1, whereas HSV-2 most commonly causes genital infection. However, both serotypes can cause genital and/or mucocutaneous infection.
- Recurrent infections occur due to reactivation of latent virus and are usually less severe than primary infections.
- Neonatal infection
 - Neonates may present with classic skin lesions or with nonspecific findings of irritability, fever, temperature instability, and poor feeding with or without a rash.
 - Skin, eye, and/or mouth (SEM) disease (40–45% of neonatal HSV) presents in the 1st–2nd week of life with rash, chorioretinitis, or keratitis. Approximately 85% of patients have visible skin lesions.
 - Disseminated neonatal HSV disease (25% of neonatal HSV) presents with a sepsis-like syndrome in the 1st–2nd week of life, commonly involving the lungs, liver, adrenals, and the central

nervous system (CNS). Approximately 60% have visible skin lesions.

- HSV CNS disease (30–35% of neonatal HSV) usually presents in the 2nd–3rd week of life with seizures, fever, and/or temperature instability.
- Oropharyngeal infection
 - Primary infection is characterized by fever, irritability, and severe pain/burning of the oral mucosa, with vesicular and ulcerative lesions on the lips, gingiva, and tongue.
 - Pharyngitis is also common in older children and adolescents.
 - Illness lasts for 2–3 weeks, with viral shedding continuing for several weeks.
- Genital infection
 - Infection is characterized by genital pain and itching, associated with tender inguinal adenopathy, fever, malaise, and rash.
 - Lesions begin as vesicles and progress to ulcers before crusting over by 2–3 weeks.
- Keratoconjunctivitis (ocular infection)
 - Presents as unilateral or bilateral conjunctivitis with preauricular adenopathy, associated eyelid edema, photophobia, tearing, and/or chemosis
- Encephalitis (CNS infection)
 - Infection is characterized by fever, headache, altered mental status, focal neurologic symptoms, and seizures.
- Disseminated HSV infection
 - Infection presents with fever or temperature instability and a sepsis-like syndrome with end-organ involvement (e.g., lungs, liver).
 - Neonates, pregnant women, transplant recipients, and other immunocompromised hosts are at increased risk for disseminated infection.

PHYSICAL EXAM

- The “classic” HSV rash consists of vesicles on an erythematous base, which subsequently ulcerate, become friable, and bleed easily.
- Lesions may not be readily apparent, particularly in cases of disseminated disease and CNS infection.

DIAGNOSTIC TESTS & INTERPRETATION

- Neonatal infection
 - Newborn conjunctival, oropharyngeal, nasal, and rectal samples should be sent for viral culture approximately 24 hours after birth (sooner if suspicious lesions are present).
 - Suspicious vesicles should be unroofed and the vesicle base thoroughly swabbed for viral culture.
 - Cerebrospinal fluid (CSF) should be sent for cell count, differential, chemistries, and HSV-polymerase chain reaction (PCR), in addition to evaluation (blood, urine, CSF) for bacterial and other viral infections.
 - Repeat HSV CSF PCR testing may be required, as false negatives of the CSF can occur early in the disease course.
 - Serum HSV PCR and liver function tests (specifically alanine aminotransferase [ALT]) should be sent in cases of suspected disseminated HSV.
 - Additional testing (ophthalmoscopy, electroencephalogram [EEG], CNS imaging [MRI], chest x-ray) is recommended in cases of disseminated, CNS, or ophthalmologic disease.
 - In asymptomatic neonates of women with genital lesions, maternal serologic status should be used to assess the risk of neonatal herpes and should, along with clinical findings, guide subsequent testing and therapy. See the 2013 clinical report from the AAP Committee on Infectious Diseases and Committee on Fetus and Newborn (reference in the “Additional Reading” section).
- Oropharyngeal HSV infection is typically diagnosed based on history and clinical exam. Viral culture and DFA are recommended for testing of questionable lesions.
- Genital herpes lesions should be diagnosed using both viral culture and HSV PCR, as the sensitivity of viral culture alone may be as low as 27% in genital ulcers and recurrent lesions.
- Encephalitis
 - CSF PCR is the diagnostic test of choice. Samples should be sent to a reliable laboratory with a low rate of false-positive results.
 - In HSV encephalitis, CSF analysis reveals a lymphocytic,

progressive pleocytosis (average 100 WBCs/mm³) and rising protein (median 80 mg/dL), although these may be normal in 5–10% of early disease.

- EEG can reveal a characteristic pattern of periodic unilateral or bilateral focal spikes.
- MRI of the brain may show temporal lobe enhancement, deep gray matter involvement, and ischemic changes in watershed distribution areas.
- HSV keratoconjunctivitis
 - Ophthalmology referral is recommended.
 - Characteristic dendritic corneal ulcerations with linear branching pattern are observed on slit-lamp examination.
 - Viral culture and HSV PCR are highly sensitive but often unnecessary.
- Disseminated HSV
 - HSV serum PCR is useful in detecting viremia in disseminated infection.
 - CNS involvement is noted in up to 70% of cases.

DIFFERENTIAL DIAGNOSIS

- Neonatal HSV disease should be distinguished from severe enteroviral and bacterial sepsis, especially in the first 4–6 weeks of life.
- Intrauterine HSV should be considered in newborns born with microcephaly, intracranial calcifications, chorioretinitis, hepatosplenomegaly, and/or skin lesions and must be distinguished from other congenital viral infections (such as cytomegalovirus [CMV] and rubella).
- Oropharyngeal HSV should be distinguished from enteroviral (e.g., coxsackie) herpangina.
- Genital HSV should be distinguished from chancroid and syphilis. Syphilis lesions are usually nonpainful, indurated ulcers. Chancroid lesions are painful, purulent ulcers due to *Haemophilus ducreyi* infection.
- Ocular HSV should be distinguished from other infectious causes of conjunctivitis (adenovirus, *Haemophilus influenzae*, *Staphylococcus aureus*, *Streptococcus pneumoniae*) and rheumatologic or traumatic

etiologies.

TREATMENT

MEDICATION

- Neonatal disease
 - Intravenous (IV) acyclovir (20 mg/kg/dose every 8 hours). The recommended minimum duration of therapy is 14 days (if the disease is limited to the skin, eye, and mouth) or 21 days (for encephalitis or disseminated disease).
 - Infants with ocular HSV should also receive topical antiviral therapy (trifluridine 1%, vidarabine 3%, or iododeoxyuridine 0.1%) in addition to parenteral therapy.
 - In cases of neonatal HSV infection (without proven disease), preemptive therapy with IV acyclovir (20 mg/kg/dose every 8 hours) should be given for 10 days (see 2013 AAP clinical guidance report).
 - Acyclovir prophylaxis (300 mg/m²/dose orally three times per day) for 6 months following initial treatment improves infant neurodevelopmental outcomes and prevents recurrent skin outbreaks.
- Oropharyngeal herpes
 - Symptomatic treatment with antipyretics and analgesia is recommended. IV hydration is sometimes needed in cases of decreased oral intake.
 - Oral acyclovir (15 mg/kg/dose five times per day for 7–10 days; max 200 mg per dose) may decrease the duration of illness if started within 72 hours at the onset of symptoms.
- Genital herpes
 - Patients ≥12 years old with primary genital HSV infection should receive oral acyclovir (400 mg/dose three times per day), valacyclovir (1 g/dose twice per day), or famciclovir (250 mg/dose three times per day) for 7–10 days or until resolution of lesions, whichever is longer. Topical therapy is not recommended.
 - Early treatment of recurrent herpes lesions (within 24 hours) with

short-course acyclovir, valacyclovir, or famciclovir can reduce severity and duration of symptoms.

- Suppressive oral therapy with acyclovir (400 mg/dose twice per day) or valacyclovir (500–1,000 mg once daily) has been shown to reduce recurrence of genital HSV. Patients should be reassessed after 1 year of therapy to determine if ongoing suppression is needed.
- Suppressive therapy (valacyclovir [500 mg/dose twice per day] or acyclovir [400 mg/dose three times per day]) should be offered to pregnant women with a history of genital herpes from 36 weeks' gestation to delivery.
- Encephalitis
 - IV acyclovir (15–20 mg/kg/dose every 8 hours if <12 years old, otherwise 10 mg/kg/dose every 8 hours) for 14–21 days is recommended for treatment of HSV encephalitis.
- HSV keratoconjunctivitis
 - Topical antiviral therapy: trifluridine 1% (every 2 hours while awake), ganciclovir ophthalmic gel 0.15% (every 3 hours while awake), or vidarabine 3% ointment (every 3 hours while awake) for 7–14 days until resolution of lesions
 - Oral acyclovir (100–400 mg/dose, three times per day; max child dose: 80 mg/kg/24 h) may be considered if topical therapy is not feasible. Oral suppression may be necessary to prevent recurrences.
- Immunocompromised patients and severe cutaneous disease (e.g., eczema herpeticum)
 - HSV lesions should be treated with oral acyclovir 200 mg/dose five times per day (patients >2 years old; max child dose: 80 mg/kg/24 h) OR IV acyclovir (750–1,500 mg/m²/24 h divided every 8 hours) for 7–14 days
 - IV acyclovir should be considered initially in patients who are immunocompromised, have severe disease (e.g., eczema herpeticum), or cannot tolerate oral therapy.

ALERT

- Use of acyclovir in therapeutic and suppressive doses has been associated with neutropenia in infants. Monitoring of the patient's

absolute neutrophil count (ANC) is recommended.

- Common side effects of acyclovir therapy in children include diarrhea, nausea, and headache. Rare, but serious side effects of acyclovir therapy may include acute renal failure, hemolytic uremic syndrome, and thrombotic thrombocytopenic purpura.

ONGOING CARE

PROGNOSIS

- Despite antiviral therapy, mortality is approximately 30% among infants with disseminated HSV disease.
- Among neonates with encephalitis, mortality is around 5% with treatment, although 70% will have neurodevelopmental sequelae.
- HSV encephalitis mortality outside the neonatal period is 70% without therapy. With treatment, mortality declines to 19%, with 38% return to normal neurologic function.
- Herpes simplex keratoconjunctivitis frequently recurs and can lead to corneal ulceration and permanent scarring.

COMPLICATIONS

The major morbidities in survivors are brain damage, seizures, and blindness.

- A60.00 Herpesviral infection of urogenital system, unspecified
- B00.1 Herpesviral vesicular dermatitis

FAQ

- Q: What is the role of suppressive therapy in immunocompromised HIV and solid organ and stem cell transplant recipients?
- A: Suppressive therapy with oral acyclovir is recommended in immunosuppressed transplant patients with a history of HSV infection or positive HSV antibody titers, and may be considered in HIV positive persons with clinical or serologic evidence of HSV-2 infection.
- Q: Is a repeat lumbar puncture necessary at the end of therapy for neonates or for children with HSV encephalitis?
- A: Repeat HSV PCR should be performed on the CSF of all children

with HSV encephalitis prior to stopping therapy. If virus is detected, therapy should be prolonged until repeat CSF PCR testing is negative.

HICCUPS (SINGULTUS)

Bradley J. Monash

BASICS

DESCRIPTION

- The hiccup (or hiccough) is an onomatopoeic name stemming from the sound made by the abrupt glottic closure following involuntary contraction of the diaphragm and intercostal muscles.
- The medical term for hiccup is singultus, which stems from the Latin singult, originally used to describe the sharp intake of breath associated with prolonged sobbing.
- Usually a benign, yet recurrent nuisance
- Prolonged bouts of hiccups can be indicative of an underlying or serious condition.

EPIDEMIOLOGY

- Fetal hiccups are common in the 3rd trimester of pregnancy, and mothers often feel the rhythmic movement.
- Newborns may spend as much as 2.5% of their time hiccapping, which decreases in infancy.
- There is no seasonal, geographic, racial, or socioeconomic predilection.
- Persistent (>48 hours) and intractable (>1 month) hiccups more commonly occur in men and adults.

GENERAL PREVENTION

Avoid precipitating factors (e.g., eating rapidly, carbonated beverages, alcohol, tobacco).

PATHOPHYSIOLOGY

- A hiccup reflex arc has been elucidated through the study of pathologic hiccups.
 - Afferent limb: receptors in the distal esophagus, stomach, and abdominal side of the diaphragm; signals travel through the phrenic nerve, vagus, and sympathetic (T6–T12) chain branches.

- Central component: the middle and dorsolateral medulla; independent from the respiratory center, the hypothalamus, and the phrenic nerve nuclei
- Efferent limb: phrenic nerve to the diaphragm; accessory nerves to the intercostal and scalene muscles, glottis structures, and the esophagus
- Hiccups are often unilateral, involving the left hemidiaphragm.

ETIOLOGY

- Hiccups have many causes, which can be characterized as environmental, peripheral or central nervous system (CNS), toxic-metabolic, psychogenic, or unknown:
 - Environmental
 - Changes in the ambient or gastrointestinal (GI) temperature, cold showers, ingestion of hot or cold beverages
 - Peripheral nervous system (any process that irritates or stimulates the phrenic or vagus nerves or other afferent receptors)
 - GI: aerophagia, ingestion of excessive food or carbonated beverages, gastric insufflation during endoscopy, gastroesophageal reflux, esophagitis, gastritis, peptic ulcer disease, GI malignancies, pancreatitis, gallbladder disease, hepatic or renal disorders, ascites, inflammatory bowel disease, appendicitis, intra-abdominal abscess
 - Thoracic: goiter, cysts, hiatal hernia, pneumonia, bronchitis, asthma, mediastinal lymphadenopathy, lung cancer
 - Cardiovascular: pericarditis, pericardial effusion, myocardial infarction, central catheter migration
 - CNS (any process that may impact the “hiccup center”)
 - Neuromyelitis optica, hydrocephalus ventriculoperitoneal shunt, stroke, arteriovenous malformation, CNS trauma, encephalitis, meningitis, brain abscess
 - Toxic-metabolic
 - Alcohol or tobacco use
 - Meds: anesthetic agents, epidural injections, corticosteroids, barbiturates, benzodiazepines, antibiotics, opioids, chemotherapy
 - Metabolic: uremia, hypocalcemia, hyponatremia, hypokalemia,

- hyperglycemia
 - Infectious: thrush, sepsis, influenza, herpes zoster, malaria, tuberculosis
- Psychogenic
 - Excitement or stress
 - Conversion disorder
 - Anorexia nervosa
 - Personality disorders
 - Malingering

DIAGNOSIS

HISTORY

- Hiccups are typically discernible by their classic appearance.
- Ascertain the onset, duration, and any adverse sequelae of hiccups.
- Obtain a complete medical and surgical history, including a thorough review of systems.
- Inquire about prescription and nonprescription medications, tobacco, alcohol, and illicit drug use.
- Screen for anxiety, depression, and other psychiatric disorders.
- Hiccups persisting during sleep suggest an organic cause.

PHYSICAL EXAM

- Head and neck exam may reveal evidence of trauma, foreign body in the ear canal, nuchal rigidity, lymphadenopathy, or goiter.
- Assess the chest for evidence of pneumonia, bronchitis, or pericarditis.
- Examine the abdomen for evidence of an inflammatory process or masses.
- Neurologic examination should be detailed, including cranial nerve assessment.

DIAGNOSTIC TESTS & INTERPRETATION

Hiccup bouts are common and do not routinely require extensive investigations. The history and physical examination will often identify the etiology.

ALERT

Persistent or intractable hiccups require a thorough evaluation.

Lab

- CBC
- Electrolytes (e.g., Na, K, Ca)
- Glucose
- Renal function (BUN and Cr)
- Liver function tests, amylase/lipase
- Toxicology screen

Imaging

Additional testing should be guided by the patient's history, physical examination, and laboratory findings:

- Chest radiograph to look for pulmonary, cardiac, and mediastinal abnormalities
- Chest or abdominal ultrasound or other advanced imaging (e.g., CT, MRI) to assess for occult tumor, infection, or other pathology
- EKG to assess for pericarditis or ischemia
- EGD or esophageal manometry if patient has dysphagia or other esophageal symptoms
- Brain MRI +/- LP to assess for tumor, CNS lesions, stroke, or infection

DIFFERENTIAL DIAGNOSIS

Hiccups present uniquely and are not often mistaken for another entity.

TREATMENT

MEDICATION

- Pharmaceutical intervention is rarely recommended for children and should be reserved for severe or refractory cases.
- There are limited high-quality data supporting any particular medication or intervention for hiccups. Most treatments stem from case series and case reports, primarily involving adult patients. A recent Cochrane review found insufficient evidence to recommend any

particular treatment for hiccups.

- When trialed, medications should target the underlying cause if possible.
- Chlorpromazine is the only FDA-approved intervention for hiccups in adults and can be given in low doses PO or IV if no response.
- A variety of other medications have been used to treat hiccups. Careful attention should be paid to risk/benefit ratio prior to initiating pharmacotherapy:
 - Promotility: metoclopramide
 - Anticonvulsants: gabapentin, phenytoin, valproic acid, carbamazepine
 - Muscle relaxants: baclofen, cyclobenzaprine
 - Antipsychotics: chlorpromazine, haloperidol, olanzapine
 - CNS stimulants: methylphenidate
 - Antiarrhythmics: quinidine sulfate
 - Antidepressants: sertraline, amitriptyline
 - Anesthetics: nebulized, oral, and IV lidocaine
 - Antihypertensives: nifedipine, nimodipine, carvedilol
 - Other: amantadine
- For refractory cases, combination therapy has been used.

ADDITIONAL TREATMENT

General Measures

- Treat the underlying cause if identified (e.g., correct electrolyte disturbances, discontinue potential culprit medications).
- Physical maneuvers often serve as the 1st-line treatment for hiccups. Consider harmful effects prior to trying any intervention:
 - Interruption of normal respiratory function: sneezing, coughing, breath-holding
 - Disruption of phrenic nerve transmission: tapping over the 5th cervical vertebra, ice applied to the skin over the area of the phrenic nerve
 - Nasopharyngeal or uvula stimulation: traction on the tongue, stimulating the pharynx with a cotton swab, lifting the uvula with a spoon, sipping ice water, gargling, swallowing a teaspoon of granulated sugar

- Increased vagal stimulation: applying a bag of ice to the face, Valsalva maneuver
- Combining physical maneuvers has also been championed (e.g., plugging both ears tightly, pushing both right and left tragus, and drinking a glass of water through a straw without pause and without releasing the pressure over the ears).

COMPLEMENTARY & ALTERNATIVE THERAPIES

- Acupuncture
- Behavioral modification
- Hypnosis
- Suboccipital release

SURGERY/OTHER PROCEDURES

- Surgical treatment is rarely performed.
- Success has been reported with phrenic nerve blockade, percutaneous phrenic nerve pacing, vagus nerve stimulation, and short-term positive pressure ventilation but mostly in adults and in those with underlying chronic illnesses.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Frequency of follow-up depends on the underlying etiology of the hiccups.
- Patients should be monitored for adverse effects of any medications trialed.
- Successful interventions can usually be stopped the day after hiccups subside.
- If a medication is ineffective after 7–10 days, an alternative treatment should be considered.

PROGNOSIS

- Usually self-limited and resolve within hours.
- Persistent (>48 hours) and intractable (>1 month) hiccups may indicate underlying disease and may lead to complications.

COMPLICATIONS

- Adverse effects that have been associated with intractable hiccups:
 - Vomiting
 - Malnutrition and dehydration
 - Insomnia
 - Fatigue
 - Psychological distress
- Rare complications:
 - Reflux esophagitis
 - Wound dehiscence
 - Pulmonary edema
 - Cardiac dysrhythmia
 - Death

FAQ

- Q: Why do we hiccup?
- A: The true physiologic function is unknown, although hiccups have recently been postulated as a mechanism to remove air from the stomachs of young suckling mammals. Despite extensive activation of the muscles of respiration, hiccups serve no known respiratory function.
- Q: How good is the evidence supporting the treatment of hiccups?
- A: Most treatments are based on observational studies, case reports, and small case series involving adults. A recent Cochrane review found insufficient evidence to recommend any particular treatment for hiccups.
- Q: Does rebreathing into a paper bag work?
- A: As a fall in PCO_2 may increase the frequency of hiccups, rebreathing air may increase PCO_2 and thus terminate hiccups. However, this runs

the risk of causing hypoxia.

- Q: Will hiccups harm my baby?
- A: Hiccups are usually harmless and are very common in babies. They can be caused by a variety of stimuli, including the swallowing of air or exposure to cold. If they are truly persistent, intractable, or disrupt sleep, they may lead to adverse effects as listed.

HIRSCHSPRUNG DISEASE

Lusine Ambartsumyan

BASICS

DESCRIPTION

- Congenital motor disorder of the gut characterized by lack of ganglion cells in the distal bowel beginning at the anal verge and extending proximally to varying lengths
- Lack of internal anal sphincter (IAS) relaxation and failure of relaxation of the aganglionic segment during peristalsis, producing a functional obstruction.

EPIDEMIOLOGY

Incidence

- Most common cause of lower intestinal obstruction in neonates: 1 in 5,000 births
- Involves the rectum and sigmoid in 75%, descending colon in 14%, whole colon in 8%, and, rarely, small bowel in 3%
- There is familial incidence in total colonic (15–21%) and total intestinal aganglionosis (50%).

Prevalence

- Male predominance with short segment disease ranging from 3:1 to 4:1
- Gender predominance <1:1 in long segment disease.
- Syndromic and nonsyndromic Hirschsprung disease (HD): In the former, there are other congenital anomalies (30% of cases), whereas in the latter, it occurs as an isolated trait.

RISK FACTORS

Genetics

- Loci implicated include those at chromosomes 3p21, 10q11, 5p13, 22q13, 1p36, and 19q12.
- RET proto-oncogene is the major susceptibility gene; mutations of RET account for 50% of familial and 20% of sporadic cases.
- ~5% of patients with HD have mutations in endothelin signaling

pathways

PATHOPHYSIOLOGY

- Defects in and failure of caudal migration of the neural crest cells result in congenital absence of distal enteric nervous system (ENS).
- Basic histologic findings are the absence of ganglion cells in the Meissner and Auerbach plexuses as well as hypertrophied nerve bundles between the circular and the longitudinal muscles and in the submucosa.

COMMONLY ASSOCIATED CONDITIONS

- Isolated trait in 70% (nonsyndromic HD)
- Associated malformations in 30% (syndromic HD)
 - Chromosomal abnormalities (12%): the most common is trisomy 21 (2–10% of trisomy 21 have HD)
 - Congenital birth anomalies (18%): cardiac, limb, sensorineural deafness, central nervous system, genitourinary, and gastrointestinal malformations (anal stenosis, imperforate anus, and small/large bowel atresias)
- Other syndromes associated with HD: Waardenburg syndrome type 4, congenital central hypoventilation syndrome, MEN2, and Smith-Lemli Opitz; dysautonomias

DIAGNOSIS

HISTORY

- 80% of patients present in the neonatal period.
- 15% diagnosed in 1st month, 40–50% within 3 months, 60% within 1 year, and 85% within 4 years.
- Adult diagnosis of HD reported in 2% of population.
- Presentation varies with age:
 - Neonatal period: delay in passage of meconium (>48 hours of life); bilious emesis, abdominal distention, complete intestinal obstruction, perforation of cecum or appendix
 - Infancy: constipation associated with fecal impactions and/or episodes of enterocolitis

- Infancy to adulthood: mild to severe constipation, recurrent fecal impactions, intractable constipation
- Neonates usually have normal weight, but growth retardation may occur when the disease is severe.
- Children with HD may have small-volume and small-diameter stools. Some may have overflow diarrhea as well.
- Enterocolitis (chronic infectious colitis of the colon) is primary presentation in up to 16.6% of patients

PHYSICAL EXAM

- On rectal exam, the sphincter tone is usually normal or increased. Removal of the finger may be followed by explosive diarrhea. In most instances, especially in older children, the rectum is empty.
- Patients may be anemic owing to chronic blood loss from the large bowel secondary to enterocolitis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

CBC: anemia, leukocytosis in the presence of enterocolitis

Imaging

- Plain film of abdomen
 - May show distended intestinal loops
 - Diffuse intestinal pneumatosis has been reported as a rare presentation.
- Barium enema
 - May be suggestive or supportive but not diagnostic
 - Normal barium enema does not exclude HD.
 - Transition zone is a funnel-shaped area of intestine with normal distal area and dilated proximal area.
 - Reveals large intestinal mucosal pattern, prominently thickened folds, and irregular margins secondary to ulceration
 - Significant delay in excretion of barium should also raise one's suspicion for HD.
 - Normal barium enema is commonly seen in the neonate (<30 days old).

Diagnostic Procedures/Other

- Anorectal manometry
 - Safe and noninvasive way to exclude HD in patients older than 3 months of age
 - Lack of IAS relaxation with rectal balloon distention is suggestive of HD.
 - Abnormal study must be confirmed with rectal biopsies.
- Rectal suction biopsy
 - Should be done ~2–4 cm from the anal verge depending on the age of the patient
 - Biopsies must have adequate submucosa.
 - The presence of ganglion cells on histology excludes HD.
 - If the suction biopsies are not conclusive, a full-thickness rectal biopsy (gold standard) is mandatory.

Histologic Findings

- Absence of ganglion cells
- Hypertrophy of preganglionic cells
- Increased acetylcholinesterase staining in the lamina propria

Pathologic Findings

- Aganglionic segment
- Zone of hypoganglionosis proximal to the aganglionic segment
- Incomplete maturation of enteric nerve plexus
- Hypertrophy of nonmyelinated nerve fibers within bowel wall

DIFFERENTIAL DIAGNOSIS

- Mechanical obstruction
- Meconium ileus
- Meconium plug syndrome
- Neonatal small left colon syndrome
- Malrotation with volvulus
- Intestinal atresia
- Intussusception
- Necrotizing enterocolitis
- Functional obstruction
- Intestinal neuronal dysplasia

- Sepsis
- Metabolic disorders (e.g., uremia, hypothyroidism)
- Disorders of intrinsic enteric nerves (diabetes or dysautonomia)
- Disorders of smooth muscle function
- Electrolyte disturbances
- Chronic constipation

ALERT

Early recognition is of utmost importance in reducing the morbidity and mortality of HD.

TREATMENT

Surgical resection of the aganglionic segment and subsequent pull-through of the ganglionic segment to the anus

GENERAL MEASURES

Stabilizing treatment if child presents with suspected enterocolitis or obstruction:

- Fluid and electrolyte resuscitation
- Nasogastric decompression
- Broad-spectrum antibiotics
- Rectal decompression via rectal tubes and irrigations with saline enemas

SURGERY/OTHER PROCEDURES

- Initial operation
 - Defunctionalizing colostomy or ileostomy for total colonic aganglionosis or if child presents with obstruction not relieved by rectal irrigations
 - Performed to avoid the hazards of enterocolitis
- Definitive surgery
 - Performed 6 months to 1 year after the initial colostomy
 - May be performed as initial procedure in stable, nonobstructed child
- A multitude of surgical techniques have been described.
- Most common surgical procedures are Swenson (rectosigmoidectomy),

Duhamel (retrorectal transanal pull-through), and Soave (endorectal pull-through).

- Recent advances include the following:
 - The introduction of entirely transanal techniques
 - Increasing use of laparoscopic assistance with various procedures
 - Transition away from multistaged procedures to a variety of definitive single-stage operations

ALERT

Clinicians must have high suspicion for enterocolitis both before and after definitive pull-through.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Most children are followed on a regular basis for the 1st decade after surgery.

COMPLICATIONS

- Enterocolitis (chronic infectious colitis of the colon) with initial presentation
 - Mortality rates between 20% and 50%
 - Develops in 15–50% of patients
- Early (<4 weeks postoperation, usually related to technical issues)
 - Anastomotic leak
 - Cuff abscess and retraction of pull-through segment
 - Disturbance of micturition
 - Wound infection, intra-abdominal adhesions
- Late
 - Voiding dysfunction: urinary incontinence
 - Sexual dysfunction due to dissection around pelvic nerve plexus
 - Defecation disorders present in >50%
 - Normal bowel function reported in ~68.7%
 - Obstructive symptoms (~11–42%): constipation, abdominal distention, difficulty passing stool
 - Anatomic (anal stenosis, anastomotic strictures, residual

- aganglionosis
 - Functional (IAS dysfunction, colonic dysmotility)
- Fecal incontinence (3–53%)
- Enterocolitis (preop: 15–32%, postsurgically in 2–42%)
- Enterocolitis is major cause of morbidity and mortality:
 - Secondary to obstruction causing an increase in intraluminal pressure and decreased intramural capillary blood flow
 - Affects the protective mucosal barrier, enabling fecal breakdown products, bacteria, and toxins to enter the bloodstream
 - Usually presents with abdominal distention, explosive diarrhea, fever, vomiting
 - Can occur both before and after definitive pull-through
 - Clinicians must have high suspicion; can be rapidly progressive and FATAL

CODES

ICD10

Q43.1 Hirschsprung's disease

FAQ

- Q: What is the likelihood that a newborn with a diagnosis of HD will have normal bowel function after surgery?
- A: There is a good likelihood, but it may take a number of years: In a 29-year review of 259 patients, 30.3% achieved normal bowel function by age 5 years, 43.9% by age 10 years, 18.9% by age 15 years, and 6.8% after 15 years of age.
- Q: How will the bowel movements change after surgery and over time?
- A: Patients report 3–5 stools per day following pull-through that decreases to 1–3 stools per day over time at long-term follow-up.
- Q: Are laxatives required after surgery?
- A: In ~20% of children, some sort of laxative therapy or rectal irrigation may be required.

HISTIOCYTOSIS

Michelle L. Hermiston

BASICS

DESCRIPTION

- Histiocytic disorders are derived from mononuclear phagocytic cells and dendritic cells. They are divided into three groups.
 - Dendritic cell disorders (e.g., Langerhans cell histiocytosis [LCH], juvenile xanthogranuloma [JXG], Erdheim-Chester disease)
 - Macrophage-related disorders (e.g., hemophagocytic lymphohistiocytosis [HLH], macrophage activation syndrome [MAS], Rosai-Dorfman disease)
 - Malignant histiocytosis (lymphoma subtype)
- LCH (the focus of this chapter) results from the clonal proliferation of immature myeloid dendritic cells that share similar morphologic expression to skin LCH cells.
- Other names include the following:
 - Histiocytosis X, Hand-Schüller-Christian syndrome, Letterer-Siwe disease, eosinophilic granuloma
 - Hashimoto-Pritzker syndrome: infant dermatologic involvement, often self-limited

EPIDEMIOLOGY

- 2–10 cases per million children
- LCH may occur at any age. Median age is 30 months.
- Single system disease in 55% of patients; multisystem disease is more common in children 1–3 years of age.
- Male-to-female ratio approximately one
- May be more common in whites of northern European descent than African Americans

RISK FACTORS

Genetics

- No evidence that relatives of LCH patients are at increased risk of

disease

- Very rare reports of recurrence within families
- Specific HLA alleles associated with disease phenotype in some case series

PATHOPHYSIOLOGY

- Single-system LCH: limited to one organ system; most commonly bone followed by skin
- Multisystem LCH involves two or more organs/systems with or without risk organs.
- Risk organs include hematopoietic system, liver, and/or spleen and portend a worse prognosis. Lungs are no longer considered a risk organ.
- CNS risk lesions: Lesions in the facial or anterior or middle cranial fossa bones are associated with a 3× increased risk of CNS involvement.
- CNS lesions can include mass lesions, pituitary stalk involvement, or neurodegenerative disease.

ETIOLOGY

LCH etiology is incompletely understood. BRAFV600E mutations are found in ~60% of cases but are not prognostic. Activation of the RAS/MAPK pathway is common regardless of BRAF mutation status. Inflammatory infiltrates and abnormal cytokine production in lesions are common, although role in disease remains unclear.

DIAGNOSIS

HISTORY

- Signs and symptoms:
 - Wide variation in presenting signs and symptoms depending on affected organ systems
 - Single-system skeletal disease may be asymptomatic, with incidental discovery of lesions on radiographs obtained for other reasons (e.g., trauma).
- Swelling, pain, or pathologic fracture from soft tissue or bone lesion

- Proptosis
- Persistent otorrhea
- Early loss of teeth; persistent oral ulcers
- Erythematous or brown papular rash
- Persistent seborrheic dermatitis
- Gait disturbance
- Failure to thrive
- Diarrhea, possibly bloody
- Fever of unknown origin
- Headache
- Abdominal pain
- Jaundice
- Polydipsia or polyuria (diabetes insipidus [DI])
- School/cognitive problems
- Dyspnea or persistent cough
- History of spontaneous pneumothorax

PHYSICAL EXAM

- Growth or pubertal delay
- Skin: brownish-red papules often involving intertriginous areas, seborrheic dermatitis (cradle cap), purpura, petechial rash especially at areas of skin contact (e.g., top of diaper); rash may become ulcerated, crusted, or scaly.
- Ears: otorrhea, hearing loss
- Skeleton: swelling or mass; may be painless or very tender to palpation; skull, axial skeleton, long bones more often affected than hands or feet
- Teeth: gingivitis, “floating teeth,” oral ulcers
- Eyes: orbital swelling, cranial nerve palsies
- Lungs: tachypnea, intercostal retractions
- GI: hepatosplenomegaly, ascites, edema, jaundice; stool with blood or mucus
- Neurologic: ataxia, cognitive difficulties

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Routine diagnostic evaluation
 - CBC with differential to evaluate for marrow involvement
 - Liver function tests (LFTs), prothrombin time (PT), partial thromboplastin time (PTT) to evaluate liver function
 - Morning urine specific gravity; urine and serum osmolality to evaluate for DI
- Other investigations
 - Pulmonary involvement: pulmonary function tests
 - Suspected diabetes insipidus (polydipsia/polyuria): endocrine evaluation including water deprivation test and evaluation of anterior pituitary hormone production
 - Auricular involvement: audiogram; ear, nose, and throat evaluation
- Bone involvement: biopsy of lesions unless diagnosis of LCH already established

Imaging

- Chest radiograph and skeletal survey (bone scan not as sensitive in most patients but may be better for infants; whole body MRI may also be used)
- Liver/spleen ultrasound
- High-resolution chest CT if pulmonary involvement suspected
- If neurologic involvement or signs of DI, MRI of brain with contrast, including detailed evaluation of sella turcica
- Dental radiographs if teeth are involved
- CT/MRI of lytic-appearing lesions often obtained prior to diagnosis to evaluate potential malignancy; classic “punched out” lesions may not require imaging beyond plain films.

Diagnostic Procedures/Other

- Biopsy of lesion to establish diagnosis
- Cytopenias or other high-risk organ involvement: bone marrow aspirate and biopsy
- Liver dysfunction: liver biopsy to evaluate for sclerosing cholangitis
- GI involvement: endoscopic biopsy of small and large intestine
- Pulmonary involvement: bronchoalveolar lavage (BAL) or lung biopsy to evaluate for infection if diagnosis of LCH not already established or if CT appearance is atypical.

Pathologic Findings

- Proliferation of immature myeloid dendritic with surrounding inflammatory infiltrate.
- LCH cells are CD1a and CD207 positive; contain Birbeck granules on electron microscopy.

DIFFERENTIAL DIAGNOSIS

- Broad differential, depending on constellation of presenting symptoms
- Bone/soft tissue lesions
 - Sarcoma (especially osteogenic sarcoma, Ewing sarcoma, or rhabdomyosarcoma)
 - Benign bone lesion (e.g., osteoma, bone cyst)
 - Infection
 - Metastatic tumor (e.g., neuroblastoma, leukemia/lymphoma)
- Skin lesions
 - Seborrheic dermatitis
 - Otitis externa
 - Tinea infection
 - Viral exanthem (especially herpes simplex virus [HSV] in neonates)
- CNS lesions
 - Teratoma or malignant germ cell tumor
 - Craniopharyngioma
 - Primary CNS tumor
 - Neurodegenerative disorder
- Pulmonary involvement
 - Infection
 - Emphysema (e.g., α_1 antitrypsin deficiency)
- Fever, lymphadenopathy (nontender, nonerythematous)
 - Lymphoma
 - Lymphadenitis (especially large DNA viruses)
 - Granulomatous (e.g., fungal, cat-scratch disease) infections
 - Rosai-Dorfman or Castleman disease
 - Rheumatologic disease
 - HLH
- Hepatic involvement
 - Infections

- Congenital hepatic and storage diseases
- HLH
- Tumor infiltration (e.g., leukemia)
- Primary sclerosing cholangitis
- Cytopenias
 - Leukemia or other tumor infiltration
 - Aplastic anemia
 - HLH
 - Myelofibrosis or storage diseases

TREATMENT

GENERAL MEASURES

- Site and extent of disease determine therapy.
- A multidisciplinary approach is imperative to ensure the best therapy. Patients should be enrolled on a clinical trial whenever possible.
- Duration: 12 months of therapy associated with decrease in reactivation from 50% to 30%
- Type of therapy depends primarily on
 - Number of organ systems affected
 - Number of bone lesions if single system
 - Involvement of “risk organs” associated with morbidity or mortality: liver, spleen, and bone marrow
- Single-system LCH (most often bone, skin)
 - Observation of isolated lesions; often remain stable or spontaneously resolve
 - Local therapy
 - Isolated bone or lymph node: excision or biopsy often curative
 - Confirmed skin-only LCH: topical steroids, nitrogen mustard, or tacrolimus
 - Systemic therapy if multiple or refractory lesions
 - Low-dose chemotherapy for some multifocal bone disease or multiple recurrent single bone lesions; superior results with multiagent regimens
 - Reduces risk of later diabetes insipidus in patients with skull,

vertebral, or CNS lesions

- Multisystem LCH
 - Chemotherapy
 - Steroid, vinblastine, plus antimetabolites depending on extent of disease and risk organ involvement
 - Limited response by 6 weeks merits intensification (e.g., 6MP, 2-CdA + AraC)
 - Limited experience with allogeneic stem cell transplantation for very high-risk refractory disease
- Treatment of disease-related morbidity
 - Lifelong intranasal desmopressin acetate often needed for the management of diabetes insipidus; posterior pituitary dysfunction is rarely reversible.
 - Organ transplantation may be necessary for high-risk patients with organ dysfunction.

MEDICATION

- Frontline: corticosteroids and vinblastine; addition of antimetabolites (6-mercaptopurine [6-MP], methotrexate) if multisystem disease and risk organ involvement
- Cladribine has been used in case series for CNS mass lesions. For neurodegenerative disease, case series report variable responses (generally stabilization) to dexamethasone, cytarabine, cladribine, vincristine, IVIg, and retinoic acid.
- Bisphosphonates is being tested for isolated bone lesions.
- Confirmed skin-only disease: topical steroids, tacrolimus, or nitrogen mustard; systemic co-trimoxazole.
- Refractory disease: 2-chlorodeoxyadenosine (2-CdA) ± cytarabine, clofarabine, etoposide,

ADDITIONAL THERAPIES

Radiotherapy rarely used; reserved for refractory or critical bone lesions (e.g., spinal cord compression)

ISSUES FOR REFERRAL

Multidisciplinary care involving several specialties may be required for coordination of chemotherapy and management of orthopedic,

endocrinologic, hepatic, hematologic, or pulmonary complications.

SURGERY/OTHER PROCEDURES

- Initial biopsy for diagnosis: often curative for solitary bone lesions even without clean margins
- Excision of isolated bone or lymph node lesions

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Evaluation at regular intervals for recurrence of lesions or new high-risk organ involvement
- Because of variable course, patients should be followed closely at centers with LCH expertise.
- Patients with CNS risk lesions should be monitored for neurodegeneration with detailed neurologic examination, evaluation of school performance, and an annual MRI for 10 years post diagnosis.

Patient Monitoring

- Laboratory and imaging follow-up as described for initial evaluation, with focus on previously affected and high-risk organ systems
- Routine follow-up typically includes history, physical exam, CBC, LFTs, and skeletal imaging.

DIET

Maintain fluid and electrolyte intake if diabetes insipidus is present.

PROGNOSIS

- Prognosis is linked to extent and location of disease. Single-system or bone/skin disease carries low risk of morbidity. Overall survival for patients with high-risk disease is 84%.
- Often, disease will “burn out” by the end of childhood. ~5% of patients will continue to have exacerbations as adults.
- Survival in neonates and younger children with high-risk disease may be poorer. Response to therapy at 6 weeks is the most important prognostic factor.

COMPLICATIONS

- Most common long-term morbidities include orthopedic problems, diabetes insipidus, and neurodegenerative disease.
- Smoking is strongly associated with development of pulmonary disease in LCH patients.
- Chronic disabilities with multisystem disease include pulmonary fibrosis, hepatic fibrosis, deafness, orthopedic problems, short stature, permanent ataxia, neurocognitive deficits, and poor dentition.

CODES

ICD10

- C96.6 Unifocal Langerhans-cell histiocytosis
- C96.0 Multifocal and multisystemic Langerhans-cell histiocytosis

FAQ

- Q: Is LCH a cancer?

- A: LCH is not strictly a cancer. It is the abnormal growth of white blood cells that normally help fight infection. Too many are made, and they form a tumor that damages the body. BRAF mutations that are associated with several types of cancer are found in approximately half of LCH cases. Similar to true cancers, LCH is frequently treated with chemotherapy.
- Q: Is LCH contagious?
- A: There is no evidence that LCH is caused by an infection or that it is contagious.

HISTOPLASMOSIS

John Arnold • Dylan Kann

BASICS

DESCRIPTION

- Histoplasmosis (also known as Ohio Valley disease, spelunker's lung, cave disease, Darling disease, Appalachian Mountain disease, and reticuloendothelial cytomycosis) is the most prevalent endemic mycosis in United States.
- Dimorphic fungus *Histoplasma capsulatum* var. *capsulatum* in United States (African var. is *duboisii*, which affects skin, LN, and bone)
- Forms include acute, chronic, primary, reactivation, and the affected disease areas (pulmonary, extrapulmonary, disseminated)

EPIDEMIOLOGY

- Endemic in central and southeastern states, classically Ohio and Mississippi River valleys; also prominent in Central America but occasionally in Europe, Asia, and Africa
- Mold form at $<35^{\circ}\text{C}$ (whereas yeast form in tissue above 37°C) grows best in soil environments: warm, moist, and rich in nitrogen (bird/bat guano); found in caves, under roosting trees, abandoned buildings
- Occasional cluster infections usually with soil disruptions (spelunking, building demolition)
- Sporadic cases with some activities: gardening, roofing, installing air-conditioning/heating, cleaning older homes, playing in hollow trees
- Only mammals can be infected (birds don't carry organism).
- No human or animal-to-human transmission except for one case of vertical transmission in infant with co-HIV infection
- Incubation typically 3–17 days but up to 5 months

Incidence

- Total infections: estimated 500,000 per year
- Chronic pulmonary: 1:100,000 cases
- Disseminated: 1:2,000 cases

Prevalence

Skin test reactivity as high as 50–80% by age 18 years in most highly endemic areas

RISK FACTORS

- Males slightly more than females
- Infections more common in 30s–40s but all ages affected
- Disseminated disease risk factors: immature cellular immunity (<2 years of age), large inoculum, acquired immunodeficiency (including TNF-alpha inhibitors), malnutrition

GENERAL PREVENTION

- Avoid areas/dust with likely mold.
- Spray water, oil, or 3% formalin in areas with dust/dirt if work planned.
- Wear cover apparel and face mask able to filter particles >1 millimicron (e.g., N95).
- Prophylaxis for certain populations

PATHOPHYSIOLOGY

- Inhaled mold spores germinate in lungs to yeast form; rarely enter via skin
- Once germinated, some lymphatic and hematologic dissemination even in self-limited disease
- Immune system takes several weeks to respond, involves T lymphocytes, IL-12, IFN-gamma and TNF-alpha; macrophages kill fungus.

ETIOLOGY

Infectious mold spores are microconidia of *H. capsulatum*.

DIAGNOSIS

HISTORY

- Of 5% who develop symptoms, most (60–90%) have pulmonary symptoms and/or flulike illness lasting days to 2 weeks for acute.
 - Most common complaints: headache, fatigue, fever, cough,

- myalgias, chest pain, which can be pleuritic
- Pharyngitis, rhinorrhea, and congestion are unusual.
- 5% of symptomatic patients have more prolonged course with additional anorexia, weight loss, arthralgia, and night sweats lasting >2 weeks.
 - “Severe” symptoms: dyspnea and hypoxemia
 - Cavitary form can have TB-like symptoms (e.g., hemoptysis) but rare in children.
- Progressive disseminated histoplasmosis (PDH) (usually <2 years of age or immunocompromised) symptoms: fever, weight loss, hepatosplenomegaly, failure to thrive (in infants)

PHYSICAL EXAM

- For acute pulmonary disease, exam is usually normal, aside from fever and occasionally crackles or decreased breath sounds; wheezing has been reported.
- More severe or diffuse pulmonary disease can present with weight loss, hypoxia, and dyspnea.
- Erythema nodosum (especially adolescent patients)
- Disseminated findings: hepatosplenomegaly, extrapulmonary lymphadenopathy and/or granulomas, oral or skin lesions, adrenal or intestinal masses, multifocal choroiditis, meningitis (60% of PDH of infancy), endocarditis, parotitis, arthritis, signs of DIC
- Other findings could include the following:
 - Pericardial effusion (10% of symptomatic pediatric patients) with potential cardiac rub
 - Pleural effusion
 - Chylothorax
 - Biliary obstruction
 - Superior vena cava syndrome

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Culture is the definitive method of diagnosis.
 - From sterile site: blood, bone marrow, CSF
 - Can take from 1–6 weeks to grow

- Culture sensitivity varies with site and host (sputum 10% positive in acute pulmonary, 60% positive in cavitary disease, 90% in BAL from HIV patients).
- Antigen tests using quantitative enzyme immunoassay (often first line)
 - Urine along with blood most common sources for testing (less sensitive but can be done on BAL, CSF)
 - 92% sensitivity: disseminated infection
 - 80% sensitivity: severe pulmonary disease
 - 34% sensitivity: self-limited pulmonary disease
 - 14% sensitivity: chronic pulmonary disease
 - Used to monitor fungal burden
 - Cross-reactivity rarely with *Paracoccidioides brasiliensis*, *Blastomyces dermatitidis*, *Coccidioides immitis*, *Coccidioides posadasii*, and *Penicillium marneffei*
- Serologic: immunodiffusion (ID) and complement fixation (CF) antibody tests
 - Most common test for localized pulmonary disease but often negative in acute period
 - Best tests for chronic meningitis
 - Less sensitive in immunocompromised patients
 - Antibody appears 4–6 weeks after infection, can become negative after 12–18 months
 - Immunodiffusion usually 1st-line serologic test (specific test with only 5% cross-reactivity but only 80% sensitive)
 - Tests for M and H bands; H bands more suggestive of acute infection
 - H bands positive in 23%, M bands positive in 76% of acute pulmonary
 - Complement fixation usually 2nd-line serologic test, as more sensitive but less specific (18% cross-reactivity)
 - Cross-reacts with *Blastomyces*, *Paracoccidioides*, and *Coccidioides*
 - 4-fold increase or single 1:32 or greater is presumptive of active/recent infection.
 - Titers 1:8 and 1:16 unclear significance

- Microscopy
 - Noncaseating granulomas
 - Intracellular yeast form in tissue, blood, bone marrow, or BAL
 - Usually examined with silver stain
- Other lab findings:
 - Mild anemia, elevated ferritin, hypercalcemia, elevated ESR/CRP
 - PDH: pancytopenia, coagulopathy, elevated liver enzymes
 - Meningitis: CSF lymphocytic pleocytosis, protein elevation, and low glucose
- Skin test: not clinically used; only used for epidemiologic studies

Imaging

- CXR
 - Majority are normal in self-limited disease, and 40–50% of cases of PDH are normal.
 - Positive findings can include hilar adenopathy, infiltrates, pleural effusions (5% of children), pericarditis (10% of children), mediastinal granuloma, mediastinal fibrosis (rare in children), mass effect, calcifications.
- Chest CT
 - Miliary nodules and calcifications more easily seen
 - Can be diffuse parenchymal consolidation
- CNS imaging
 - Leptomeningeal enhancement (often basilar), focal brain or spinal cord lesions, strokes, and encephalitis

DIFFERENTIAL DIAGNOSIS

- Pulmonary histoplasmosis
 - Tuberculosis and other mycobacteria
 - Pneumonia (atypical)
 - Other fungal lung infections (blastomycosis, sporotrichosis, and coccidioidomycosis)
 - Pneumocystis jirovecii (can mimic PDH symptoms)
 - Nocardia and Actinomyces
- Mediastinal lymphadenopathy
 - Malignancy

- Sarcoidosis
- PDH
 - Malignancy
 - Sepsis
 - Opportunistic infections (coinfection is common in immunodeficiency)
 - Hemophagocytic lymphohistiocytosis/macrophage activation syndrome (can be sequelae of PDH as well)
 - Brucella, Q-fever, leishmaniasis

ALERT

- Most children will not require treatment for *H. capsulatum* pulmonary disease.
- Arthritis, pericarditis, and erythema nodosum do not necessitate antifungals.
- Children with PDH should be screened for HIV and immunodeficiency.
- Alert lab of any specimen suspected of *Histoplasma* (lab hazard if grown).

TREATMENT

MEDICATION

- Immunocompetent patients with primary acute uncomplicated (nonsevere) pulmonary histoplasmosis less than 4 weeks' duration do not require treatment.
- Therapy indicated for severe/complicated pulmonary disease, after high inoculum, PDH, infection in immunocompromised
- Pulmonary disease (moderate but >1 month)
 - PO itraconazole 5–10 mg/kg/24 h divided b.i.d. × 6–12 weeks (max 400 mg daily)
- Pulmonary disease (severe)
 - Amphotericin B lipid formulation (unless renal involvement) 3–5 mg/kg/24 h depending on formulation (lipid complex vs. liposomal) or deoxycholate 1 mg/kg daily IV × 1–2 weeks followed by PO

- itraconazole 5–10 mg/kg/24 h divided b.i.d. (max 400 mg daily) for 12 weeks
- Methylprednisolone (controversial in children) 1–2 mg/kg daily IV during first 1–2 weeks for patients with worsened hypoxemia or distress
 - Disseminated (without HIV infection)
 - Amphotericin B lipid formulation (as above) × 4–6 weeks.
Alternative: lipid formulation of amphotericin B (as above) for 2–4 weeks followed by itraconazole PO 5–10 mg/kg/24 h divided b.i.d. for 3–6 months until urine antigen concentration less than 2 mcg/mL
 - Disseminated (with HIV infection)
 - Liposomal amphotericin B 5 mg/kg/24 h IV × 2–6 weeks followed by oral itraconazole for at least 1 year to life 5–10 mg/kg/24 h divided b.i.d. (max of 400 mg/24 h)
 - If HAART given for 6 months, CD4 >150 cells/mm³, antifungal taken for 1 year, and antigen levels low, can consider stopping secondary prophylaxis
 - Meningitis
 - Liposomal amphotericin B 5 mg/kg/24 h IV × 4–6 weeks then oral itraconazole 5–10 mg/kg/24 h divided b.i.d. × 12 months and then until resolution of CSF profile; monitor antigen levels.
 - Mediastinitis (rare)
 - Amphotericin B × 1–2 weeks then oral itraconazole for 6 months
 - Fibrosing mediastinitis (rare)
 - Itraconazole for 3 months
 - May not have any effect on fibrosis
 - Pericarditis/rheumatologic manifestations
 - Pericardiocentesis if severe tamponade
 - NSAID (usually indomethacin) for 2–12 weeks
 - Consider oral prednisone (1 mg/kg/24 h).
 - Compression by granulomatous disease
 - Consider surgery and corticosteroid with concurrent use of itraconazole.
 - Vertical transmission in newborn
 - Amphotericin B (lipid formulation)

- Although the Infectious Diseases Society of America (2007) guidelines state that lipid preparations of amphotericin are “not preferred” in children (except HIV patients), as nonlipid preparations are well tolerated, lipid formulations are most often used due to overall favorable side effect profile.
- Salvage therapy can be done with posaconazole and/or voriconazole; fluconazole is inferior to itraconazole.
- Prophylaxis for CD4 <150 cells/μL, in hyperendemic areas or solid organ transplant recipients, those scheduled to receive TNF inhibitors, or those undergoing intensive chemotherapy with a history of histoplasmosis in the past 2 years: oral itraconazole 5 mg/kg/24 h divided b.i.d. (max 200 mg/24 h)

GENERAL MEASURES

Standard precautions adequate for hospital isolation

INPATIENT CONSIDERATIONS

Patients receiving amphotericin may need prolonged IV access.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Patient monitoring
 - In PDH, follow antigen levels monthly during therapy and 12 months post therapy
 - Itraconazole blood levels should be measured after >2 weeks of therapy (goal serum level >1 mcg/mL).

PROGNOSIS

- Overall good prognosis except for untreated PDH disease, which is highly fatal
- Self-limited pulmonary patients recover in 2–3 weeks.
- Most treated PDH patients have significant improvement after 2 weeks of IV antifungals.

COMPLICATIONS

- Lymphatic, GI, esophageal, vascular, and biliary obstruction

- Renal stones
- Multifocal choroiditis
- Calcified nodules
- Fibrosis
- Pleural effusion
- Pericarditis
- Chylothorax
- Superior vena cava syndrome
- Macrophage activation syndrome (MAS)

CODES

ICD10

- B39.9 Histoplasmosis, unspecified
- B39.4 Histoplasmosis capsulati, unspecified
- B39.2 Pulmonary histoplasmosis capsulati, unspecified

FAQ

- Q: What are the most common clinical presentations of histoplasmosis?
- A: Asymptomatic, mild primary pulmonary disease. Moderate to severe pulmonary, disseminated, and cavitary are uncommon.
- Q: How is histoplasmosis best diagnosed?
- A: Isolation or identification of the organism is definitive. Antigen testing of urine or blood is used for acute infections, especially severe infections. Serologic testing can be helpful but lack sensitivity and specificity. Skin test is not useful.
- Q: Does histoplasmosis need to be treated with antifungal therapy?
- A: For mild primary disease in an immunocompetent patient, no treatment is necessary. More severe or disseminated disease is treated.
- Q: Do patients with histoplasmosis need to be isolated?
- A: Isolation of infected patients is not required.

HODGKIN LYMPHOMA

Elizabeth Robbins

BASICS

DESCRIPTION

B lineage malignant lymphoid neoplasm. Typically presents with painless lymphadenopathy, often cervical (70–80%) or supraclavicular (25%). Mediastinal mass present in 50%. Constitutional symptoms (e.g., fatigue, fever, night sweats, weight loss, cough, pruritus) may or may not be present. Constitutional symptoms sometimes precede development of lymphadenopathy.

EPIDEMIOLOGY

Incidence

- Represents 7% of childhood cancer
- 11.7 cases/million/yr age <20 years
- Most common cancer for ages 15–19 years
- Rarely seen in children < age 5 years
- M > F age <15 years
- F > M age 15–19 years
- Bimodal age distribution in adults: early peak mid/late 20s; late peak > age 50 years

RISK FACTORS

- Few known risk factors include the following:
 - Immune deficiency (e.g., HIV infection)
 - Autoimmune disorders
 - Lower socioeconomic status for childhood form (age 14 years or younger)
 - Higher socioeconomic status for young adult form
- Decreased risk if
 - Multiple older siblings
 - Exposure to common infections in preschool

Genetics

- Familial HL rare, accounting for 4.5% of cases.
- Familial cases may reflect
 - Genetic influences, including inherited immunodeficiency states
 - Environmental factors
 - Exposure to viruses

PATHOPHYSIOLOGY

- Reed-Sternberg cells, a clonal population of large binucleate cells arising from B cells, are the malignant cells in HL. Surface antigen expression includes CD30 but not CD20.
- Only 1% of cells in involved nodes are Reed-Sternberg cells and morphologic variants; the rest are inflammatory cells: lymphocytes, macrophages, fibroblasts, plasma cells, eosinophils.

Classification

Two clinically distinct subtypes of HL recognized:

- Classical HL (90–95% of cases)
 - Nodular sclerosing
 - Mixed cellularity
 - Lymphocyte depleted
 - Lymphocyte rich
- Nodular lymphocyte predominant (5–10% of cases)

ETIOLOGY

- Cause unknown
- Association between Epstein-Barr virus (EBV) infection and HL: 20–50% of patients with classical HL have monoclonal or oligoclonal proliferation of EBV-infected cells.

DIAGNOSIS

HISTORY

- Painless lymphadenopathy slowly increasing in size. Lymphadenopathy often present for weeks to months before presentation. Cervical or supraclavicular sites most common.

- Constitutional (“B”) symptoms: 1 or more occur in 20% of children.
 - Fever $>38.0^{\circ}\text{C}$, not otherwise explained
 - Weight loss $>10\%$ within 6 months preceding diagnosis, not explained
 - Drenching night sweats
- Other constitutional symptoms include fatigue, pruritus, cough, and orthopnea.
- Patients with large mediastinal mass may have symptoms of superior vena cava syndrome: dyspnea, facial swelling, cough, orthopnea, headache.

PHYSICAL EXAM

- General appearance: Patients with advanced disease may be tired-appearing and cachectic.
- Fever, if present, is usually intermittent.
- Lymph nodes: Nodes larger than 1 cm are considered abnormal. Cervical, supraclavicular (especially left), and axillary nodes are most common. Other sites include epitrochlear, inguinal, and femoral.
 - Lymph nodes are usually firm, rubbery, nontender, and sometimes matted.
- Lungs: Decreased breath sounds or rhonchi may be noted in patients with large mediastinal mass. Some patients unable to lie flat due to respiratory distress.
- Abdomen: Splenomegaly may be present; hepatomegaly is less common.
- Skin: Pallor due to anemia may be present. Erythematous and excoriated areas may be present in patients with pruritus. Bruises and petechiae rare. Icteric sclera and/or jaundice may be noted in cases with autoimmune hemolytic anemia (rare).

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- No specific lab assay is diagnostic of HL.
- Erythrocyte sedimentation rate (ESR): useful as tumor marker if elevated at diagnosis
- CBC with differential

- Bilateral bone marrow biopsy in selected cases (e.g., patients with B symptoms or advanced disease [Stage III or IV])
- Liver and renal function studies
- Thyroid function (if radiation planned)
- Baseline electrocardiogram, echocardiogram
- Pulmonary function tests (pre-bleomycin)

Imaging

To evaluate extent of disease at diagnosis for staging and to follow response to treatment

- Chest radiograph (posterior-anterior and lateral) to evaluate for mediastinal mass
- CT scan of neck, chest, abdomen, pelvis
- PET or PET/CT: Functional imaging with PET has replaced previous staging modalities such as splenectomy, lymphangiogram, and gallium scan. Used at diagnosis and to follow response to therapy.

Diagnostic Procedures/Other

- Fine needle aspirate or core needle biopsy may occasionally be adequate for diagnosis provided typical Reed-Sternberg cells can be identified.
- Excisional biopsy of lymph node is usually necessary for diagnosis.
- Biopsy tissue studies include the following:
 - Flow cytometry (classic HL usually CD30+)
 - Cytogenetics
 - Culture for aerobic, anaerobic, and acid-fast bacilli if indicated

ALERT

General anesthesia is usually contraindicated in patients with mediastinal mass or tracheal deviation because of the possibility of airway collapse from loss of smooth muscle tone during anesthesia.

- Ann Arbor staging criteria:
 - Stage I—involvement of a single lymph node region (I) or of a single extralymphatic organ or site (I_E)
 - Stage II—involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site and one or more lymph node regions on

the same side of the diaphragm (II_E)

- Stage III—involvement of lymph node regions on both sides of the diaphragm (III), which may be accompanied by involvement of the spleen (III_S) or by localized involvement of an extralymphatic organ or site (III_E) or both (III_{SE})
- Stage IV—diffuse or disseminated involvement of one or more extralymphatic organs or tissues with or without associated lymph node involvement
- Modifiers: A/B—presence of one or more B symptoms (see “[History](#)”) is designated by the suffix B; A denotes absence of B symptoms.

DIFFERENTIAL DIAGNOSIS

- Other malignant process (lymph nodes usually nontender to palpation)
 - Non-HL
 - Soft tissue sarcoma, germ cell tumor
 - Metastatic adenopathy—soft tissue sarcoma, nasopharyngeal carcinoma
- Infection (lymph nodes may be tender to palpation)
 - Epstein-Barr virus
 - Atypical Mycobacterium
 - Histoplasmosis
 - Toxoplasmosis
 - Tuberculosis
 - Cat-scratch disease
 - Staphylococcus aureus, Streptococcus
- Drug reaction (e.g., phenytoin)

TREATMENT

MEDICATION

- Long-term survival in pediatric patients with HL is >90%. Recent treatment strategies have therefore focused on decreasing intensity of therapy to minimize late effects. Chemotherapy combined with radiation therapy has been the standard approach historically, but HL is

increasingly being treated with chemotherapy alone. Response to treatment as measured by PET serves to guide treatment decisions; patients whose disease is no longer PET-avid after 2–4 courses of chemotherapy are often treated with chemotherapy alone.

- Chemotherapy regimens (28-day cycles):
 - ABVD: doxorubicin (Adriamycin), bleomycin, vinblastine, dacarbazine; standard 1st-line regimen for adults
 - COPP/ABV: cyclophosphamide, vincristine (Oncovin), procarbazine, prednisone, doxorubicin (Adriamycin), bleomycin, vinblastine
 - VAMP: vinblastine, doxorubicin (Adriamycin), methotrexate, prednisone
 - BEACOPP: bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine, prednisone, procarbazine; efficacy similar to ABVD but with more acute toxicities, risk of secondary leukemia, nearly universal infertility

ADDITIONAL THERAPIES

- Radiation therapy
 - Used in combination with chemotherapy
 - Provides effective local control for areas of bulky disease, defined as a mediastinal mass $>1/3$ the thoracic diameter measured at the dome of the diaphragm on a PA CXR or a large nodal aggregate >6 cm (10 cm by some criteria).
 - Radiation doses and fields have been reduced over the past decade, but late effects including cardiac disease and secondary malignancies including breast cancer are still significant.
- Radiotherapy is commonly employed in the following:
 - Patients with bulky disease (some treated with chemotherapy alone)
 - Patients whose disease is responding poorly to chemotherapy
 - As part of a combined modality treatment strategy with lower dose radiation and less intense alkylator therapy (e.g., Stanford V or recent COG regimens)
 - Salvage therapy for relapsed disease
- Long-term survival ~50% for patients with recurrence. Specific salvage therapy based on remission duration and initial therapy. Typical

salvage includes reinduction followed by high-dose chemotherapy and autologous stem cell transplant. Radiation may also be used.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Patients are monitored for evidence of disease recurrence and for long-term toxicity from chemotherapy/radiation therapy. Two thirds of recurrences occur within the first 2 years of diagnosis.
- Monitoring for disease recurrence includes the following:
 - History, physical exam q 3 months during 1st 2 years off therapy; q 6 months for 3rd, 4th years off therapy; then annually
 - Lab studies including ESR if elevated at diagnosis; CBC
 - Surveillance CT scans q 3–6 months 1st few years off therapy mandated by many protocols; however, some providers follow clinically to avoid radiation exposure and because detecting recurrence by imaging, presumably earlier than clinically, may not result in improved survival. PET scan if recurrence suspected.
 - Periodic CXR: Some providers follow CXR 1st few years off therapy if mediastinal disease.
 - Monitoring for late effects depends on the patient's treatment.
 - Cardiac: periodic echocardiogram, EKG if anthracycline therapy or mediastinal radiation
 - Pulmonary: periodic pulmonary function tests if bleomycin or mediastinal radiation
 - Reproductive: hormonal testing (LH, FSH, estradiol/testosterone) beginning at puberty or by age 12 years
 - Thyroid: annual thyroid function (T₄, TSH) if radiation
 - Secondary malignancies
 - Breast: monthly breast self-exam; yearly mammogram with adjunct MRI beginning 8 years after radiation or age 25 years, whichever is later
 - Thyroid: yearly thyroid exam if radiation
 - Colon: colonoscopy q 5 years beginning age 35 years if radiation

- Leukemia: yearly CBC, platelets, differential for 10 years after exposure to etoposide, alkylating agents, anthracyclines

PROGNOSIS

- Overall 5-year survival >90% regardless of stage. Prognosis for 5-year disease-free survival depends on stage at diagnosis:
 - >90% for low-stage disease (stage I, II, non-bulky, no B symptoms)
 - 65–90% for advanced disease (stage III, IV)

COMPLICATIONS

- Acute complications of treatment:
 - Chemotherapy
 - Hair loss, nausea, vomiting, cytopenias resulting in infection, bleeding
- Late complications of treatment:
 - See “[Cancer Therapy Late Effects](#)” chapter.
 - Chemotherapy
 - Cardiomyopathy, decreased pulmonary function, pulmonary fibrosis, alterations in fertility, secondary leukemia
 - Radiation therapy
 - Breast cancer, other secondary malignant neoplasm, cardiomyopathy, coronary artery disease with myocardial infarction, pericarditis, accelerated atherosclerosis with increased stroke risk, pulmonary fibrosis, hypothyroidism, impaired growth of bones and soft tissue

- C81.92 Hodgkin lymphoma, unspecified, intrathoracic lymph nodes

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Hiwot Hiruy • Allison Agwu

BASICS

DESCRIPTION

- HIV-1 and HIV-2 are the etiologic agents of HIV infection and AIDS. Infection is lifelong.
- HIV-1 is more common worldwide, whereas HIV-2 is mainly prevalent in West Africa.
- Typically, an acute phase with flulike symptoms develops 2–4 weeks after acquiring infection, followed by a long asymptomatic period (5–15 years in adults, shorter in children), then the development of nonspecific signs and symptoms (weight loss, adenopathy, hepatosplenomegaly, failure to thrive) and mild clinical immunodeficiency.
- Without treatment, the infected person will experience progressive immunologic deterioration and eventually become susceptible to opportunistic infections and cancers (AIDS).

GENERAL PREVENTION

- HIV infection is almost completely preventable.
- Risk of transmission to newborns of HIV-infected women can be decreased:
 - With antenatal 3-drug regimens, delivery via elective cesarean section for selected cases, and 6 weeks of postnatal zidovudine, perinatal transmission rates are now 2% or less in HIV specialty care sites.
 - All pregnant women should be offered HIV testing at the first prenatal visit. In areas of high incidence, repeat testing should be done at 36 weeks of gestation.

EPIDEMIOLOGY

HIV infection is transmitted via the following:

- Sexual contact
 - Male-to-female transmission more efficient than female to male
 - Anal receptive sex more likely to transmit than vaginal sex
- Exposure to infected blood or bodily fluids
 - Usually parenteral exposure to infected blood (via transfusions or sharing needles)
 - Risk of transmission from an HIV-contaminated needle is 1/300.
- Breast milk
 - Overall risk of breastfeeding is ~15%.
 - In countries where breastfeeding is the norm, up to 30% of perinatally acquired HIV infections occur through breastfeeding.
- Perinatal infection can occur either in utero or during labor and delivery:
 - Of perinatally infected infants, 5–10% are believed infected in utero, whereas ~20% acquire infection around the time of birth.
 - Risk of an HIV-infected mother (not on treatment) giving birth to an infected infant is ~20% (in the absence of breastfeeding), with increased rate of transmission for women with low CD4 counts or higher viral titers. Vaginal delivery, especially with rupture of membranes >8 hours, appears to increase the risk of infant infection.
 - Presence of untreated sexually transmitted infections (STIs), chorioamnionitis, and prematurity all increase the risk of mother-to-child transmission of HIV.
- HIV is not believed to be transmitted by the following:
 - Bites
 - Sharing utensils, bathrooms, bathtubs
 - Exposure to urine, feces, vomitus (except where these fluids may be grossly contaminated with blood, and even then transmission is rare, if it happens at all)
 - Casual contact at home, school, or day care center

DIAGNOSIS

HISTORY

Clinical signs, symptoms, and scenarios in which HIV testing should be

performed:

- Infants with maternal HIV status that is unknown or positive
- IV drug use
- Noninjectable drug use
- STIs, especially syphilis
- All adolescents (particularly those endorsing sexual activity), at least annually
- Transfusions before 1986
 - Frequent infections, including recurrent sinopulmonary infections, recurrent pneumonia/invasive bacterial disease:
- Severe acute pneumonia (Pneumocystis)
- Recurrent or resistant thrush, especially after 12 months of age
- Congenital syphilis
- Acquired microcephaly
- Progressive encephalopathy, loss of developmental milestones
- History of idiopathic thrombocytopenic purpura/thrombocytopenia
- Failure to thrive
- Recurrent/chronic diarrhea
- Recurrent/chronic parotid gland enlargement
- Generalized lymphadenopathy

PHYSICAL EXAM

- May be normal in the first months of life
- 90% have exam findings by 2 years of age
- Most common findings are generalized adenopathy, hepatosplenomegaly, failure to thrive, recurrent/resistant thrush, (especially after 1 year of age)
- Recurrent or chronic parotitis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Enzyme-linked immunosorbent assay (ELISA) antibody screen
 - For children >18 months of age, repeatedly reactive ELISA antibody screen, followed by confirmation with Western blot analysis, is diagnostic of HIV infection.
 - Any positive test should always be repeated before a definitive

diagnosis is discussed with family.

- In 1st year of life, positive HIV ELISA and Western blot antibody tests simply confirm maternal infection because the antibody test is IgG based and maternal anti-HIV antibodies readily cross placenta. Maternal antibodies may remain detectable in the infant until 15 months of age.
- HIV-1/2 antigen/antibody combination point-of-care testing is a qualitative immunoassay that simultaneously detects presence of HIV p-24 antigen and HIV 1/2 antibodies is available for children >13 years of age
 - The test can help identify patients with acute HIV infection, which may have not been identified by antibody testing alone.
 - Note that this test is NOT FDA approved for use in newborns and children younger than 12 years of age.
- HIV RNA or DNA polymerase chain reaction (PCR) DNA testing
 - Most reliable way of diagnosing HIV infection in infancy
 - Both tests have sensitivities and specificities >95% after 2 weeks of age.
- Elevated IgG levels: generally reaches twice the normal values by 9 months of age
- CD4 counts
 - Obtained at diagnosis and every 1–3 months
 - Results need to be evaluated based on age-adjusted normal values. Absolute CD4 counts are elevated in childhood, with normal median values $>3,000/\text{mm}^3$ in the 1st year of life, which then gradually decline with age, reaching values comparable with adult levels ($800\text{--}1,000/\text{mm}^3$) by age 7 years.
 - For children <5 years of age, CD4% should be used instead of absolute CD4 count.
- Quantitative viral RNA PCR assays
 - Termed “viral loads,” results are reported in a range from undetectable, usually <20 copies/mL (cpm), to upper values of >10 million cpm.
 - Long-term prognosis is closely related to viral loads.
 - Viral loads that remain $>100,000$ are associated with poor short-

term (2- to 5-year) outcomes.

- Also used as a marker of efficacy of treatment; goal is to suppress viral replication to the undetectable range for as long as possible. 50–80% of pediatric patients presently followed at tertiary sites have an undetectable viral load.
- Test is done at time of diagnosis (twice) to establish baseline, 1 month after initiating or changing therapies, and approximately every 3 months thereafter.
- Neurologic evaluation, with consideration of psychometric testing (baseline) and subsequently, particularly if abnormal. Neuroimaging is indicated in those with abnormal results.
- Postimmunization antibody levels to assess B-cell function
- Other frequent lab abnormalities include thrombocytopenia, anemia, and elevated liver enzymes.

DIFFERENTIAL DIAGNOSIS

- Neoplastic disease
 - Lymphoma
 - Leukemia
 - Histiocytosis X
- Infectious
 - Congenital/perinatal cytomegalovirus
 - Toxoplasmosis
 - Congenital syphilis
 - Acquired Epstein-Barr virus
- Congenital immunodeficiency syndromes
 - Wiskott-Aldrich syndrome
 - Chronic granulomatous disease

ALERT

Failure to screen for HIV infection during pregnancy results in inability to offer antiretroviral therapy during pregnancy, which may lead to failure of preventing infant infection, as well as the inability to prescribe *Pneumocystis carinii* pneumonia prophylaxis to infected newborns.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- Active immunizations
 - All infected children receive standard childhood immunizations, including the pneumococcal conjugate vaccine.
 - Infected children should receive yearly influenza A/B immunizations and 23- valent pneumococcal vaccine at age 2 years.
 - Symptomatic children should not receive the varicella vaccine, and those with severely low CD4 counts should not receive measles-mumps-rubella vaccination.
- Postexposure passive immunization (immunoglobulin) is recommended for the following:
 - HIV-infected children without history of previous chickenpox or those that did not receive two doses of vaccine who are exposed to chickenpox
 - HIV-infected children with severe immunosuppression and tetanus-prone wound
 - HIV-infected children with severe immunosuppression who are exposed to measles
- Immune enhancement
 - Passive: Studies done before the present era of antiretroviral therapy indicate that monthly gamma globulin infusions somewhat decreased febrile episodes and pneumococcal bacteremia. The children who benefit the most are those not on antibiotic prophylaxis for *P. carinii* pneumonia and/or who have had at least 2 episodes of invasive bacterial infections.
- Prophylaxis: One of the major advances has been the ability to offer prophylaxis against the most common opportunistic infections.

MEDICATION

Antiretroviral therapy

- Specific combination antiretroviral therapy prolongs life, delays progression of illness, promotes improved growth, and improves neurologic outcome.
- There is one report (2013) of a toddler initiated on antiretroviral

therapy within hours of life who attained “functional cure,” but detectable levels of HIV were found in the child less than one year later. More studies are underway to evaluate early antiretroviral therapy.

- Standard of care now involves the administration of combination therapy (usually 3 or more drugs), termed highly active antiretroviral therapy (HAART). There are now 5 different drug classes and as multiple multiclass combination pills.
- Given the complexities of therapy, antiretroviral therapy should always be prescribed in consultation with a specialist in pediatric/adolescent HIV infection.
- Adherence to prescribed schedules is critical. When patients miss even 10–20% of doses, the durability of response is short.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Family psychosocial support is critical.
- All infected patients should be comanaged with an HIV specialty care site.
- Patients should be seen every 1–3 months to monitor adherence, immune status (CD4 counts), and virologic suppression (quantitative plasma viral RNA).

PROGNOSIS

Due to HAART, morbidity and mortality have both greatly decreased:

- Median survival is now into adulthood.
- Incidence of new opportunistic infections (AIDS-defining illnesses) has decreased greatly, as have hospital admissions.

COMPLICATIONS

- *P. jiroveci* (previously *P. carinii*) pneumonia
 - Most common early fatal illness in HIV-infected children (peak age 3–9 months) mortality is 30–50%. A high index of suspicion is necessary for prompt diagnosis (by lavage) and initiation of therapy.
 - 40% of new cases of HIV-related pediatric *P. jiroveci* pneumonia

involve infants not previously recognized as HIV infected.

- Lymphocytic interstitial pneumonitis
 - Frequently asymptomatic; can lead to slow onset of chronic respiratory symptoms
 - Causes a distinctive diffuse reticulonodular pattern on chest radiographs
 - Usually diagnosed between 2 and 4 years of age; related to dysfunctional immune response to Epstein-Barr virus infection
 - Definitive diagnosis is made by lung biopsy.
 - For symptomatic patients, prednisone is effective.
- Recurrent invasive bacterial infections
 - Prior to the use of pneumococcal conjugate vaccines and HAART, the risk of bacteremia/pneumonia was ~10%/year in HIV-infected children.
 - Pneumococcal bacteremia is the most common invasive bacterial disease.
 - Bacterial pneumonia, sinusitis, and otitis media are common.
- Progressive encephalopathy
 - Diagnosed between 9 and 18 months of age, the hallmark is progressive loss of milestones or neurologic dysfunction.
 - Cerebral atrophy, with or without basal ganglion calcifications, on neuroimaging
- Disseminated Mycobacterium avium intracellulare
 - Older children, usually >5 years of age, with severe immunodeficiency ($CD4 \leq 100$)
 - Symptoms include prolonged fevers, abdominal pain, anorexia, and diarrhea.
- Candida esophagitis: Older children with severe immunodeficiency usually present with dysphagia or chest pain and oral thrush. Diagnosis indicated by barium swallow, but definitive diagnosis made by biopsy
- Disseminated cytomegalovirus disease
 - Retinitis less common in HIV-infected children than in adults
 - Cytomegalovirus may also cause pulmonary disease, colitis, and hepatitis.
- HIV-related cancers: Non-Hodgkin lymphoma most common cancer,

with primary site usually located in the CNS.

- Other organ dysfunction associated with HIV-infection in children: cardiomyopathy, hepatitis, renal disease, thrombocytopenia, idiopathic thrombocytopenic purpura

FAQ

- Q: Should HIV-positive mothers breastfeed?
- A: The recommendation for HIV-positive mothers in resource-rich

areas is to NOT breastfeed, as breastfeeding poses continued risk of exposure and infection with HIV to the infant. In areas where there are no affordable and safe substitutes of breastfeeding, exclusive breastfeeding is advised.

- Q. What are the recommendations for HIV screening in adolescents?
- A. The Centers for Disease Control and Prevention (CDC) recommend routine HIV testing for individuals aged 13–65 years. As part of anticipatory guidance, the American Academy of Pediatrics recommends offering HIV testing for adolescents aged 16–18 years of age at least once if prevalence of HIV in the area is $>0.1\%$. Continued HIV screening is also recommended for youth with high-risk behavior and those undergoing STI evaluations.

HUMAN PAPILLOMA VIRUS

Elizabeth M. Wallis • Sarah E. Winters

BASICS

DESCRIPTION

- Members of the Papillomaviridae family, the human papillomaviruses (HPV), which cause warts of the skin and mucous membranes
 - Exophytic venereal warts or condylomata acuminata are primarily caused by HPV types 6 and 11.
 - Warts can be found on the external genitalia and the urethra, vagina, cervix, anus, and mouth. HPV types 6 and 11 are also associated with squamous cell carcinoma of the external genitalia.
 - Virus types 16, 18, 31, 33, and 35 typically cause subclinical infection in the anogenital region and have been associated with intraepithelial genital carcinomas.
- HPV can also cause recurrent respiratory papillomatosis (RRP) in infants and young children. RRP primarily impacts the larynx but can also cause lesions anywhere along the respiratory tract.
- Increasing evidence that HPV may play a role in squamous cell carcinomas of the oropharynx

EPIDEMIOLOGY

- General
 - HPV is the most common viral sexually transmitted infection (STI).
 - Genital warts and HPV infection are diseases of young adults 16–25 years of age.
 - Cervical cancer is the 3rd most common female cancer worldwide.
- Genital HPV
 - Peak prevalence among women 18–24 years of age
 - At least 40% of sexually active adolescents are infected with HPV.
 - <1% of adolescents develop genital warts.
 - 500,000 new cases of cervical cancer diagnosed each year internationally
- RRP

- RRP impacts 4.5 per 100,000 children, mostly those age 2–3 years.
- 67% of children with RRP are born to mothers who had condyloma during pregnancy.

RISK FACTORS

- Infants
 - Primarily vertical transmission at birth
- Adolescents
 - Behavioral risks, including young age at 1st coitus, multiple partners, cigarette use, and having older male partners
 - Biologic risk in adolescent girls secondary to cervical anatomy

GENERAL PREVENTION

- Vaccination to prevent HPV types 6, 11, 16, and 18. Vaccination is recommended for female and male patients starting at age 11 years and is approved for use for persons aged 9–26 years.
- Condom use may diminish transmission.
- Examine partners; treat those infected.
- Pap smear in adult women to assess for cervical dysplasia
- HPV infection is not a reportable disease.

PATHOPHYSIOLOGY

- Transmission
 - Primarily through sexual contact
 - Can also be acquired during the birth process
 - Transmission from nongenital sites is rare.
- The incubation period is variable and ranges from 3 months to several years.
- The virus is trophic for epithelial cells and infects the basal layer of actively dividing cells.
- Infection results in koilocytosis and nuclear atypia. Genital infections may progress to severe dysplasia and carcinoma in situ (CIS).
- Spontaneous regression of clinical disease occurs in 90% of low-risk types and 75% of high-risk types.
- Recurrence is common.

COMMONLY ASSOCIATED CONDITIONS

- Epidermodysplasia verruciformis
- Other STIs

DIAGNOSIS

HISTORY

- Genital HPV
 - Most patients have no symptoms.
 - Presence of warts, often painless
 - Vaginal, urethral, or anal discharge; bleeding; local pain
 - Dysuria
 - Pruritus
- RRP
 - Infants have hoarse or weak cry, stridor, and failure to thrive.
 - Older children have hoarseness, stridor, dysphonia, and obstructive sleep apnea.

PHYSICAL EXAM

- Genital HPV
 - Warts appear as soft, sessile tumors with surfaces ranging from smooth to rough with many fingerlike projections.
 - HPV may also cause flat keratotic plaques that project only slightly with a hyperpigmented surface and are difficult to identify without the addition of acetic acid.
 - Subclinical infection is common, causing many foci of epithelial hyperplasia invisible to the examiner.
 - In males, infection is found on the penis, urethra, scrotum, and perianal areas.
 - In females, infection involves the urethra, vagina, cervix, and perianal area.
 - Diagnosis is made by visual inspection of the anogenital region. Cervical dysplasia is not clinically apparent on exam.
- RRP
 - Often normal exam but, on visualization of trachea, multiple verrucous, polypoid growths on vocal cords, subglottic region, and

trachea can be seen.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Application of 3–5% acetic acid for 5 minutes causes lesions to appear white and thus more readily apparent and can help with the detection of cervical disease.
- Tissue specimens may show koilocytosis typical for HPV infection.
- Pap smear with liquid cytology to assess for evidence of cervical dysplasia resulting from HPV infection
- Colposcopy aids the diagnosis of cervical lesions.
- Polymerase chain reaction is commercially available for HPV typing and is used in patients >21 years with abnormal Pap smears.

Diagnostic Procedures/Other

- Genital HPV
 - Pap smear or colposcopy to screen for cervical dysplasia
- RRP
 - Direct visualization of the airway through laryngoscopy

DIFFERENTIAL DIAGNOSIS

- Genital HPV
 - Condyloma lata (syphilis infection)
 - Molluscum contagiosum
 - Pink pearly papules or hypertrophic papillae of the penis
 - Lipomas
 - Fibromas
 - Adenomas
- RRP
 - Croup
 - Vocal cord paralysis
 - Other forms of nasal, laryngeal, pharyngeal, or tracheal obstruction

TREATMENT

MEDICATION

Table 1. Treatment for external warts		
Medication	Procedure	Side effect
Podofilox 0.5%	Patient applies medicine with a cotton swab b.i.d. for 3 days. After 4 days, it is repeated as necessary for 4 cycles. The area for treatment should not exceed 10 cm ² , and total drug should not exceed 0.5 mL/24 h.	Local
Imiquimod 5% cream	Patient applies cream at bedtime 3 times per week for up to 16 weeks. It is washed off after 6–10 hours.	Local
Podophyllin 10–25%	A practitioner applies a small amount to each wart and allows it to air dry. It is washed off 1–4 hours later. Dose is limited to 0.5 mL per treatment to avoid systemic toxicity. Dose may be repeated once weekly up to 4 doses. External lesions only	Local
Trichloroacetic acid (TCA) 80–90%	The practitioner applies this sparingly to each wart directly. Talc is applied to remove unreacted acid. It is washed off after 4 hours. Can be used on mucosal lesions	Local
Laser surgical excision	Requires special equipment and training; often requires general anesthesia; controlled tissue destruction	Local
Cryotherapy	Liquid nitrogen or cryoprobe is used every 1–2 weeks by a specially trained provider.	Local

ADDITIONAL TREATMENT

General Measures

- To date, no therapy exists that eradicates the virus. Recurrences are likely.
- Most patients require a course of therapy rather than a single treatment.
- Genital HPV
 - Lesions on mucosal surfaces respond better to topical treatments.
 - All available therapies have equal efficacy in eradicating warts, ranging from 22 to 94%, with the significant rate of relapse of 25% within 3 months (see table in “[Medication](#)”):
 - Consider size, location, number of warts, previous treatment, and patient preference.
 - Also consider patient preference, expense, and side effects.
 - Patients with extensive lesions should be referred to physicians who routinely treat these lesions.
 - Treatment:
 - External: See table in “[Medication](#).”
 - Meatal: cryotherapy or podophyllin
 - Anal: cryotherapy or trichloroacetic acid
 - Vaginal: trichloroacetic acid
 - Cervical: Refer to an expert.
- RRP
 - Primarily surgical excision, may regress after puberty

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Follow-up should continue until the warts have disappeared.
- Latent infection and recurrent disease are common.
- United States Preventive Services Task Force (USPSTF), American Cancer Society (ACS), and American College of Obstetrics and Gynecology (ACOG) recommend initial Pap smear at 21 years of age.
- Pap smears may be indicated in sexually active patients younger than 21 years of age if they have HIV, solid-organ transplantation, or chronic immunosuppression.

PROGNOSIS

Therapy will not eradicate the virus; thus, HPV causes recurrent disease.

CODES

ICD10

A63.0 Anogenital (venereal) warts

FAQ

- Q: What treatment is indicated during pregnancy?
- A: Most experts recommend surgical removal if necessary. Podophyllin is absolutely contraindicated.
- Q: Should partners of patients with genital warts be referred for examination?
- A: Recurrence is due to reactivation of the virus; reinfection plays no role. Partner may benefit from an examination to evaluate for the presence of warts and for education and counseling. There is no information regarding prophylaxis to prevent infection, so treatment for this is not indicated. Most partners have subclinical infection. Female partners should follow the routine recommendations for Pap smear screening.
- Q: Are genital warts in children always indicative of sexual abuse?
- A: No. The HPV virus has an incubation period of many months. Thus, warts transmitted to infants at the time of birth may not become clinically apparent for 1–2 years. Whether the incubation period can be longer than this time period remains unknown. Thus, maternal history and, potentially, examination are both important factors. However, all children with anogenital warts should be evaluated by a clinician experienced in child abuse evaluations. It is possible that caregivers may transmit the virus to children through close but nonsexual contact; thus, this history is also important in older children.
- Q: Will young women still need to get Pap smears if they have received the HPV vaccine?
- A: Yes. The vaccine does offer good protection against the strains most commonly associated with genital warts and cervical cancer, 6, 11, 16, and 18. However, these strains are not the only ones that can cause infection or lead to cervical cancer. It is important to continue regular screening to ensure that one has not been exposed to other strains that may cause cervical dysplasia.

HYDROCELE

Sophia D. Delpe • Adam B. Hittelman

BASICS

DESCRIPTION

A hydrocele is the accumulation of fluids around the testicle, within the tunica vaginalis or processus vaginalis.

- Can be communicating, fluid passing from peritoneal cavity into patent processus vaginalis, or noncommunicating, fluid confined within the processus vaginalis (hydrocele of the cord) or tunica vaginalis
- Abdominal-scrotal hydrocele has fluid collection within processus vaginalis, extending into retroperitoneum.
- Reactive hydrocele (noncommunicating) is accumulation of fluid within tunica vaginalis caused by infection, trauma, or other inflammatory conditions.

EPIDEMIOLOGY

- 2–5% of male neonates have hydrocele.
- Male more common than female
 - Female: “cyst” or “hydrocele” in the canal of Nuck. May be communicating or noncommunicating
- Right more common than left
- Majority asymptomatic
- Simple (noncommunicating): commonly seen at birth, frequently bilateral, may be large
 - Majority spontaneously resolve in 12–24 months.
- Persistent hydroceles beyond 24 months and those presenting after birth more likely to be communicating
- Age >12 years old: majority noncommunicating
- Adolescent/adult hydroceles are generally acquired (reactive) and idiopathic in origin.

RISK FACTORS

- Similar to inguinal hernia

- Prematurity, low birth weight, gestational progestin use, connective tissue anomalies, cystic fibrosis, cryptorchidism, posterior urethral valves, and other syndromic disorders
- Trauma or infection
- Lymphatic obstruction (i.e., varicocele, filariasis, pelvic radiation, malignancy)

PATHOPHYSIOLOGY

- Communicating hydrocele can become indirect inguinal hernia, with potential for incarceration.
- Noncommunicating hydrocele generally thought to be low clinical concern
- Potential damage in large, tense hydroceles
 - Raised intrascrotal temperature can cause potential testicular harm.
 - Tense hydrocele may cause pressure atrophy.
 - Increased resistive index observed in subcapsular artery.
 - Absent testicular diastolic flow

ETIOLOGY

- Similar to indirect inguinal hernia
- In testicular descent, lip of peritoneum descends with testicle, the processus vaginalis, and covers testicle, tunica vaginalis.
- Patent processus in girls (canal of Nuck) related to descent of round ligament to labia, female equivalent of gubernaculum
- Communicating hydrocele essentially is an indirect inguinal hernia (defined by contents entering through patent processus vaginalis: peritoneal fluid versus fat or visceral organ).
- Related to delayed closure of processus vaginalis
 - Complete closure on both side in 18% of newborns
 - 40% close in first 2 months of life.
 - 60% close by 2 years
 - Patent processus vaginalis commonly associated with undescended testicles
 - Adult autopsy data demonstrate 15–30% patent.
- Reactive (acquired) hydrocele is imbalance between fluid production and absorption.

- Majority are idiopathic.
 - Defective lymphatic drainage
 - Aspirated fluid similar protein content to lymphatic fluid
- Varicocelelectomy 2nd most common cause
- Result of inflammation from trauma, testicular torsion, torsion of testicular appendage, epididymo-orchitis

DIAGNOSIS

HISTORY

- Inguinal or scrotal/labial swelling
- Age of onset
 - Birth, after birth, >12 years old
- Laterality
- Fluctuation in size: smaller in morning and larger over day in response to activity and upright position; change with crying/straining
 - May be preceded by constipation, upper respiratory infection, vomiting
- Undescended testicle
- Infection, trauma, torsion
- Pain/discomfort
- History of varicocele or other inguinal surgery

PHYSICAL EXAM

- Palpate scrotal/labial swelling
 - Soft or tense
 - Compressible/reducible
 - Palpate testicle
 - Confirm descent
 - Rule out mass, trauma, infection
 - Bowel contents—rule out hernia.
- Transilluminate scrotum to confirm fluid; not diagnostic

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Urine analysis and culture if concerns for epididymo-orchitis

- Tumor markers (HCG, α -fetoprotein [AFP]) if concern for testicular mass

Imaging

- Imaging not required in an uncomplicated scrotal hydrocele with palpable testicle.
- Transscrotal ultrasound if testicle difficult to palpate or concerns for concomitant problem
 - Assess testicle for pathology, blood flow, and inflammation/infection.
 - Differentiate bowel loops (hernia) from fluid.
 - Fluid tracking to peritoneal cavity can differentiate communicating versus noncommunicating.
 - Fluid tracking to abdominal component (retroperitoneal collection) demonstrates abdominoscrotal hydrocele.

DIFFERENTIAL DIAGNOSIS

- Indirect hernia
- Varicocele
- Spermatocele/epididymal cyst
- Epididymo-orchitis
- Hematocele
- Scrotal lymphedema
- Nephrotic syndrome

ALERT

If palpation of testicle is limited by tense hydrocele, transscrotal ultrasound is important to assess for testicular location, viability, and potential pathology.

TREATMENT

GENERAL MEASURES

- Conservative management for babies presenting at birth with noncommunicating hydrocele (no fluctuation in size) for 24 months
 - Consider surgical intervention if persistent >24 months.

- Fluid aspiration discouraged in babies due to risk of infection.
- Treatment for communicating hydrocele essentially same as inguinal hernia
 - Some surgeons advocate observation for 6–12 months for potential spontaneous resolution.
- Reactive hydrocele managed conservatively
 - Antibiotics for epididymo-orchitis
 - Surgery reserved for pain or patients self-conscious regarding size/appearance.

SURGERY/OTHER PROCEDURES

- Inguinal approach for communicating hydrocele
 - Concomitant orchiopexy (undescended testicle) or orchiectomy (testis mass) when clinically indicated
- Transscrotal approach for reactive hydroceles in adolescent (>12 years old) and adult
 - Consider surgical intervention if persistent >24 months.
- Transscrotal aspiration, with or without sclerosing agent, reserved for postoperative hydroceles.

CODES

ICD10

- N43.3 Hydrocele, unspecified
- N43.2 Other hydrocele
- P83.5 Congenital hydrocele

FAQ

- Q: Does this need to be corrected?
- A: Noncommunicating hydroceles can be managed conservatively and commonly will resolve within the first 12–24 months of life. Recommendations for watchful waiting are recommended in this age group. Persistent hydroceles after age 2 years are assumed to be communicating hydroceles. Communicating hydroceles are managed similar to indirect inguinal hernias. Some surgeons advocate monitoring asymptomatic communicating hydrocele for 6–12 months to see if they resolve. Hydroceles progressing to inguinal hernia require surgical intervention. Reactive hydroceles are treated if patient is symptomatic, self-conscious of size, or testicle is difficult to palpate.
- Q: What are the potential consequences of leaving hydrocele untreated?
- A: There are no clear long-term adverse consequences for having noncommunicating hydrocele. Potential concerns raised for testicular growth and function, though, may be correctable with hydrocele repair. Hydrocele may continue to grow in size, causing discomfort and distress. Untreated communicating hydrocele may progress to inguinal hernia.
- Q: Are there risks of a hydrocele developing on the other side?
- A: Similar to inguinal hernia, communicating hydroceles have risk of metachronous development of hydrocele on contralateral side. Inguinal hernia will present on other side 8.5–15% of time, although not clearly defined in communicating hydrocele. Visualization of a contralateral patent processus vaginalis does not always correlate with metachronous development of a contralateral inguinal hernia or communicating hydrocele.
- Q: What are the risks of the surgery?
- A: Risks of the surgery are similar to inguinal hernia repair and include

anesthetic risks, injury to testicle or spermatic cord structures (gonadal vessels, vas deferens), injury to ilioinguinal nerve, subsequent atrophy of the testicle, and recurrent hydrocele.

HYDROCEPHALUS

Jennifer A. Markowitz

BASICS

DESCRIPTION

- Accumulation of CSF in the ventricles and subarachnoid spaces, leading to their enlargement
- Overall head size may enlarge in response, depending on age and cause.

PATHOPHYSIOLOGY

- Normal pathway of CSF: choroid plexus and interstitial fluid (sources), lateral ventricles, foramina of Monro, 3rd ventricle, aqueduct of Sylvius, 4th ventricle, foramina of Luschka and Magendie, subarachnoid space, arachnoid villi, and venous circulation
- Hydrocephalus results from obstruction to CSF flow, impaired reabsorption, or overproduction of CSF.
- Noncommunicating (obstructive) hydrocephalus results from obstruction within the ventricular system.
- Communicating hydrocephalus usually results from impaired CSF reabsorption or (rarely) overproduction (e.g., due to a choroid plexus papilloma).
- The noncommunicating/communicating distinction has no prognostic significance but has implications for etiology and choice of therapeutic intervention.

ETIOLOGY

- Intraventricular hemorrhage is most commonly due to prematurity but may also occur with trauma. It results in impaired CSF absorption due to meningeal adhesions, granular ependymitis, and clots. Posthemorrhagic hydrocephalus (PHH) occurs in 35% of all neonates surviving intraventricular hemorrhage; its incidence increases with increasing severity of hemorrhage.
- Tumors or cysts near the foramina or the aqueduct or within the

ventricular system

- Infection (meningitis, intrauterine infection) can lead to leptomeningeal adhesions and granulations that block reabsorption of CSF.
- Developmental
 - Chiari malformation, type II (associated with myelomeningocele, brain migrational disorders, small posterior fossa, inferior displacement of medulla and cerebellar vermis, kinking of the brainstem, aqueductal stenosis, beaking of the tectum)
 - Dandy-Walker malformation (absence of cerebellar vermis, small cerebellar hemispheres, enlarged posterior fossa, often with cystic 4th ventricle)
 - X-linked and autosomal dominant hydrocephalus; the former is often associated with aqueductal stenosis and mutations in L1CAM on Xq28.
 - Sporadic primary aqueductal stenosis
 - Dysmorphic syndromes (e.g., Apert syndrome, Cockayne syndrome, Crouzon syndrome, Pfeiffer syndrome, trisomy 13, trisomy 18, trisomy 21, triploidy)
 - Alexander disease
 - Mucopolysaccharidoses (e.g., type II [Hunter], type VI [Maroteaux-Lamy])
 - Migrational disorders/congenital muscular dystrophies (e.g., Miller-Dieker, muscle-eye-brain disease, Fukuyama congenital muscular dystrophy, Walker-Warburg syndrome)
 - Achondroplasia
 - Neurocutaneous syndromes (e.g., neurofibromatosis type 1, rare)
 - Idiopathic

DIAGNOSIS

HISTORY

Presenting concerns:

- Infants: enlarging head, irritability, vomiting, somnolence, poor feeding
- Older children: headache, vomiting, double vision, somnolence

PHYSICAL EXAM

- Vital signs: in advanced acute hydrocephalus, Cushing triad (hypertension, reflex bradycardia, respiratory irregularities): This is not generally seen in infants prior to fusion of the sutures.
- Rapidly increasing head circumference in infants. Fullness of the anterior fontanelle neither sensitive nor specific, but should be noted. May observe splaying of the sutures.
- Mental status: irritability or somnolence in infants, behavioral changes in children (acute or chronic)
- Cranial nerves: “setting sun” sign due to paralysis of upgaze, disconjugate gaze, papilledema, optic atrophy, and visual changes in the chronic setting
- Motor: gait ataxia; spastic paraparesis in chronic hydrocephalus related to pressure on white matter tracts surrounding the ventricles
- Reflexes: increased in chronic hydrocephalus

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- Head ultrasound
 - Standard screening test for neonates with suspected hydrocephalus or intraventricular hemorrhage
 - Anterior fontanelle must be patent for this test.
 - Demonstrates ventricular size, presence or absence of blood, associated structures, and anomalies
- Unenhanced CT of the brain
 - Mainly used in infants and children whose anterior fontanelles have closed and following shunt procedures
 - Better visualization of 4th ventricle/brainstem and calcifications than with ultrasound; standardized technique that is less operator dependent; better availability in the emergency room setting
- MRI
 - Definitive test for analyzing brain anatomy
 - Can identify posterior fossa developmental malformations such as Chiari and Dandy-Walker
 - Rapid brain MRI protocols for shunt evaluation are replacing CT at

some institutions with this capability.

- MR technique of diffusion tensor imaging may help to estimate local pressure on white matter adjacent to ventricles as a correlate of increased intracranial pressure. The FIESTA sequence (fast imaging employing steady-state acquisition) can show obstruction in the CSF space.

Note: When imaging to diagnose shunt malfunction, it is important to consider the lifetime cumulative radiation exposure for each child and, depending on patient stability, the use of an alternate approach to CT such as rapid brain MRI.

ALERT

Head CT often will not show developmental malformations that may accompany hydrocephalus. MRI is the imaging procedure of choice for elective study.

DIFFERENTIAL DIAGNOSIS

- Other causes of macrocephaly:
 - Familial macrocephaly/“benign external hydrocephalus”
 - Pericerebral effusions
 - Congenital anomalies of intracerebral or extracerebral veins
 - Tumors, intracranial cysts
 - Primary megalencephaly, hemimegalencephaly
 - GM2 gangliosidosis
 - Some leukodystrophies (e.g., Alexander disease, Canavan disease)
 - Head-sparing intrauterine growth retardation (relative macrocephaly)
 - Rapid catch-up growth following prolonged malnutrition
- Other causes of ventriculomegaly, typically with normal head circumference: brain atrophy and chronic ethanol or corticosteroid exposure (reversible)
- Enlargement of the subarachnoid spaces: usually bifrontal, normal to mildly enlarged ventricles. May be seen in children with macrocephaly, who if otherwise normal are diagnosed with “benign external hydrocephalus.” Recognize that metabolic and genetic disorders can also present with enlarged subarachnoid spaces (e.g.,

glutaric aciduria type I, others listed earlier).

TREATMENT

SURGERY/OTHER PROCEDURES

Acute interventions

- Ventricular shunt
 - Indication: progressive or acute symptomatic hydrocephalus
 - Contraindications: active central nervous system infection, active intraventricular hemorrhage, and poor overall prognosis
 - Components: ventricular catheter, reservoir (target of shunt taps), valve, distal catheter
 - Distal sites: Peritoneum is the most common choice; pleura, ureter, venous system, gallbladder, and right atrium are other options.
 - Approach: usually performed as an open procedure; endoscopic procedures available in some centers
 - Complications
 - ▢ Shunt failure occurs in 40% of shunts within the 1st year after placement and 50% within the first 2 years. Causes are obstruction, infection, disconnection, or fracture of components; migration of shunt components; overdrainage; and erosion into an abdominal viscus. Presents with symptoms similar to those of acute hydrocephalus
 - ▢ Infections occur at a rate of ~8–10% per shunt manipulation, usually during the first 6 months after surgery. Present with low-grade persistent fever and less commonly with erythema of overlying skin. Most common organism is *Staphylococcus epidermidis*; reinfection occurs in 30% of patients harboring this organism.
 - ▢ Siphon effect: drop in ventricular pressure on sitting or standing causing headache; newer shunt systems with antisiphon mechanisms are available.
 - ▢ Newer shunts have programmable valve mechanisms; one must be cautious when obtaining an MRI in patients with this type of shunt in place, as the magnet may affect valve settings.

ALERT

- Timing of shunt placement is critical and problematic: Sometimes watchful waiting can obviate the procedure, whereas waiting too long may result in brain damage.
- Don't assume hydrocephalus is "cured." Late shunt failure may occur years after placement, often due to fracture of tubing, and can result in death from acute hydrocephalus causing herniation.
- PHH in the neonate may be managed initially with serial lumbar puncture; this has been shown to improve cerebral perfusion in these patients. Most do not require shunt placement. Ultimately, some may require ventriculosubgaleal or ventriculoperitoneal shunts.
- 3rd ventricle fenestration (endoscopic 3rd ventriculostomy):
 - Indications: most effective for obstructive hydrocephalus due to aqueductal stenosis or space-occupying lesions
 - Endoscopic 3rd ventriculostomy combined with choroid plexus cauterization shows benefit for infants, including selected babies with PHH.
 - Complications: overall rate of serious complications 9.4%; these include infection, CSF leak, neurologic deficits, extraparenchymal hemorrhage; rare risk of damage to the basilar artery

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- When the etiology or need for shunt placement is unclear, it is important to follow clinical status, head circumference, and ventricular size (by head ultrasound or CT).
- Chronic hydrocephalus is often accompanied by spastic paraparesis, visual problems, and learning problems.
- Most interventions are supportive:
 - Physical therapy, occupational therapy, and orthopedic therapies for spasticity; interdisciplinary cerebral palsy clinics can be critical in providing easy access to these resources.
 - Special education programs may be appropriate for children with severe developmental delay.

ALERT

- It is important for long-term patients in intensive care nurseries to have head circumferences recorded at least twice weekly. Macrocephaly is not always obvious on visual inspection.
- Absence of papilledema does not exclude chronic increased intracranial pressure.

PATIENT EDUCATION

Parent Internet Information: National Hydrocephalus Foundation,
<http://www.nhfonline.org>

PROGNOSIS

Depending on the severity and cause of hydrocephalus, efficacy of treatment, and presence or absence of concomitant neurologic disorders, outcome may vary widely from normal neurologic development to severe impairment or death.

COMPLICATIONS

- Acute hydrocephalus: Herniation syndromes may be fatal.
- Chronic hydrocephalus
 - Macrocephaly
 - Spastic paraparesis may lead to gait and motor problems.
 - Vision loss
 - Developmental delay
 - Precocious puberty due to pressure on the hypothalamus

- G91.0 Communicating hydrocephalus
- G91.1 Obstructive hydrocephalus

FAQ

- Q: When does an infant need a head ultrasound?
- A: Any infant whose head circumference increases by more than a quartile on the growth chart needs a head ultrasound. Preterm infants below a certain gestational age or birth weight (varies from hospital to hospital) should all receive screening head ultrasounds while in the intensive care nursery.
- Q: When should an infant or child receive an MRI rather than an ultrasound or CT?
- A: Although MRI may be superior in many cases, the logistics of ordering the proper sequences and the need for sedation or anesthesia

for long studies (although some institutions now have rapid MR sequences for shunt evaluation) must be strongly considered.

Consultation with a neurologist or neurosurgeon is generally advised.

- Q: What is the workup for shunt obstruction and shunt infection?
- A: Symptoms and signs of increased intracranial pressure should lead to a neurosurgical evaluation; the most useful studies include head CT or rapid brain MRI (to assess ventricular size and placement of ventricular catheter) and shunt series (plain films of the entire shunt system to check for disruptions). “Pumping” the shunt reservoir is a procedure with a low positive predictive value for shunt failure.

Tapping the shunt to assess pressure must be done with discretion, as repeated taps may disrupt the valve mechanism. Fever is the most important indication for a shunt infection evaluation (shunt tap with CSF cell count, protein, glucose, Gram stain, and culture). Often, patients will be evaluated for both complications.

HYDRONEPHROSIS

J. Christopher Austin • Michael C. Carr

BASICS

DESCRIPTION

- Hydronephrosis: dilation of the renal pelvis (pelviectasis) and calyces (caliectasis) due to excess urine in the collecting system of the kidney
- Hydroureteronephrosis: dilation of the renal collecting system and the ureter to the level of the bladder

EPIDEMIOLOGY

- Incidence of genitourinary abnormalities noted on routine prenatal ultrasound is 0.2%.
- 87% of these are antenatally detected hydronephrosis/hydroureteronephrosis.
- 5% of fetuses with hydronephrosis are due to ureteropelvic junction obstruction.
- Posterior urethral valves and triad syndrome account for 6% of cases.

ETIOLOGY

- Ureteropelvic junction obstruction
 - Intrinsic narrowing or an aperistaltic segment of distal ureter. These are also called megaureters.
- Vesicoureteral reflux
 - In primary reflux (grades I–V depending on the severity), it is due to an insufficient flap valve–type mechanism at the ureterovesical junction.
 - Hydroureteronephrosis is usually seen only with higher grades of reflux (grades III–V) or secondary reflux (reflux in the presence of an abnormal bladder, in which the reflux is often due to high storage or voiding pressures within the bladder). Secondary reflux is not graded.
- Ureterocele
 - Hydroureteronephrosis secondary to obstruction of the ureter from a

- cystic dilation of the intravesical portion of the distal ureter
- Most often associated with the upper pole ureter in duplicated collecting system; less frequently associated with a single system
 - Ureterocele is further classified as intravesical (contained completely within the bladder) or ectopic (extending down the bladder neck and often into the urethra).
- Ectopic ureter
 - A ureter that drains into an abnormal location away from the trigone
 - The hydroureteronephrosis can be the upper pole ureter of a duplicated collecting system or a single system.
 - Ectopic ureters can drain at various sites along the lower urinary tract depending on the sex of the child. In boys, they can drain into the bladder neck, prostatic urethra, vas deferens, seminal vesicle, or epididymis. In girls, they can drain into the bladder neck, urethra, introitus, and vagina.
 - The ectopic locations often require passage through the bladder neck or urogenital diaphragm, which produces obstruction of the distal ureter.
 - Urolithiasis
 - Obstructing calculi often produce dilation of the urinary tract proximal to its location.
 - Stone disease is rare in infancy except in preterm infants who receive furosemide.
 - The hydronephrosis is usually associated with renal colic.
 - Posterior urethral valves
 - Hydroureteronephrosis: nearly always bilateral, produced by outflow obstruction of the bladder from valve leaflets in the prostatic urethra
 - Because both kidneys are affected, there is a significant risk of chronic renal insufficiency and development of end-stage renal disease.
 - Triad syndrome
 - Hydroureteronephrosis, often with massively dilated ureters, and a large bladder
 - Also known as prune belly syndrome or Eagle-Barrett syndrome

- These boys have a triad of hypoplastic abdominal wall musculature (leading to a prunelike appearance), bilateral undescended testes, and a dilated urinary tract.
- Many have associated urethral atresia, imparting worse renal function prognosis.
- Exact cause of triad syndrome remains elusive.
- Significant risk of renal insufficiency in these patients
- A similar syndrome may occur in girls with a prunelike appearance to the abdomen and anomalies of the urogenital tract; however, it is very rare.

DIAGNOSIS

HISTORY

- Newborns
 - Antenatal hydronephrosis: Presence of hydronephrosis or hydroureteronephrosis
 - If unilateral, severity of hydronephrosis and the status of contralateral kidney
 - If bilateral, presence of bladder wall thickening, bladder enlargement, bladder emptying, or a dilated posterior urethra (keyhole sign) may indicate posterior urethral valves or triad syndrome.
 - If oligohydramnios is present, pulmonary hypoplasia is a concern. The presence of oligohydramnios, increased renal echogenicity, and cystic changes in the kidneys are indicators of poor renal function and dysplasia.
- Older children
 - History of urinary tract infections or gross hematuria
 - General health and growth (poor growth with chronic renal insufficiency or acidosis)
 - Daytime incontinence, poor urinary stream, or symptoms of voiding dysfunction may be an indicator of bladder dysfunction due to posterior urethral valves.
 - History of episodic abdominal (which may not lateralize well),

flank, or back pain in the presence of hydronephrosis is often due to symptomatic ureteropelvic junction obstruction (see topic “[Ureteropelvic Junction Obstruction](#)”).

PHYSICAL EXAM

- Neonate
 - Signs of oligohydramnios (Potter facies, lateral patellar dimples, clubfeet, and other limb deformities) and respiratory distress
 - Palpable abdominal mass
 - Palpable walnut-sized bladder (posterior urethral valves)
 - Patent urachus
 - Ascites
 - Development of abdominal wall musculature (wrinkled prunelike appearance in triad syndrome)
- Older children
 - Presence of abdominal mass
 - Abdominal or flank tenderness

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Newborn
 - Hydronephrosis or hydroureteronephrosis with a normal contralateral kidney does not require any immediate laboratory testing.
 - If both kidneys are affected or a solitary kidney is affected, there is a need for serial assessments of renal function (serum electrolytes and creatinine).
- Older children
 - Urinalysis to detect hematuria or pyuria. Culture if infection suspected
 - In cases where both kidneys are affected or there is a solitary kidney, renal function should be evaluated.

Imaging

- Infants with antenatally detected hydronephrosis may be evaluated with 3 imaging studies:
 - Renal/bladder ultrasound

- Voiding cystourethrogram
- Renal scan
- The timing can be elective for a unilateral lesion with a normal contralateral kidney, but if both kidneys are affected or a solitary kidney is involved, prompt evaluation of the newborn should be undertaken.
- Renal/bladder ultrasound
 - Because of a period of relative oliguria of a newborn in the first 24–48 hours of life, an ultrasound may underestimate the degree of hydronephrosis during this time and thus should be postponed until the infant is at least 48 hours old.
 - This should not preclude evaluating an infant during this time as long as a study is repeated in 4–6 weeks.
 - In cases where both kidneys were affected or there is a solitary affected kidney, the evaluation should not be delayed.
 - Ultrasound of the kidneys should reveal the severity of dilation of the renal pelvis and calyces, changes in the amount and echogenicity of the parenchyma, and presence of cortical cysts.
 - Evaluation of the full bladder is important as well. It will show dilated distal ureters, which may indicate ureterovesical junction obstruction, vesicoureteral reflux, or hydroureteronephrosis from posterior urethral valves or triad syndrome.
- Voiding cystourethrogram
 - Evaluates presence of vesicoureteral reflux
 - Allows grading the severity of reflux as well
 - Bladder shape, presence of diverticulum, and trabeculations may indicate hypertrophy from posterior urethral valves, neurogenic bladder dysfunction, or voiding dysfunction (in older children).
 - Test can be delayed until after discharge from nursery unless there is concern about posterior urethral valves, in which case it should be done in the early postnatal period.
 - The Society for Fetal Urology consensus statement on the evaluation and management of antenatal hydronephrosis states that there is no clear evidence to support or to avoid postnatal imaging for vesicoureteral reflux. The overall incidence of vesicoureteral

reflux is up to 30% in children with antenatal hydronephrosis, and currently, it remains unproven whether the identification and treatment of children with vesicoureteral reflux confers any clinical benefit. Without the presence of ureteral dilation on the ultrasound, an argument can be made to defer performing a voiding cystourethrogram study.

- Renal scan
 - Can quantify the differential renal function or the amount each kidney contributes to overall renal function (the normal differential function is $50\% \pm 5\%$ for each kidney)
 - The 2 most commonly used radionuclides are mercaptoacetyltriglycine-3 (MAG-3) and diethylenetriamine penta-acetic acid (DTPA). MAG-3 is the best choice for infants and babies.
 - In addition to the ability to detect diminished function, if there is poor drainage of the affected kidney, furosemide is given to wash out the radiotracer. The duration for washing out $\frac{1}{2}$ of the accumulated radiotracer ($T_{1/2}$) is often given in the report. A prompt $T_{1/2}$ (<10 minutes) is indicative of a nonobstructed kidney. A slower $T_{1/2}$ may be indicative of obstruction when it is >20 minutes. A 10–20-minute $T_{1/2}$ is indeterminate for obstruction. Many factors affect the $T_{1/2}$, making it less reliable for indicating obstruction. These factors include the hydration status, presence of vesicoureteral reflux, and overall kidney function (very poorly functioning kidneys have a poor response to diuretics).
- IV pyelogram
 - Most useful for evaluating the anatomy of the kidney and the ureters
 - Also useful for evaluating older child with intermittent symptoms of abdominal or flank pain
 - Can be diagnostic of an intermittent ureteropelvic junction obstruction as the cause of the child's pain
- CT scan
 - Most commonly done in cases where the hydronephrosis is symptomatic
 - Noncontrast spiral CT is the most sensitive way to detect stones, as

even stones radiolucent on plain films (uric acid) will be detected by CT.

- Magnetic resonance urography is being used more widely in the evaluation of hydronephrosis which avoids the use of ionizing radiation. Refinements in the technique and comprehensive automated functional analysis is now available. Ongoing issues remain concerning the use of sedation and the overall expense of the study which continue to limit its overall applicability.

DIFFERENTIAL DIAGNOSIS

- Cystic renal tumor
 - Most commonly Wilms tumor
 - Distinguished from hydronephrosis by ultrasound or CT scanning
- Multicystic dysplastic kidney
 - Can be difficult to distinguish from severe hydronephrosis with marked parenchymal thinning
 - Renal scan will show no function or perfusion with multicystic dysplastic kidney.

TREATMENT

ADDITIONAL TREATMENT

General Measures

Neonates with hydronephrosis are started on prophylactic antibiotics (1/4 the therapeutic dose given once a day) of amoxicillin. When the baby is 2 months old, the antibiotic can be changed to trimethoprim, trimethoprim/sulfamethoxazole, or nitrofurantoin.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Ureteropelvic junction obstruction
 - After initial evaluation, infants are usually followed with serial studies, either ultrasound or renal scans, depending on the degree of

functional impairment, the severity of the hydronephrosis, and the pattern of drainage on the renal scan.

- From more information, see topic “[Ureteropelvic Junction Obstruction](#).”
- Ureterovesical junction obstruction
 - After initial evaluation, children are followed with serial studies as with ureteropelvic junction obstruction.
 - These lesions are much less common than ureteropelvic junction obstruction, and most of the time, the affected kidneys have normal function and can be followed conservatively.
 - If the function of the kidney is significantly diminished (differential function of 35–40%), surgical treatment of the obstruction is indicated.
- Vesicoureteral reflux
 - Infants with reflux are kept on prophylactic antibiotics.
 - In the absence of breakthrough infections, they are reevaluated annually.
 - If persistent high-grade reflux continues or breakthrough infections are a problem, surgical correction is carried out.
 - For more information, see topic “[Vesicoureteral Reflux](#).”
- Ureterocele/ectopic ureter: Because these are obstructive lesions, they are generally treated surgically early in life at the time of diagnosis.
- Posterior urethral valves
 - Full-term infants undergo cystoscopic valve ablation, whereas preterm infants may require a temporary vesicostomy until endoscopic treatment is feasible.
 - These boys require careful follow-up from a pediatric urologist and nephrologist through adolescence.
 - For more information, see topic “[Posterior Urethral Valves](#).”
- Triad syndrome: Typically, these boys will undergo bilateral orchiopexy with or without an abdominoplasty depending on the severity of abdominal wall hypoplasia during the first 6–12 months of life.

PROGNOSIS

Perinatal mortality associated with hydronephrosis has ranged from 13–

72% but is most strongly correlated with the presence of chromosomal abnormalities, multiple system abnormalities, detection earlier in gestation, oligohydramnios, and evidence of infravesical obstruction.

CODES

ICD10

- N13.30 Unspecified hydronephrosis
- N13.39 Other hydronephrosis
- Q62.0 Congenital hydronephrosis

FAQ

- Q: If my baby has hydronephrosis affecting only one kidney, will he need a kidney transplant?
- A: In the absence of oligohydramnios and bilateral hydroureteronephrosis, it would be very rare that a child would develop renal failure requiring transplantation.
- Q: My unborn baby has hydronephrosis in only one kidney, and the other kidney is normal. What are the chances that it is a ureteropelvic junction obstruction?
- A: The chances are ~45% that isolated hydronephrosis is due to a ureteropelvic junction obstruction.
- Q: My male unborn baby has bilateral hydronephrosis but a “normal”

bladder. Is there still a chance that he has posterior urethral valves?

- A: Yes. Although it is less likely to be due to posterior urethral valves than if a thick-walled, enlarged, poorly emptying bladder were seen, prenatal ultrasonography is operator dependent. Ultrasound can miss dilated ureters or bladder abnormalities.

HYPERCALCEMIA

Philippe F. Backeljauw

BASICS

DESCRIPTION

Hypercalcemia represents an elevation in ionized and total calcium concentrations.

EPIDEMIOLOGY

- Less common than hypocalcemia
- Less common in children than adults
- Adults: >90% caused by a tumor or hyperparathyroidism (HPT)
- Children: more diverse etiologies dependent on age of presentation

RISK FACTORS

- Family history of hypercalcemia
- Family history of renal stones
- Chronic renal failure
- Immobilization
- Certain genetic syndromes
- Certain malignancies
- History of neck irradiation
- Gestational maternal hypocalcemia

PATHOPHYSIOLOGY

- Increased calcium influx from the intestinal tract or the skeleton
- Increased renal tubule calcium reabsorption

ETIOLOGY

ALERT

The first step in the determination of an etiology of hypercalcemia is measurement of an intact serum parathyroid hormone (intact PTH) concentration.

Hypercalcemia with INCREASED PTH

- Familial isolated primary HPT
 - Autosomal dominant (AD)
 - Parathyroid hyperplasia or adenoma(s)
 - MEN1, HRPT2, HRPT3 mutations
- Multiple endocrine neoplasia (MEN)
 - MEN1 (AD)
 - MEN1-inactivating mutation
 - Parathyroid tumors in 90%
 - Pancreatic and pituitary tumors
 - MEN2A (AD)
 - RET proto-oncogene mutations
 - Parathyroid tumors in 20%
 - Medullary thyroid carcinoma and pheochromocytoma
- Sporadic parathyroid adenoma
 - CyclinD1/PRAD1, MEN1 mutations
- Parathyroid carcinoma (rare)
- Neonatal severe HPT (NSHPT)
 - Homozygous inactivating calcium-sensing receptor (CaSR) mutations

Hypercalcemia with NORMAL PTH

- Familial benign hypercalcemia or familial hypocalciuric hypercalcemia (FHH)
 - Heterozygous inactivating CaSR mutations (AD)
 - Typically asymptomatic
 - Mild hypercalcemia
 - PTH usually normal (may be slightly elevated)
 - Fractional calcium excretion <1%

Hypercalcemia with LOW PTH

- Williams syndrome
 - 15% with (transient) hypercalcemia
 - Contiguous gene deletion syndrome involving the gene encoding the transcription factor TFII-I. TFII-I negatively regulates cellular calcium entry. Without TFII-I, transient receptor potential C3 (TRPC3) channels are overexpressed in kidneys and intestine, leading to hypercalcemia.

- Associated features: supraaortic stenosis, cognitive impairment, “elfin facies”
- Jansen metaphyseal chondrodysplasia
 - Heterozygous mutations in PTHR1 lead to constitutive activation of PTH/PTHrP receptor.
 - Short-limbed short stature
- Idiopathic hypercalcemia of infancy (Lightwood syndrome)
 - Some cases due to loss of function mutations in CYP24A1

Other causes of hypercalcemia (mostly PTH-independent):

- Medications:
 - Thiazides, lithium, vitamin A and D
- Malignancy
 - Local osteolysis (PTHrP, cytokine production, chemotherapy)
 - Humoral hypercalcemia of malignancy (HHM) (PTHrP)
 - Ectopic 1,25(OH)₂-vitamin D production (lymphomas)
 - Ectopic PTH production
- Granulomatous disease
 - Sarcoidosis, tuberculosis
 - Increased 1,25(OH)₂-vitamin D production due to dysregulated 1- α hydroxylase expression in monocytes/macrophages
- Renal disease
 - Chronic renal failure may lead to secondary and tertiary HPT.
- Endocrine disorders:
 - Thyrotoxicosis, acute adrenal insufficiency, hypophosphatasia
- Inborn errors of metabolism:
 - Blue diaper syndrome (defect in tryptophan metabolism)
 - Congenital lactase deficiency
 - Infantile hypophosphatasia (deficiency of tissue nonspecific alkaline phosphatase)
- Immobilization
 - More common in adolescence
 - Spinal cord injury, quadriplegia
 - May see low serum alkaline phosphatase, hypercalciuria
- Subcutaneous fat necrosis (SCFN)
 - After complicated delivery

- Often a history of birth asphyxia
- Excessive 1,25(OH)₂-vitamin D production

HISTORY

- Clinical presentation is dependent on age of child, degree of hypercalcemia and the underlying disorder.
- Mild hypercalcemia (10–12 mg/dL)
 - Patients often asymptomatic
 - Failure to thrive
 - Hematuria
 - Nephrolithiasis
 - Nephrocalcinosis
- Moderate hypercalcemia (12–14 mg/dL)
 - Constipation
 - Anorexia
 - Abdominal pain
 - Weakness
 - Hematuria
 - Polyuria
 - Dehydration (in infants)
- Severe hypercalcemia (>14 mg/dL)
 - Nausea, vomiting
 - Dehydration
 - Encephalopathy
 - Psychological changes,
 - Poor feeding, hypotonia, and apnea (in newborns)

PHYSICAL EXAM

- Usually normal—unless syndromic
- Parathyroid mass usually not palpable
- Hypertension
- Dehydration
- Soft tissue calcifications uncommon

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Confirm hypercalcemia and obtain intact PTH, serum phosphate, and

magnesium, plus electrolyte panel.

- Collect urine to measure calcium excretion and examine calcium/creatinine ratio:
 - Normal spot urine calcium creatinine varies by age (<7 months of age, <0.86 mg/mg; 7–18 months of age, <0.60 mg/mg; 19 months to 6 years, <0.45 mg/mg; >6 years to adults, <0.22 mg/mg.
 - In children with low muscle mass, can use urine calcium-to-osmolality ratio instead
- Hypercalcemia + low or inappropriately normal urinary calcium indicate FHH (or NSHPT).
- Hypercalcemia, hypophosphatemia, and hyperphosphaturia, plus increased PTH indicate primary HPT.
- Hypercalcemia, hypophosphatemia, and hyperphosphaturia, with a decreased PTH, indicate HHM if PTHrP is elevated.
- Hypercalcemia/hypercalciuria with normal or increased phosphate point toward other causes (vitamin D or A excess, endocrine disorders, drugs).

Imaging

- Radiography may show soft tissue calcifications in skin, subcutaneous soft tissues, and gastric mucosa
- Radiography may show subperiosteal resorption (distal phalanges), tapering of the distal clavicles, “salt and pepper” appearance of the skull, bone cysts and “brown tumors,” called osteitis fibrosa cystica (prolonged hypercalcemia due to HPT).
- Renal ultrasound may show nephrocalcinosis/nephrolithiasis.
- Doppler ultrasound or sestamibi scintigraphy for preoperative assessment of parathyroid adenomas

Diagnostic Procedures/Other

Electrocardiogram may show shortened QTc interval.

ALERT

- In hypoalbuminemia, measured calcium should be corrected for the abnormality in albumin.
- Corrected calcium = measured calcium (in mg/dL) + 0.8 (4.0 – albumin [in g/dL])

- Some prefer to measure ionized calcium in such situations.

TREATMENT

GENERAL MEASURES

- Management depends on the etiology and the severity of hypercalcemia.
- Prompt therapy is needed for severe hypercalcemia (calcium >14 mg/dL).
- In mild/asymptomatic hypercalcemia, no treatment may be needed (FHH).

ALERT

Important to diagnose FHH and distinguish it from other forms of hypercalcemia to avoid unnecessary drug therapy and parathyroid surgeries

GENERAL PRINCIPLES

- Rehydration
- Increase urinary calcium excretion.
- Inhibit bone resorption.
- Decrease intestinal absorption:
 - Depending on cause of hypercalcemia, consider low-calcium diet.

MEDICATION (DRUGS)

- Hydration therapy (saluresis)
 - Isotonic saline 3,000 mL/m² over 24–48 hours intravenously
- Promote calciuresis (after hydration):
 - Furosemide 1 mg/kg every 6 hours intravenously
- Decrease bone resorption:
 - For persistent moderate to severe hypercalcemia
 - Acutely: calcitonin 4 units/kg subcutaneously every 12 hours
 - Bisphosphonate therapy (pamidronate 0.5–1 mg/kg intravenously over 4–6 hours)
- Glucocorticoids
 - Inhibit 1- α hydroxylase and reduce intestinal absorption

- Prednisone 1–2 mg/kg/24 h
- Calcimimetics (cinacalcet) bind the CaSR and suppress PTH secretion:
 - At this time, caution in using cinacalcet in children given pediatric death in a research study using this drug.

SURGERY/OTHER PROCEDURES

- Dialysis: last resort
- Surgery (for primary HPT)

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Postsurgical hypocalcemia is common after parathyroidectomy—especially after severe HPT (“hungry bone syndrome”), and requires calcium and phosphate supplementation, and sometimes calcitriol treatment.

PROGNOSIS

- Depends on cause
- Permanent hypoparathyroidism may result from total parathyroidectomy.

- E83.52 Hypercalcemia
- P71.8 Other transitory neonatal disord of calcium & magnesium metab
- E21.3 Hyperparathyroidism, unspecified

FAQ

- Q: When should vitamin D or vitamin A levels be measured?
- A: If there is a history of alternative medicine, over-the-counter drugs, or supplements
- Q: When should one consider bisphosphonate therapy?
- A: In hypercalcemia mainly due to mobilization of calcium from bone (e.g. severe HPT, immobilization, tumor)
- Q: When should one consider glucocorticoids?
- A: In hypervitaminosis D or A and in excessive 1,25(OH)₂-vitamin D production

HYPERIMMUNOGLOBULINEMIA E SYNDROME

Rachel G. Robison

BASICS

DESCRIPTION

Hyperimmunoglobulinemia E syndrome (HIES) is a primary immunodeficiency with markedly elevated serum IgE associated with recurrent skin abscesses, pulmonary infections, and eczematoid dermatitis.

EPIDEMIOLOGY

- Rare
- True incidence and prevalence is unknown; affects equal numbers of males and females

RISK FACTORS

Genetics

- Autosomal dominant cases (AD-HIES) are caused by mutations in signal transducer and activator of transcription 3 (STAT3).
- Autosomal recessive cases (AR-HIES) have mutations in the dedicator of cytokinesis-8 gene (DOCK8).
- AR-HIES patients differ in phenotype from AD-HIES patients.
- Sporadic cases do occur.

PATHOPHYSIOLOGY

- STAT3 is integral in secretion and signaling of multiple cytokines involved in proinflammatory and anti-inflammatory responses.
- A failure of Th 17 cell differentiation and failure of IL-17 secretion makes patients susceptible to *Candida* infections.
- Deficiency in IL-11 signaling results in tooth abnormalities and craniosynostosis.
- DOCK8 deficiency results in failure of dendritic cells to migrate to lymph nodes and affects long-term memory B cells and viral-specific CD8⁺ T cells.

DIAGNOSIS

HISTORY

- Recurrent infections
 - Skin
 - Abscesses
 - Furuncles
 - Cellulitis
 - Lymphadenitis
 - Sinopulmonary infections
 - Pneumonia with aberrant healing forming pneumatoceles and bronchiectasis
 - Fungal infections: mostly mucocutaneous candidiasis
 - Typical organisms: Staphylococcus aureus, Streptococcus pneumoniae, Haemophilus influenzae
 - Opportunistic infections with Pneumocystis jiroveci pneumonia
 - Those with AR-HIES have viral skin infections, including molluscum, warts, and/or recurrent herpes.
- Rash
 - Present in newborn period
 - Can resolve or become eczematoid
- Retention of primary teeth
 - Delayed exfoliation of 3 or more teeth in 70% of patients
- Vascular anomalies
 - Tortuosity, dilation, and aneurysms of medium-sized vessels

PHYSICAL EXAM

- Facial features are noted in late childhood to early adolescence, including:
 - Asymmetric facies
 - Prominent forehead/chin
 - Wide-set eyes
- Dermatitis
- Skeletal anomalies
 - Scoliosis

- Craniosynostosis
- Hyperextensible joints
- Osteopenia leading to resultant bone fractures from minor trauma
- Hard palate anomalies, high-arched palate

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Total serum IgE of $>2,000$ IU/mL
 - Elevation may not be present in newborns.
 - Can decline to normal levels in adult years
 - Level does not correlate with disease severity.
- Peripheral eosinophilia
 - Does not correlate with IgE
 - Present in $>90\%$ of patients
- Immunoglobulin levels
 - IgG and IgM are usually normal.
 - IgA may be normal or low.
 - IgM is often decreased in AR-HIES.
- Specific antibody response is variable.
- Reduced CD45RO⁺ memory T cells and memory B cells with normal total lymphocyte counts
- Neutropenia may be present in a subset of patients.

Imaging

CT of the lungs if history of pneumonia to look for bronchiectasis and/or pneumatoceles

DIFFERENTIAL DIAGNOSIS

- Atopic dermatitis
- Wiskott-Aldrich syndrome
- Severe combined immunodeficiency (SCID)
- Omenn syndrome
- Immune dysregulation, polyendocrinopathy, enteropathy X-linked syndrome (IPEX)
- Netherton syndrome

TREATMENT

MEDICATION

- Prophylactic antibiotics, typically trimethoprim/sulfamethoxazole, for prevention of staphylococcal infection
- Immunoglobulin replacement therapy in the case of concomitant hypogammaglobulinemia
- Consideration of antifungal prophylaxis if recurrent/chronic candida infections

ADDITIONAL TREATMENT

General Measures

- Implement good management of dermatitis with regular hydration and emollient use.
- Control pruritus with antihistamines.
- Dilute bleach baths to decrease staphylococcal skin colonization.
- Promptly and aggressively treat all infections.
- Physical therapy for joint pain related to hyperextensibility

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Blood pressure monitoring in patients, especially those with known vascular anomalies, as hypertension is common

COMPLICATIONS

- Parenchymal lung changes from aberrant healing. Pulmonary surgery to correct these is associated with an increased risk of further complications.
- Increased chance of malignancy, most commonly lymphoma

CODES

ICD10

D82.4 Hyperimmunoglobulin E [IgE] syndrome

FAQ

- Q: How do AD-HIES and AR-HIES differ?
- A: Aside from arising from different mutations, AD-HIES has more skeletal and facial anomalies, whereas AR-HIES is more often associated with viral skin infections and has a higher chance of malignancy.
- Q: Will HIES patients show signs typical of infection?
- A: HIES patients may lack classical signs of infection such as warmth and redness. Skin infections have been referred to as "cold" abscesses.
- Q: What are the other names for HIES?
- A: HIES has been referred to as Buckley syndrome, Job-Buckley syndrome, and Job syndrome in the literature. In the initial 1966 case series, Davis and colleagues wrote that the "appearance of these patients and the history of recurrent abscesses and skin infections makes the name 'Job's syndrome' seem suitable." The reference is to the Biblical character Job, who was smote "with sore boils from the sole of his foot unto his crown" (Job, Chapter 2; Verse 7).

HYPERINSULINISM

Katherine Lord • Diva D. De León

BASICS

DESCRIPTION

Hyperinsulinism (HI) is a disorder of dysregulated insulin secretion resulting in hypoglycemia. Congenital HI refers to a permanent inborn condition, other forms can be transient.

EPIDEMIOLOGY

Most common cause of persistent or recurrent hypoglycemia in children

Incidence

- Annual incidence estimated at ~1:40,000–50,000 live births in United States.
- May be as high as 1:2,500 in select populations (Saudi Arabians, Ashkenazi Jews)

Genetics

- K_{ATP} HI: inactivating mutations in K_{ATP} channel genes ABCC8 and KCNJ11 (on 11p15)
 - Mutations inherited in an autosomal recessive manner result in diffuse involvement throughout the pancreas (diffuse HI).
 - Autosomal dominantly inherited mutations can also rarely cause diffuse HI.
 - Non-Mendelian inheritance: A paternally inherited recessive mutation of K_{ATP} channel gene and a loss of maternal alleles on the imprinted chromosome region 11p15, leads to paternal uniparental disomy; results in focal adenomatous lesion (focal HI)
- Glucokinase-HI: autosomal dominant–activating mutations of glucokinase (GCK)
- GDH-HI: autosomal dominant–activating mutations of glutamate dehydrogenase (GDH), encoded by GLUD1; known as hyperinsulinism/hyperammonemia (HI/HA) syndrome
- SCHAD-HI: autosomal recessive mutations of mitochondrial enzyme

short-chain-3-hydroxyacyl-CoA dehydrogenase (SCHAD), encoded by HADH

- UCP2-HI: autosomal dominant mutations of mitochondrial carrier uncoupling protein 2 (UCP2), encoded by UCP2
- HNF4A and HNF1A-HI: autosomal dominant mutations in transcription factors, HNF4A and HNF1A. Mutations in HNF4A and HNF1A also are known to cause familial monogenic diabetes.
- MCT1-HI: autosomal dominant mutations in the regulatory region of SLC16A1—encoding monocarboxylate transporter 1 (MCT1)
 - Causes exercise-induced HI

PATHOPHYSIOLOGY

- These mutations result in uncoupling of insulin secretion from the glucose-sensing machinery of the pancreatic β cell.
 - Leads to inappropriate insulin secretion even in the face of low plasma glucose concentrations
 - In the absence of functional K_{ATP} channels, plasma membrane is depolarized leading to opening of voltage-dependent calcium channels and constant insulin secretion.
- In the focal form of the disease (~60% of cases), a cluster of pancreatic β cells are affected, whereas in diffuse HI, all β cells are abnormal.
- In HI/HA syndrome, activating mutations of GDH (an enzyme that regulates amino acid-stimulated insulin secretion) cause dysregulated insulin secretion (particularly after ingestion of protein) and persistently elevated ammonia levels.
- Glucokinase acts as “glucose sensor” of the β cell. Activating mutations result in lower glucose threshold for insulin secretion.
- SCHAD is an inhibitory regulator of GDH. Inactivating mutations of HADH result in insulin dysregulation due to loss of GDH inhibition.
- UCP2 is a negative regulator of insulin secretion. Loss-of-function mutations lead to HI.
- In exercise-induced HI, ectopic expression of MCT1 allows transport of pyruvate, elevated during anaerobic exercise, into the β cell; leads to an increased ATP-to-ADP ratio, thus stimulating insulin secretion

ETIOLOGY

- Mutations in 9 genes have been associated with congenital HI: Genes coding for the two subunits of the β cell K_{ATP} channel [SUR1, sulfonylurea receptor (ABCC8); Kir6.2, inwardly rectifying potassium channel (KCNJ11)]; glucokinase (GCK), glutamate dehydrogenase (GLUD1), SCHAD (HADH), UCP2 (UCP2), HNF4A, HNF1A and monocarboxylate transporter-1 (SLC16A1).
- A transient form of HI has been associated with perinatal stress (small for gestational age [SGA] birth weight, maternal hypertension, precipitous delivery, or hypoxia), but the mechanism has not been elucidated.

COMMONLY ASSOCIATED CONDITIONS

HI can be associated with Beckwith-Wiedemann syndrome and congenital disorders of glycosylation (CDG). The underlying mechanism of HI in these disorders is not clear.

DIAGNOSIS

HISTORY

- Symptoms of hypoglycemia in the infant:
 - Poor feeding
 - Hypotonia
 - Lethargy
 - Cyanosis
 - Tachypnea
 - Tremors
 - Seizures
- May have high IV glucose infusion requirements (>10 mg/kg/min)

ALERT

Infants with severe hypoglycemia may be asymptomatic.

PHYSICAL EXAM

- Large for gestational age
 - Suggests $K_{ATP}HI$
- Small for gestational age

- Suggests transient HI or CGD
- Macroglossia, umbilical hernia, hemihypertrophy
 - Suggest Beckwith-Wiedemann syndrome
- No midline defects, including normal palate and genitalia
 - Midline defects suggest hypopituitarism as cause of hypoglycemia.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Obtain critical sample at time of hypoglycemia (plasma glucose <50 mg/dL).
- Evidence of excess insulin action at time of hypoglycemia:
 - May have detectable insulin
 - Suppressed levels of β -hydroxybutyrate (<0.6 mm) and free fatty acids (< 0.5 mm)
 - Glycemic response to 1 mg glucagon (blood glucose rise >30 mg/dL in 40 minutes)
- Elevated plasma ammonia levels
 - Indicate HI/HA syndrome
- Elevated plasma 3-hydroxybutyrylcarnitine and urinary 3-hydroxyglutarate
 - Indicate SCHAD
- Low cortisol and growth hormone at time of hypoglycemia is not diagnostic of adrenal insufficiency/growth hormone deficiency.
 - Perform appropriate stimulation tests to confirm.

ALERT

Insulin levels may not be elevated or detectable at time of hypoglycemia in some patients with HI. Base diagnosis on other evidence of insulin excess.

Imaging

- ^{18}F -DOPA PET scans at specialized HI centers to identify and to localize focal lesions
- Traditional imaging studies such as US, CT scan, and MRI are not helpful in identifying focal HI lesions.

Pathologic Findings

- Two major forms of pancreatic histology in children with HI due to

K_{ATP} channel mutations:

- Diffuse HI: abnormally enlarged islet cell nuclei found throughout the pancreas
- Focal HI: discrete area of islet cell hyperplasia surrounded by normal pancreas

DIFFERENTIAL DIAGNOSIS

- Infant of diabetic mother (IDM)
- Beckwith-Wiedemann syndrome
- Neonatal (pan)hypopituitarism
- Congenital disorders of glycosylation
- Children with dumping syndrome after fundoplasty can have severe postmeal hypoglycemia due to excessive insulin secretion after a meal.

TREATMENT

GENERAL MEASURES

- The major goal is prevention of brain damage.
- IV dextrose infusions should be given to stabilize blood glucose acutely.
 - For an acute hypoglycemic event, give a bolus of 2–3 mL/kg of 10% dextrose (0.2–0.3 g/kg).
 - Use dextrose infusion to maintain blood glucose >70 mg/dL.
 - May require central line to administer higher concentrations of dextrose and to avoid fluid overload
- Frequent oral feeds are not sufficient as treatment for hypoglycemia due to HI.

MEDICATION

- Diazoxide, a K_{ATP} channel agonist, at 5–15 mg/kg/24 h PO divided q12h
 - Most K_{ATP}HI patients do not respond.
 - Patients with HI/HA, SCHAD-HI, or transient HI typically respond well.
 - Diuretic may be necessary due to fluid retention.

- Octreotide, a somatostatin analog, at 5–20 mcg/kg/24 h divided q6h or given by continuous IV infusion at 0.08–0.40 mcg/kg/h
 - Tachyphylaxis and hyperglycemia may occur.
 - May increase the risk of necrotizing enterocolitis in neonates
- Glucagon, at 1 mg/24 h by continuous IV infusion, may stabilize blood glucose levels prior to surgery.

SURGERY/OTHER PROCEDURES

- Pancreatectomy in children refractory to medical therapy or in those with focal lesions. Near total pancreatectomy with gastrostomy tube for those with diffuse disease. Resection of pancreatic adenomatous lesion for focal disease
- For focal HI, surgery can be curative.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Up to 30–44% of patients can have neurodevelopmental abnormalities due to hypoglycemia.
- Patients who undergo near total pancreatectomy are at very high risk of developing diabetes later in life.

Patient Monitoring

- Home blood glucose monitoring, especially with longer fasts or intercurrent illnesses
- Hospitalizations for IV glucose infusions may be necessary during intercurrent illnesses with vomiting or poor oral intake.
- Follow-up fasting studies may be needed to evaluate safety and/or disease regression.
- Diazoxide may cause fluid retention and hypertrichosis.
- Neonates treated with octreotide should be closely monitored for evidence of necrotizing enterocolitis.
- Octreotide can suppress GH secretion, so close observation of linear growth is necessary. Thyroid function tests should also be monitored.
- Evaluation of pancreatic exocrine function after near-total pancreatectomy

- Periodic neurodevelopmental assessments

DIET

- Avoidance of long fasts
- Avoidance of protein loads in those with HI/HA, SCHAD, and $K_{ATP}HI$, as high-protein diets may stimulate insulin secretion

COMPLICATIONS

- Severe refractory hypoglycemia
- Cognitive deficits
- Seizures
- Coma
- Permanent brain damage
- Glucose intolerance or frank diabetes mellitus after pancreatectomy
- Pancreatic exocrine insufficiency after pancreatectomy

CODES

ICD10

E16.1 Other hypoglycemia

FAQ

- Q: What is the chance of HI in the sibling of an affected child?
- A: 25% in the autosomal recessive type; 50% in the autosomal dominant type; <1% for siblings of children with focal HI
- Q: How low and for how long can glucose go before brain damage occurs?
- A: The definition of hypoglycemia has been the subject of controversy in pediatrics, but activation of glucose counterregulatory systems occurs when blood glucose levels reach the 65–70-mg/dL range; symptoms of hypoglycemia present at the 50–55-mg/dL level, and cognitive dysfunction occurs when blood glucose levels are in the 45–50-mg/dL range. Taking these data into account, blood glucose concentration should be maintained >70 mg/dL. The duration of hypoglycemia necessary for brain damage to occur is unknown.
- Q: What is the chance that HI will eventually resolve without surgery?
- A: Only ~40–50% of cases are controlled with medication alone. Patients with K_{ATP} HI may be more likely to require surgery, and in those patients with focal disease, surgery can be curative. Perinatal stress-induced HI usually resolves within the first 6 months of life.

HYPERLEUKOCYTOSIS

Monica Khurana • Caroline Hastings

BASICS

DESCRIPTION

Hyperleukocytosis is a total white blood cell (WBC) count of $\geq 100,000/\mu\text{L}$.

RISK FACTORS

ALERT

Children with trisomy 21 (Down syndrome) have an increased risk of developing transient leukemoid reactions and have an increased risk of developing acute leukemia, more commonly acute lymphoblastic leukemia (ALL).

- Presentation with hyperleukocytosis depends on the type of leukemia.
- Percent with hyperleukocytosis
 - Chronic myeloid leukemia (CML) especially in blast crisis ~100%
 - Acute myeloid leukemia (AML) especially in infants 5–25%
 - ALL (especially with mediastinal mass) 8–13%
- Factors associated with more severe clinical course:
 - Coagulopathy
 - Metabolic derangements
 - Presentation with clinical evidence of central nervous system (CNS) or pulmonary leukostasis

PATHOPHYSIOLOGY

The primary mechanism for symptoms is leukostasis due to increased viscosity and impaired blood flow. Contributory factors other than number of leukemic cells include their shape and size, which increases viscosity, as well as endothelial cell damage, which further impedes microcirculation.

- WBCs lack the concave shape that enables reversible deformability of

cellular contents of red blood cells (RBCs) to pass through the microvasculature. As compared to normal WBCs, blasts are much larger with less deformability.

- Myeloblasts are twice the size of lymphoblasts, which are 25% larger than mature neutrophil granulocytes. Monoblasts are larger than myeloblasts. Aggregates of these large, undeformable cells cannot pass through capillaries.
- In addition to increased cell-to-cell adhesions, leukemic blast cells have increased adhesion to the damaged endothelium, which promote additional cell aggregates through endothelial toxin and cytokine release.
- Leukemic cells have a hypersensitive response to cytokines, which may account for clinical leukostasis at lower peripheral blast counts.
- Leukostasis impairs blood flow and exacerbates hypoxemia; as expected, leukemic blasts have increased oxygen consumption due to a high rate of cell division.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hyperleukocytosis occurs primarily secondary to malignancy but may be seen with a leukemoid reaction secondary to infection or physiologic stress.
- Malignancy
 - ALL
 - AML
 - CML
 - Transient myeloproliferative disorder (TMPD) is primarily associated with Down syndrome
- Leukemoid reaction
 - Leukemoid reactions are WBC counts more than 50,000/ μ L and consist of myeloid precursor cells in the peripheral blood at all stages of maturity rather than proliferation of an immature WBC clonal population characteristic of malignancies.
 - Leukemoid reactions reflect a physiologic bone marrow response to

cytokine secretion prompted by external stimuli such as infection or inflammation.

- Nucleated RBCs (also seen in malignancy)

HISTORY

- Symptoms and signs of hyperleukocytosis relate to the organ involved. Clinical evidence of leukostasis is most apparent in the CNS, lungs, retina, and penis.
- CNS
 - Headache
 - Confusion
 - Blurred vision
 - Tinnitus
 - Paresis
 - Nausea/vomiting
- Pulmonary
 - Dyspnea
 - Shortness of breath
 - Chest pain
- Genitourinary (males)
 - Anuria/oliguria
 - Erection
- Retina
 - Decreased visual acuity

PHYSICAL EXAM

- CNS
 - Coma
 - Somnolence
 - Altered mental status
 - Agitation
 - Seizures
 - Papilledema
 - Sluggish pupils
- Pulmonary
 - Hypoxia

- Tachypnea
- Hematologic
 - Hemorrhage
 - Thrombosis
- Reticuloendothelial system
 - Hepatomegaly
 - Splenomegaly
 - Enlarged lymph nodes
- Genitourinary (males)
 - Priapism

ALERT

- Symptomatic hyperleukocytosis as a result of leukostasis represents an oncologic emergency.
- Confused and/or hypoxic patients are at risk for severe late effects or death and require emergent intervention.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

ALERT

- Confirm presence of leukemic blasts. Automated counting machines may mistake leukemic blasts for atypical/reactive lymphocytes or even monocytes.
- Confirmation may require a manual differential and a pathologist or oncologist to review the peripheral smear.
- Peripheral blood analysis with morphology and flow cytometry aid in immediate diagnosis of acute leukemia.
- Evaluate other cell lines. Concurrent presence of anemia and/or thrombocytopenia supports an underlying marrow disorder and may require interventions such as transfusions.
- Tumor lysis laboratory evaluation includes the following:
 - Electrolytes
 - BUN, creatinine
 - Calcium
 - Phosphorous

- Magnesium
- Lactate dehydrogenase (LDH)
- Uric acid

Imaging

- Obtain CXR, even if asymptomatic.
 - Evaluate for mediastinal mass.
 - Evaluate for pulmonary infiltrates.
- If clinically indicated, obtain MRI or CT.

Procedures

Bone marrow aspirate may be required per clinical trial criteria, which includes cytogenetics for future prognostic/therapeutic decision making.

TREATMENT

- The goal of treatment is to quickly make a correct diagnosis and implement definitive therapy while simultaneously identifying and addressing the potential complications of leukostasis secondary to hyperleukocytosis.
- Leukoreduction refers to interventions that result in a rapid decline of the WBC. Leukoreduction is an absolute indication if a patient shows symptoms or signs of leukostasis. It is a relative indication in an asymptomatic patient with a WBC count $\geq 100,000\text{--}300,000/\mu\text{L}$ (depending on type of leukemia). Controversy exists about its impact on decreasing morbidity, risk of CNS hemorrhage, or mortality.
- Induction chemotherapy
 - This is the definitive therapy for hyperleukocytosis secondary to malignancy.
 - Initiate chemotherapy as soon as malignant diagnosis is confirmed.
- Management
 - Aggressive hydration at 2–4 \times maintenance
 - Identify and correct metabolic abnormalities.
 - ▢ Tumor lysis syndrome
 - ▢ Hyperuricemia, indication for rasburicase
 - Identify and correct coagulopathies.

- Transfuse for cytopenias.
 - Do not transfuse packed RBCs if hemodynamically stable due to increased blood viscosity.
 - Do not exceed hemoglobin 10 g/dL.
 - Transfuse platelets to maintain platelets $>10,000/\mu\text{L}$; will not affect blood viscosity
- Cytoreduction
 - Leukapheresis
 - Benefit: Each pheresis session decreases the circulating WBC count by 20–50%. During pheresis, FFP may be administered to reduce risk of hemorrhage.
 - Limitation: availability of equipment, trained personnel, and anticoagulation
 - Caution: Leukapheresis only transiently decreases blast counts until definitive treatment can be initiated.
 - Exchange transfusion, including partial
 - Benefit: This technique is preferred over leukapheresis when (1) patient is an infant or <10 kg and (2) there is concurrent severe anemia and/or (3) need for concurrent administration of coagulation factors (i.e., FFP to treat CNS hemorrhage). Partial exchanges minimize volume overload and hyperviscosity.
 - Limitation: higher risk of infection
 - Caution: Patients are at high risk for tumor lysis syndrome (TLS).
 - Hydroxyurea (HU)
 - Mechanism of action: This antimetabolite inhibits ribonucleoside diphosphate reductase, which halts cells in the G_1 phase and interferes with DNA repair.
 - Dose: 20–30 mg/kg/day
 - Benefit: HU is an oral medication and easily administered. It may be dissolved in water for NGT/OGT administration. Time to peak onset is only 1–4 hours.
 - Caution: may also worsen thrombocytopenia

ISSUES FOR REFERRAL

Obtain immediate oncology consult.

ONGOING CARE

PROGNOSIS

- Patients usually require treatment in a pediatric intensive care unit because they require rapid and continuous monitoring at presentation and during early phase of therapy due to complications of leukostasis and TLS.
- Presence of organ failure or coagulopathy correlates with poor prognosis, specifically death, during induction chemotherapy, despite supportive care.

ALERT

- Early deaths are primarily due to intracranial and pulmonary complications.
- Coagulopathy are most common in AML patients, in particular M3 or M4 subtypes.
- The CNS and lungs are the two most common organs damaged by leukostasis.

CODES

ICD10

- D72.829 Elevated white blood cell count, unspecified
- C91.00 Acute lymphoblastic leukemia not having achieved remission
- C92.10 Chronic myeloid leukemia, BCR/ABL-positive, not having achieved remission

FAQ

- Q: Is there a linear relationship between the WBC count and the presence/severity of clinical disease and complications?
- A: No. Clinically significant hyperleukocytosis usually occurs at WBC $\geq 200,000/\mu\text{L}$ or $\geq 300,000/\mu\text{L}$ in patients with AML or ALL and CML in blast crisis, respectively; however, symptoms may present with a WBC as low as $50,000/\mu\text{L}$.
- Q: Is there a linear correlation between the WBC count and presence of TLS?
- A: Yes. Risk increases as the tumor burden increases. With high WBC counts and rapid cell turnover, the lysis/death of malignant cells release by-products, leading to electrolyte and metabolic abnormalities known as TLS. TLS is more common in ALL patients as compared to AML or CML. Components of TLS include hyperkalemia, hyperphosphatemia, hyperuricemia and hyperuricosuria, and hypocalcemia.
- Q: Because transfusions for other cytopenias increase total blood viscosity, what are the current guidelines for transfusions?
- A: For anemia, if hemodynamically unstable, transfuse to maintain hemoglobin 8–9 g/dL. Do not exceed hemoglobin levels >10 g/dL as increasing hematocrit increases blood viscosity. For thrombocytopenia, transfuse to maintain platelet $>20,000/\mu\text{L}$ because platelet transfusions minimally increases blood viscosity. If CNS hemorrhage is present, maintain platelets at 75,000–100,000/ μL .

HYPERLIPIDEMIA

Zeina M. Nabhan

BASICS

DESCRIPTION

Hyperlipidemia is an elevation of serum lipids. These lipids include cholesterol, cholesterol esters (compounds), phospholipids, and triglycerides. Lipids are transported as part of large molecules called lipoproteins.

- 5 major families of lipoproteins
 - Chylomicrons
 - Very-low-density lipoproteins (VLDL)
 - Intermediate-density lipoproteins (IDL)
 - Low-density lipoproteins (LDL)
 - High-density lipoproteins (HDL)
- Normal serum lipid concentrations
 - Total cholesterol: 170 mg/dL (borderline, 170–199 mg/dL)
 - LDL cholesterol: <110 mg/dL (borderline, 110–129 mg/dL)
 - HDL cholesterol: ≥ 35 mg/dL
 - Total triglycerides: 100 mg/dL (borderline, 100–140 mg/dL)
 - More detailed age- and gender-specific values are available (refer to Table 2 of 2008 Clinical report: lipid screening and cardiovascular health in childhood).
- Primary hypercholesterolemia or hypertriglyceridemia: elevation in serum cholesterol or triglyceride as a result of an inherited disorder of lipid metabolism (i.e., familial hypercholesterolemia)
- Secondary hypercholesterolemia or hypertriglyceridemia: elevation in serum cholesterol or triglyceride as a result of another disease process (e.g., diabetes mellitus)

EPIDEMIOLOGY

- The prevalence of homozygous familial hypercholesterolemia (FH) is 1 in 1,000,000; the incidence of the heterozygous state is 1 in 500.
- Unknown causes result in hypercholesterolemia and/or

hypertriglyceridemia, occurring in 2% of the population.

- National Health and Nutrition Examination Surveys (NHANES I-III) provides information about pediatric serum cholesterol concentrations.
 - For all children 4–17 years, the 95th percentile for serum total cholesterol is 216 mg/dL and the 75th percentile is 181 mg/dL.
 - Before puberty, average total and LDL cholesterol levels are significantly higher in girls than boys.
 - The mean total cholesterol level for all children from 4 to 11 years old peaks at age 9–11 years and then gradually decreases until mid to late adolescence.

RISK FACTORS

Genetics

- FH: dominantly inherited defect of LDL receptor
- Familial combined hyperlipidemia (FCHL): dominantly inherited lipid disorder, polygenic
- Familial hypertriglyceridemia (FHTG): autosomal recessive disorder due to defects in lipoprotein lipase

GENERAL PREVENTION

- Fat intake is generally unrestricted prior to 2 years of age. After 2 years of age, two complementary approaches are recommended.
- Diet and lifestyle guidelines are to promote:
 - Consuming an overall healthy diet
 - Maintaining a healthy body weight (BMI <85% for children)
- Recommended lipid levels
 - LDL cholesterol <110 mg/dL
 - HDL cholesterol >50 mg/dL in women, >40 mg/dL in men
 - Triglycerides <150 mg/dL
- Normal, age-appropriate BP
- Normal blood glucose level (fasting blood glucose \leq 100 mg/dL)
- Remaining physically active
- Avoiding use of and exposure to tobacco products

DIAGNOSIS

HISTORY

- Family history of premature heart disease or dyslipidemia
 - Almost all cases of primary hyperlipidemia are of dominant inheritance.
- Smoking
 - Smoking reduces HDL cholesterol levels and increases the risk of vascular disease.
- Use of oral contraceptives
 - Birth control pills have been shown to cause elevations in lipoprotein levels and, when coupled with already elevated lipid levels, can increase the risk of atherosclerosis.
- Diet
 - Children with increased intake of fat, carbohydrates, sugar-added drinks, and fast foods are likely to be overweight/obese.
- Obesity
 - Obese children are more likely to have abnormal serum lipids.

PHYSICAL EXAM

- Eye exam
 - Arcus corneae: deposits of cholesterol, resulting in a thin, white circular ring located on the outer edge of the iris
- Skin exam
 - Tendon xanthomas: thickened tissue surrounding the Achilles and extensor tendons
 - Xanthelasma: yellowish deposits of cholesterol surrounding the eye
 - Palmar xanthomas: pale lines in palmar creases
 - Eruptive xanthomas: characteristic of hypertriglyceridemia; papular yellowish lesions with a red base that occur on the buttocks, elbows, and knees
 - Enlarged tender liver may present in association with fatty liver.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Starting age 2–8 years
 - Screen children and adolescents who have:
 - Positive family history of dyslipidemia or premature

cardiovascular disease (CVD) (≤ 55 years old for men, ≤ 65 years old for women), such as coronary atherosclerosis, documented myocardial infarction (MI)

- Unknown family history
- Obesity (BMI ≥ 95 th percentile) or overweight (BMI ≥ 85 th– <95 th percentile)
- Cigarette smoking exposure
- Hypertension
- Diabetes mellitus
- Screen using a fasting lipid profile (FLP): total cholesterol, HDL cholesterol, LDL cholesterol, and triglycerides.
- If FLP is within normal range, repeat test in 3–5 years.
- Age 9–11 years: NHLBI-AAP recommend universal screening.
 - Screen using either an FLP or nonfasting lipid profile (LP): if done nonfasting and non-HDL >145 mg/dL, then repeat as FLP.
 - Non-HDL = total cholesterol–HDL
- Age 12–16 years
 - Screen children and adolescents with risk factors as with 2–8 years group.

Consider other testing:

- Chemistry panel (glucose, ALT, AST, bilirubin, BUN, creatinine, urinalysis)
 - Screening test for diabetes, liver, and kidney disease
- Thyroid evaluation (thyroxine [total T_4], thyroid stimulating hormone [TSH])
 - Determines the presence of hypothyroidism

ALERT

- Serum total cholesterol is inaccurate when serum triglycerides are >400 mg/dL.
- Hypertriglyceridemia is associated with falsely lowered serum Na.

DIFFERENTIAL DIAGNOSIS

- Hypercholesterolemia
 - Primary hypercholesterolemia (see [above](#))
 - Hypothyroidism

- Nephrotic syndrome
- Liver disease (cholestatic)
- Renal failure
- Anorexia nervosa
- Acute porphyria
- Medications (antihypertensives, estrogens, steroids, microsomal enzyme inducers, cyclosporine, diuretics)
- Pregnancy
- Dietary: excessive dietary intake of fat, cholesterol, and/or calories
- Hypertriglyceridemia
 - Primary hypertriglyceridemia (see [above](#))
 - Acute hepatitis
 - Nephrotic syndrome
 - Chronic renal failure
 - Medications (diuretics, retinoids, oral contraceptives)
 - Diabetes mellitus
 - Alcohol abuse
 - Lipodystrophy
 - Myelomatosis
 - Glycogen storage disease
 - Dietary: excessive dietary intake of fat and/or calories

TREATMENT

MEDICATION

- Drug therapy should be considered only for children ≥ 8 years of age after an adequate trial of diet therapy (for 6–12 months) and if they have one of the following:
 - LDL cholesterol level remains >190 mg/dL
 - LDL cholesterol level remains >160 mg/dL, and there is a family history of premature CVD (≤ 55 years of age for men, ≤ 65 for women) or ≥ 2 other risk factors are present (obesity, hypertension, cigarette smoking).
 - LDL ≥ 130 mg/dL and have diabetes mellitus
- Physicians caring for overweight and obese children who have lipid

disorders should emphasize the importance of diet and exercise rather than drug therapy for most of their patients.

- Statins (first-line drug therapy)
 - Decrease endogenous cholesterol synthesis and increase clearance of LDL from circulation
 - Similar safety and efficacy in the treatment of lipid disorders in children as in adults
 - Side effects include hepatitis and myositis.
- Bile acid-binding resins
 - Bind cholesterol in bile acids in intestine and prevent reuptake into enterohepatic circulation
 - Associated with GI discomfort
 - Very poor compliance in children
- Niacin
 - Lowers LDL and triglycerides while increasing HDL
 - Poorly tolerated in children due to side effects in >50%, including flushing, itching, and elevated hepatic transaminases
- Drugs needing further pediatric studies: cholesterol absorption inhibitors and fibrates

ADDITIONAL TREATMENT

General Measures

- Outpatient management unless secondary hyperlipidemia caused by liver or renal failure, which would necessitate inpatient management of primary illness. Note: The cause of secondary hyperlipidemia should be treated with disease-specific therapy to reduce elevated lipid levels.
- Risk assessment and treatment
 - Population approach
 - General emphasis on healthy lifestyle to prevent development of dyslipidemias
 - Recommendations include increasing intake of fruits, vegetables, fish, whole grains, and low-fat dairy products; reducing intake of fruit juice, sugar-sweetened beverages and food.
 - Individual approach
 - Focuses on patients who are high risk
 - Initial intervention is focused on changing diet, but patients often

require pharmacologic intervention.

ADDITIONAL THERAPIES

Activity

- 60 minutes of moderate to vigorous play or physical activity daily
- Reduce sedentary behaviors (e.g., watching TV, playing videogames, using computers)
- Participation in organized sports

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- For patients with primary hyperlipidemia who are off medication, follow-up should be performed every 1–2 years with a lipoprotein profile evaluation. For those patients on medication, follow-up should be conducted every 3–6 months.
- For all other patients with risk factors and normal lipid profile, a monitored lifestyle and dietary changes should be strongly recommended at every office visit.

DIET

- Dietary modification is safe in the treatment of hyperlipidemia in children >2 years of age:
 - Restrict saturated fat to <7% daily calories.
 - Restrict dietary cholesterol to 200 mg/day.
 - Limit trans fatty acids to <1% daily calories.
 - Supplemental fiber at goal dose of child's age + 5 g/day (up to 20 g/day)
- For children between 12 months and 2 years who are overweight, obese, or have a family history of dyslipidemia or CVD, the use of reduced fat milk can be considered.

PROGNOSIS

- Familial hypercholesterolemia
 - Homozygotes: coronary artery disease in 1st or 2nd decade of life

- Heterozygotes: 50% of males develop premature heart disease by age 50 years (females, age 60 years).
- Familial combined hyperlipidemia: occurs in 1–2% of the population and accounts for 10% of all premature heart disease. A reduction of LDL cholesterol by 1% reduces risk by 2%.
- Children and adolescents with high cholesterol levels are more likely than the general population to have high levels as adults.

COMPLICATIONS

- Hypercholesterolemia has been linked to premature coronary artery disease and vascular disease.
- Severe hypertriglyceridemia can cause pancreatitis.

CODES

ICD10

- E78.5 Hyperlipidemia, unspecified
- E78.0 Pure hypercholesterolemia
- E78.1 Pure hyperglyceridemia

FAQ

- Q: When should I screen for dyslipidemia, and what test should I use for screening?
- A: All children between ages 9 and 11 years should be screened for dyslipidemia using a non-FLP. Children between 2–8 years and 12–16 years should be screened using an FLP only if they have risk factors.
- Q: What should my initial management of a child with dyslipidemia include?
- A: The management plan of any child with dyslipidemia is dependent on the age of the child and should include dietary recommendations, a focus on all aspects of heart health, and in selected cases, the use of pharmacotherapy.

HYPERTENSION

Stephanie Nguyen

BASICS

DESCRIPTION

- Hypertension: average systolic and/or diastolic blood pressure (BP) above the 95th percentile for age, gender, and height percentile on at least 3 separate occasions
- Prehypertension: BP between the 90th percentile and 95th percentile or BP $\geq 120/80$ mm Hg in adolescents
- Stage 1 hypertension: BP 95–99% plus 5 mm Hg
- Stage 2 hypertension: BP >99 th% plus 5 mm Hg
- Primary (essential) hypertension: hypertension for which there is no underlying cause
- Secondary hypertension: hypertension for which an underlying cause can be identified
- White coat hypertension: elevated BP readings in a medical setting with normal BP on ambulatory blood pressure monitoring (ABPM)
- Masked hypertension: normal BP readings in a medical setting with elevated BP readings on ABPM

EPIDEMIOLOGY

- Primary hypertension is now identifiable in children and adolescents and is associated with overweight status, metabolic syndrome, and family history of hypertension.
- The prevalence of hypertension is increasing due to the epidemic of youth obesity and the metabolic syndrome.
- Hypertension in the pediatric population is estimated to be between 1% and 4%.
- 30% of children with body mass index (BMI) >95 % have prehypertension or hypertension.

RISK FACTORS

- Primary hypertension: obesity, sedentary lifestyle, low birth weight,

smoking, alcohol use, hyperlipidemia, family history, stress, sodium intake, sleep apnea

- Secondary hypertension: renal or urologic disease, transplant, congenital heart disease, umbilical artery catheterization, urinary tract infection (UTI), diabetes mellitus, elevated intracranial pressure, or medications known to raise BP
- The younger the child and the more elevated BP, the greater likelihood of a secondary cause.

Genetics

- The genetic basis of primary hypertension is polygenic but more likely to develop in individuals when there is a strong family history.
- The genetics of secondary causes depend on the underlying condition, for example
 - Polycystic kidney disease: autosomal dominant, autosomal recessive
 - Neurofibromatosis: autosomal dominant
 - Glucocorticoid-remediable aldosteronism: autosomal dominant

GENERAL PREVENTION

Avoidance of excess weight gain and regular physical activity can prevent obesity-related hypertension.

ETIOLOGY

- Secondary causes
 - Renal: acute glomerulonephritis, chronic renal failure, polycystic kidney disease, reflux nephropathy
 - Renovascular: fibromuscular dysplasia, neurofibromatosis, vasculitis
 - Cardiac: coarctation of the aorta
 - Endocrine: pheochromocytoma, hypo/hyperthyroid, neuroblastoma, glucocorticoid-remediable aldosteronism, Conn syndrome, apparent mineralocorticoid excess, congenital adrenal hyperplasia, Liddle syndrome, Gordon syndrome
 - Neurologic: increased intracranial pressure
 - Drugs: corticosteroids, oral contraceptives, sympathomimetics, illicit drugs (cocaine, phencyclidine)

- Other: pain, burns, traction
- Reduced nephron number secondary to premature birth, low birth weight, or postnatal insults are associated with hypertension.

PATHOPHYSIOLOGY

Blood pressure is a product of cardiac output and total peripheral vascular resistance. Increases of either or both of these products lead to hypertension. The various causes of hypertension alter blood pressure through different mechanisms such as volume overload (sodium retention, excess sodium intake), volume distribution, renin-angiotensin excess, sympathetic activation, insulin, and endothelin.

DIAGNOSIS

- Hypertensive emergency: severely elevated BP with evidence of target organ injury (encephalopathy, seizures, renal damage)
- Hypertensive urgency: severely elevated BP with no evidence of secondary organ damage

HISTORY

- Headache, blurry vision, epistaxis, unusual weight gain or loss, chest pain, flushing, fatigue
- UTIs can be associated with reflux nephropathy and hypertension.
- Gross hematuria, edema, and fatigue may suggest renal disease.
- Birth history: umbilical artery catheterization
- Medications: corticosteroids, cold preparations, oral contraceptives, illicit drugs
- Family history: hypertension, diabetes, obesity, familial endocrinopathies, renal disease
- Trauma: arteriovenous (AV) fistula, traction
- Review of symptoms: sleep apnea, obesity

PHYSICAL EXAM

- BP
 - Children >3 years of age should have their BP measured during a health care episode or younger if they have any risk factors for

hypertension.

- Child should be seated quietly for 5 minutes, feet on the floor with the right arm supported at the level of the heart. Routine BPs are measured in the right arm.
- Use the proper cuff size. The inflatable bladder should completely encircle the arm and cover ~80–100% of the upper arm. A cuff that is inappropriately small will artificially increase the measurement.
- Elevated BPs obtained by oscillometric devices should be repeated by auscultation.
- When hypertension is confirmed, BP should be measured in both arms and in a leg. Normally, BP is 10–20 mm Hg higher in the legs. If leg BP is lower than arm, consider coarctation of the aorta.
- Tachycardia in hyperthyroidism, pheochromocytoma
- Body habitus: thin, obese, growth failure, virilized, stigmata of Turner or Williams syndromes
- Skin: café au lait spots, neurofibromas, rashes, acanthosis, malar rash
- Head/neck: moon facies, thyromegaly
- Eyes: fundoscopic changes, proptosis
- Lungs: rales
- Cardiovascular: rub, gallop, murmur, femoral pulses
- Abdomen: mass, hepatosplenomegaly, bruit
- Genitalia: ambiguous, virilized
- Neurologic: Bell palsy

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- The laboratory evaluation to determine the cause of hypertension should proceed in a stepwise fashion. In adolescents with stage 1 hypertension, it is reasonable to evaluate for white coat hypertension using ABPM as a first step before other testing.
- Patients should have the following: urinalysis, serum electrolytes, blood urea nitrogen, creatinine, calcium, cholesterol, CBC, ECG, echocardiogram (the most sensitive study to monitor end-organ changes), renal ultrasound, retinal exam
- Further evaluation is based on history, physical exam, and/or to prove secondary causes: voiding cystourethrogram, DMSA renal scan, 3D

CT angiogram, MRA, urine or plasma for catecholamines and metanephrines, plasma renin activity, aldosterone levels

- More invasive studies include renal angiogram; renal vein renin concentrations; meta-iodobenzylguanidine (MIBG) scan; renal biopsy; genetic studies to identify rare causes of hypertension

Diagnostic Procedures/Other

- Ambulatory BP monitoring refers to a procedure in which a portable BP device, worn by the patient, records BP over a specified period, usually 24 hours.
- Ambulatory BP monitoring may be helpful in cases in which the diagnosis of hypertension is uncertain (e.g., white coat hypertension) or in assessing the effectiveness of antihypertensive agents. ABPM may also be useful in assessing children at high risk of cardiovascular disease (e.g., diabetes mellitus, labile hypertension).
- Systolic hypertension on ABPM is a better predictor for the development of left ventricular hypertrophy (LVH) when compared to office BP measurements.

DIFFERENTIAL DIAGNOSIS

The initial objective after diagnosing hypertension in children is distinguishing primary from secondary causes. Generally, the younger the child and more elevated the BP measurements, the more likely the cause of hypertension is secondary.

TREATMENT

MEDICATION

- Classes of antihypertensive agents include α - and β -blockers, diuretics, vasodilators (direct and calcium channel blockers), ACE inhibitors, and angiotensin receptor blockers (ARBs).
- Therapy should be initiated with a single drug.
- Avoid multiple medications with the same mechanism of action.
- Elicit a history of adverse effects and adjust medications accordingly.
- Specific classes should be used with concurrent medical conditions: ACE inhibitors or ARBs in children with diabetes and

microalbuminuria or proteinuric renal diseases; β -blockers or calcium channel blockers with migraine headaches.

- Certain classes of medication should be avoided in patients with specific conditions, such as asthma and diabetes (β -blockers) and bilateral renal artery stenosis (ACE inhibitors).
- ACE inhibitors are associated with congenital malformations and are contraindicated during pregnancy; calcium channel blockers and β -blockers are alternatives.

ADDITIONAL TREATMENT

General Measures

- If BP is >95th percentile, it should be repeated on 2 more occasions.
- If BP is >99th percentile plus 5 mm Hg, prompt referral for evaluation and therapy should be made.
- If the patient is symptomatic, immediate referral and treatment are indicated.
- Mild primary hypertension may be managed with nonpharmacologic treatment: weight reduction, exercise, sodium restriction, avoidance of certain medications such as pseudoephedrine.
- Pharmacologic therapy should be directed to the cause of secondary hypertension when this is known or for severe, sustained hypertension.
- Medications may be needed in children with mild to moderate hypertension if nonpharmacologic therapy has failed or if end-organ changes, kidney disease, or diabetes is present.

ADDITIONAL THERAPIES

- Regular aerobic physical activity (30–60 minutes at least 5 days a week)
- Limitation of sedentary activities to <2 hours per day
- Patients with uncontrolled stage 2 hypertension should be restricted from high-static competitive sports until the BP is in normal range.

SURGERY/OTHER PROCEDURES

- Dialysis may be needed for hypertension in chronic renal failure.
- Surgical correction of renovascular hypertension and coarctation of the aorta. Percutaneous transluminal angioplasty has been used for renal

artery stenosis.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Hypertensive emergencies should be treated with IV BP medications, aiming to decrease the BP by 25% over the first 8 hours and gradually normalizing BP over 24–48 hours.
- Hypertensive urgencies can be treated by either IV or PO antihypertensives depending on symptomatology.

Admission Criteria

- Hypertensive emergencies should be admitted to the ICU if indicated.
- Hypertensive urgencies should be admitted to the hospital.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- The reduction of BP with medication should be gradual to avoid side effects.
- Ongoing monitoring is required for medication side effects, such as exercise intolerance (β -blockers), headaches (vasodilators), renal insufficiency or hyperkalemia (ACE inhibitors), or hypokalemia (diuretics).
- Regular monitoring for development of LVH (echo or ECG) is recommended.
- Patients with white coat hypertension require ongoing monitoring, as they are at risk for developing true hypertension.

DIET

- Dietary increase in fresh vegetables, fresh fruits, potassium, fiber, and nonfat dairy
- Restriction of sodium, calories, saturated fat, and refined sugar
- Low-sodium (DASH) diet: <2.3 g of sodium per day for adolescents

PATIENT EDUCATION

- Diet

- Increase in fresh vegetables, fresh fruits, fiber, and nonfat dairy
- Restriction of sodium and calories
- Activity
 - Regular aerobic physical activity (30–60 minutes at least 5 days a week)
 - Limitation of sedentary activities to <2 hours per day
- Prevention
 - Avoidance of excess weight gain, smoking, and alcohol use; regular physical activity

PROGNOSIS

The patient's prognosis depends on the underlying cause of the hypertension. It is excellent if the BP is well controlled.

COMPLICATIONS

- LVH and heart failure
- Renal failure
- Encephalopathy
- Retinopathy

CODES

ICD10

- I10 Essential (primary) hypertension
- I15.9 Secondary hypertension, unspecified
- I15.1 Hypertension secondary to other renal disorders

FAQ

- Q: What is the value of ambulatory BP monitoring?
- A: This device is similar to a Holter monitor and measures BPs over a 24-hour period while the patient is awake and asleep. By reviewing the BPs, one can determine if a significant proportion of readings are elevated and whether or not the normal dip in BP during sleep is seen. Thus, conditions such as white coat hypertension can be verified or discounted.
- Q: What are the indications for invasive studies, such as angiography?
- A: This decision should be individualized and based on the severity of the hypertension, response to medication, the clinical presentation (e.g., neurofibromatosis), and results of other studies. In general, young children and all children with severe, unexplained hypertension should be completely evaluated.
- Q: Can adolescents with elevated BP compete in sports?
- A: Adolescents with hypertension should be encouraged to participate in athletics if their BP is well controlled. The use of stress testing in this population is controversial.
- Q: Do I need to worry about isolated systolic hypertension?
- A: Studies in adults have shown that sustained systolic hypertension may be just as important as diastolic hypertension.

HYPOCALCEMIA

Pisit Pitukcheewanont • Chawkaew Kongkanka

BASICS

DESCRIPTION

- Severity varies from asymptomatic to acute life-threatening condition.
- Etiology is important for appropriate management.
- Neonates
 - Term/premature >1,500 g: total calcium <8 mg/dL (2 mmol/L) if serum protein normal (ionized < 1.1 mmol/L)
 - Premature <1,500 g: total calcium <7 mg/dL (1.75 mmol/L); ionized <0.8 mmol/L
- Children: total serum calcium <8.5 mg/dL (2.1 mmol/L) and ionized calcium <4.5 mg/dL (ionized <1.1 mmol/L).

EPIDEMIOLOGY

- Many normal neonates have serum calcium <8 mg/dL during first 3 weeks of life owing to physiologic transient hypoparathyroidism.
- Parathyroid gland (PTG) immaturity can lead to deficient PTH release and exaggerated fall in calcium during the first 3 days of life.
- Relative immaturity of renal phosphorus handling and PTH response can lead to late neonatal hypocalcemia precipitated by a high-phosphate diet.
- Prevalence of vitamin D deficiency in neonate with mother at risk or maternal vitamin D deficiency is about 52–90%.
- Following total thyroidectomy, 10% develop transient hypoparathyroidism; of these, <50% remain permanently hypoparathyroid.

RISK FACTORS

- Neonate
 - Maternal disorders: diabetes mellitus, toxemia, preeclampsia, hyperparathyroidism, severe vitamin D deficiency
 - Maternal drugs; anticonvulsants, high intake of alkali, magnesium

- sulfate antacid
- Prematurity, low birth weight, IUGR, perinatal stress/asphyxia, sepsis
- Hyperbilirubinemia, phototherapy, citrated blood product use, exchange transfusion
- Nutrients/drugs; lipid infusion, phosphate therapy, phytate, aminoglycosides, bicarbonate, loop diuretics, glucocorticosteroids, anticonvulsants
- Osteopetrosis type II
- Phosphate load; high dietary phosphate (such as cow's milk), phosphate enema, chronic renal insufficiency
- Hypomagnesemia rarely hypermagnesemia
- Vitamin D deficiency: malabsorption, renal insufficiency, and liver disease
- Osteopenia of prematurity
- Hypoparathyroidism
 - Transient neonatal hypoparathyroidism
 - PTG dysgenesis/agenesis
 - Several identified genetic causes including isolated hypoparathyroidism (GCM2, PTH, SOX3), DiGeorge syndrome (DGS) (TBX1), mitochondrial fatty acid disorders (Kearns-Sayre, Pearson, mitochondrial encephalopathy, lactic acidosis, stroke-like—MELAS)
 - PTH insensitivity
 - Blomstrand chondrodysplasia (PTHR1)
 - Pseudohypoparathyroidism type IA (PHP IA)
 - Dyshormonogenesis
 - Autoimmune hypoparathyroidism
 - Autoimmune polyglandular syndrome type I (AIRE1)
 - Activating antibodies to the calcium sensing receptor (CaSR)
 - Acquired
 - Postsurgical, PTG radiation destruction
 - PTG infiltrative disease (excessive iron or copper deposition, granulomatous or neoplastic invasion)
 - Enzyme deficiencies

- Deficiency of 25-hydroxylase (CYP2R1)
 - Deficiency of 25OH-vitamin D₃-1-hydroxylase (CYP27B1)
- Loss of function vitamin D receptor mutations
- Calcium deficiency
 - Nutritional deprivation
 - Hypercalciuria
- Hypomagnesemia
 - Malabsorption
 - Hypermagnesuria
 - Primary (CLDN16)
 - Bartter syndrome type V (CaSR)
 - Renal tubular acidosis
 - Acute renal failure
 - Chronic inflammatory bowel disease, intestinal resection
 - Diuretics
- Hyperphosphatemia
 - Renal failure
 - Phosphate administration
 - Tumor lysis syndrome
 - Rhabdomyolysis

COMMONLY ASSOCIATED CONDITIONS

- Hypoproteinemia
- Hyperventilation
- Drugs: furosemide, bisphosphonates, calcitonin, anticonvulsants, ketoconazole, antineoplastic agents, citrated blood products
- “Hungry bone syndrome”
- Sepsis, acute pancreatitis, shock
- Organic acidemia

PATHOPHYSIOLOGY

- Calcium is most abundant mineral ion in body; 99% of total body calcium is deposited in bone. Three forms of calcium in serum: protein-bound (50%), complex with serum anions (5%), and ionized form (45%).
- Calcium homeostasis is regulated by many factors: hormones and their

receptors (PTH/PTHr, vitamin D/VDR, calcitonin), organs (bone, kidneys, PTGs, intestine, and liver), CaSR (the serum calcium set point), and others such as serum pH.

- Tetany is a manifestation of neuromuscular irritability in patients with hypocalcemia.
- Hypocalcemia may present with seizure or other nonspecific symptoms.

ETIOLOGY

- Abnormal hormonal response
 - Hypoparathyroidism
 - Abnormal PTH production: PTG agenesis/dysfunction, acquired hypoparathyroidism, abnormal PTH secretion
 - Pseudohypoparathyroidism
 - Vitamin D disorder: deficiency/resistance
- Abnormality of calcium-regulating organs
 - Kidneys, bone, intestine
- Abnormal CaSR
 - Gain of function mutation of CaSR gene
 - Antibodies to the CaSR
- Other causes of hypocalcemia
 - Phosphate load
 - Calcium sequestration or clearance
 - Decreased ionized calcium

DIAGNOSIS

HISTORY

- In neonates and infants, include relevant maternal history, prematurity, nutrition, IUGR, perinatal illness
- Other nonspecific symptoms; apnea, poor feeding
- Family history of calcium disorders
- Current illness and drug use
- History of neck surgery
- Recurrent infection

- History of seizure
- Muscle cramps
- Paresthesia, a tingling sensation, usually present around the mouth, fingers, and toes

PHYSICAL EXAM

- Neuromuscular irritabilities
 - Tetany, hyperreflexia
 - Chvostek sign (usually in 1 month to 2 years of age): twitching of the orbicularis oris muscle with light tapping at anterior external auditory meatus on the CN VII
 - Peroneal sign: dorsiflexion and abduction of the foot on tapping the peroneal nerve on the lateral surface of the fibula just before the knee
 - Trousseau sign: carpopedal spasm when BP cuff maintained 20 mm Hg above SBP for 3 minutes
 - Lethargy
 - Muscle weakness
 - Focal or generalized seizure
 - In neonate: laryngospasm, apnea, bradycardia/ tachycardia, hypotension, cyanosis, emesis
- Prolonged hypocalcemia
 - Basal ganglia calcification
 - Subcapsular cataracts
 - Papilledema (occasional)
 - Dental enamel hypoplasia, particularly of the primary teeth
- Features associated with genetic syndrome/inherited causes of hypocalcemia
 - Dysmorphic features
 - Hearing loss
 - Congenital heart disease
 - Clinical signs of rickets, alopecia
 - Mucocutaneous candidiasis, ectodermal dysplasia, vitiligo
 - Albright hereditary osteodystrophy (AHO)
 - PHP IA has AHO features: short stature, husky-obese body habitus, shortening of the 3rd–5th metacarpal bones and distal phalanx of the

1st finger (brachydactyly), syndactyly between the 2nd and 3rd toes, round face, flat nasal bridge, short neck, subcutaneous calcifications (heterotopic ossification), cataract, and developmental delay in some patients.

DIAGNOSTIC TESTS & INTERPRETATION

Initial Lab Tests

- Blood: total and ionized calcium, albumin, arterial pH, phosphate, intact PTH, Mg, alkaline phosphatase, creatinine, 25-hydroxyvitamin D; consider 1,25-dihydroxyvitamin D
- Urine: calcium, creatinine
- 12-lead ECG
 - Prolonged QT interval associated with early after-repolarizations and triggered dysrhythmias
 - ECG abnormalities common but serious dysrhythmias infrequent
- If hypoalbuminemia present: correction calculated by: calcium measured + 0.8 [4 – albumin (mg/dL)]
- When serum pH increased (alkalosis), Ca^{2+} bound to protein
- Phosphate is an indirect index of PTH activity; low and high phosphate levels may reflect a raised and a reduced PTH, respectively.
- Hypoparathyroidism: low/subnormal serum calcium and high serum phosphate with normal or inappropriately low serum iPTH after ruled out hypo/hypermagnesemia
- Parathyroid hormone insensitivity
 - In PHP IA, low serum calcium, high serum and urine phosphate, and elevated PTH
 - No increased serum calcium, urinary cyclic AMP or phosphate after rhPTH1-34 (unresponsive to exogenous PTH)
- Hypomagnesemia inhibits PTH secretion and activity.
- Hypermagnesemia suppresses PTH secretion and decreases renal tubular calcium reabsorption.
- Urine calcium/urine creatinine: normal values for spot collections vary by age. For 0–6, 7–12, and >24 months are <0.8, <0.6, and <0.21 mg/mg, respectively.
- Alkaline phosphatase: bone formation marker
- Serum Cr is used to exclude renal failure.

- Vitamin D disorders: low/ subnormal serum calcium, low/normal phosphate with secondary hyperparathyroidism. In vitamin D deficiency, serum 25-hydroxyvitamin D <30 ng/mL. Serum 1,25-dihydroxyvitamin D₃ inappropriately low in patients with severely compromised renal function, hypoparathyroidism, and deficiency of 25OH-vitamin D3-1-hydroxylase.

TREATMENT

MEDICATION

Neonatal hypocalcemia

- Asymptomatic neonatal hypocalcemia
 - Increased oral calcium intake, calcium glubionate/carbonate 50–100 mg of elemental Ca/kg/day divided q4–6h if no feeding intolerance (be careful, high osmolality of oral calcium in whom at risk of necrotizing enterocolitis), or 10% calcium gluconate continuous IV infusion for 48 hours. Calcium glubionate is preferable in neonates.
 - Once serum calcium normalizes, can taper supplements
- Symptomatic neonatal hypocalcemia
 - 10% calcium gluconate IV over 10 minutes (elemental Ca 9.3 mg/mL), 18.6 mg elemental Ca (2 mL)/kg/dose (max. 20 mg elemental Ca/kg), diluted 1:1 with 5% dextrose, with cardiac monitoring
 - If severe hypocalcemia with poor cardiac function, may give calcium chloride 20 mg/kg via central line over 10–30 minutes
 - Maintenance of 50–100 mg of elemental Ca/kg/day, continuous IV infusion for 48 hours
 - If serum calcium is normal at 48 hours, taper to 50% dose for next 24 hours and then stop/continue depending on etiology; may switch to oral calcium on the last day before stopping or for continued treatment
 - Avoid extravascular extravasation.
- Treatment for specific causes
 - Calcium supplement doses depend on patient requirement and cause of hypocalcemia.

- Hypomagnesemia: Give 50% (500 mg/mL) MgSO_4 50–100 mg/kg (0.1–0.2 mL/kg) IV/IM q12h for 2 doses with cardiac monitoring. A maintenance dose is 100 mg (0.2 mL)/kg/day PO for 3 days.
- Phosphate load: Encourage exclusive breastfeeding or use low-phosphate formula (similac PM 60/40, Ca : P = 1.6:1). Phosphate-binding gels are not recommended.
- Hypoparathyroidism: Supplement 1, 25(OH) $_2$ vitamin D $_3$ /calcitriol 20–60 ng/kg/day or 0.5–1 mcg/day PO.
- Vitamin D deficiency: Supplement vitamin D $_2$ or D $_3$ (age 0–1 year) 2,000 IU daily for 6 weeks to achieve level above 30 ng/mL, then maintenance therapy 400–1,000 IU daily.

Hypocalcemia in childhood and adolescence

- Asymptomatic hypocalcemia
 - Likely long-standing; may not require immediate treatment
 - Supplement oral calcium 25–100 mg of elemental Ca/kg/day q4–6h. Calcium citrate may be preferable.
- Symptomatic hypocalcemia
 - Give 10% (100 mg/mL) calcium gluconate 200 mg (2 mL)/kg/dose IV, slow rate over 10 minutes with cardiac monitoring; may repeat dose q6–8h
 - Maintenance by 20–80 mg of elemental Ca/kg/day, continuous IV infusion for 48 hours
 - If hypocalcemia is caused by hypomagnesemia, give 50% (500 mg/mL) MgSO_4 50–100 mg (0.1–0.2 mL)/kg IM with cardiac monitoring.
- Higher supplemental calcium doses required in patient with severe bone demineralization (hungry bone syndrome)
- In hypoparathyroidism: calcitriol 20–60 ng/kg/day PO and calcium 30–75 mg elemental Ca/kg/day q4–6h
- Additional medication: Thiazide (hydrochlorothiazide [HCTZ] 0.2 mg/kg/day) combined with a low-salt diet may increase renal tubular reabsorption of Ca and lower calcitriol requirement.
- Others: Recombinant human PTH therapy in adults can be considered; black box warning in children
- In chronic hypocalcemia, goals are to control symptoms and avoid

complications. Maintain serum calcium at the lower end of normal range, $\text{Ca} \times \text{phosphate} < 55$ (higher products could precipitate calcium phosphate in soft tissue: kidney, lens, and basal ganglia), and urine $\text{Ca/urine creatinine} < 0.2$ to avoid hypercalcemia, hypercalciuria, nephrocalcinosis, and nephrolithiasis, especially in hypoparathyroidism.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Regular serum and urine monitoring during initial therapy and dose adjustment and 3–6-month interval if stabilized
- Annual renal ultrasound, slit-lamp, and ophthalmoscopic examination are recommended.

PROGNOSIS

Depends on etiology

COMPLICATIONS

Precipitation of calcium–phosphate salts in soft tissues (e.g., kidney, lens, and basal ganglia), hypercalcemia, hypercalciuria, nephrocalcinosis, nephrolithiasis, renal insufficiency

FAQ

- Q: What is the relationship between calcium and phosphate in hypocalcemic setting?
- A: It depends on abnormal hormonal regulation and etiology of hypocalcemia.

Hormonal problems	Serum calcium	Serum phosphate
Parathyroid hormone deficiency/resistant	Low	High
Vitamin D deficiency/resistant	Normal/ low	Normal/ low

- Q: When should parenteral or oral calcium supplement be used?
- A: Every patient can be treated with oral calcium supplement except in acute symptomatic hypocalcemia such as seizure and individuals who temporally hold on enteral feeding or have active malabsorption issue.
- Q: What is the treatment goal of hypocalcemia in children?
- A: Keep serum calcium level in the lower normal range without symptoms of hypocalcemia to reduce the long-term complications, especially nephrocalcinosis.

HYPOGAMMAGLOBULINEMIA

Rachel G. Robison

BASICS

DESCRIPTION

- A disorder of the humoral immune system characterized by deficient or absent immunoglobulins and the inability to produce specific antibody
- Subtypes include primary immunodeficiency and secondary deficiency due to other extrinsic disease (i.e., malignancy).

EPIDEMIOLOGY

Incidence and prevalence depends on underlying defect or cause. Antibody deficiency syndromes represent ~70% of primary immune deficiencies.

RISK FACTORS

Genetic defects have been identified in many cases, which are identified in the “Differential Diagnosis.”

DIAGNOSIS

HISTORY

- Recurrent upper and lower respiratory tract infections (otitis media, pneumonia, and sinusitis)
- Infections with encapsulated bacteria such as *Streptococcus pneumoniae*, *Haemophilus influenzae*
- May have diarrhea, infections with *Giardia*
- Chronic cough and chronic rhinitis may be present.

PHYSICAL EXAM

- May be normal if an infection is not present
- Evaluate for growth delay and failure to thrive.
- Patients with X-linked agammaglobulinemia (XLA) may have absent or minimal tonsillar tissue.
- Digital clubbing may be present in cases with history of severe

infections.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC with differential
 - Can rule out associated anemia, thrombocytopenia, and neutropenia
- Quantitative immunoglobulins: IgG, IgM, IgA, and IgE
 - Look for low or absent isotypes.

ALERT

Normal immunoglobulin levels vary by age.

- Qualitative antibody titers specifically to tetanus, H. influenzae type B, S. pneumoniae postvaccination
 - Absent response after vaccination can identify specific antibody deficiencies.
- Evaluate for presence of isohemagglutinins (primary IgM antibodies to the main blood groups) in unvaccinated children.
- Flow cytometry to evaluate B cell numbers

Imaging

- Chest radiography, CT chest and/or sinus
 - To evaluate for acute disease and if with history of multiple infections, to look for chronic parenchymal changes such as bronchiectasis

DIFFERENTIAL DIAGNOSIS

Primary Defects in Antibody Production

- Selective IgA deficiency
 - Most common cause of hypogammaglobulinemia
 - Low to undetectable levels of IgA with normal other immunoglobulin classes
 - Prevalence of 1/300–1/800 in Caucasians
 - Most are asymptomatic, a proportion may have recurrent infections (upper and lower respiratory infections), risk of giardiasis, and GI infections
 - May develop anaphylactic reactions to blood products due to presence of antibodies to IgA

- Common variable immunodeficiency
 - The second most common cause of hypogammaglobulinemia
 - Peaks in 1st and 3rd decades of life
 - Affects both sexes equally; incidence of 1/20,000–1/100,000
 - Characterized by decreased IgG (2 SD below the age-adjusted mean) and impaired humoral response to polysaccharide antigens
 - Risk of development of malignancy such as non-Hodgkin lymphoma, gastric cancer
 - Can be associated with autoimmunity in up to 25% (i.e., rheumatoid arthritis, idiopathic thrombocytopenic purpura, autoimmune hemolytic anemia)
 - Genetic defects have been identified in TACI, ICOS, BAFF-R, and CD19, although only 10% have a family history of disease.
- XLA
 - X-linked mutation in Bruton tyrosine kinase (Btk) gene leading to a defect in B cell maturation
 - Reported in 1/379,000 U.S. births
 - Patients often present with infections after waning of maternal IgG after 3 months of age.
 - Labs reveal low serum immunoglobulin levels and <2% circulating B cells.
 - Patients are susceptible to viral infections such as enterovirus.
 - Autosomal recessive agammaglobulinemia occurs in ~15% without Btk mutations and can occur in females; has a similar phenotype.
- Transient hypogammaglobulinemia of infancy
 - Prolongation of the “physiologic” hypogammaglobulinemia of infancy, which is normally observed during the first 3–6 months of life
 - IgG levels should be at least 2 SD below the mean age-matched controls.
 - Typically recover by 9–15 months of age and have normal Ig levels by 2–4 years
 - Must be diagnosed in retrospect after immune recovery and patients should be followed with serial immunoglobulin levels.
 - Etiology remains unknown.

- Antibiotic prophylaxis and/or immunoglobulin replacement should be considered in those with severe recurrent infections.
- Disorders of immunoglobulin class-switch recombination (Ig-CSR)
 - CD40L mutation: X-linked hyper IgM syndrome (HIGM)
 - Also known as HIGM1
 - Estimated frequency of 1 in 500,000 live male births
 - Due to a mutation in the CD40 ligand gene
 - IgM may be elevated or normal. IgG, IgA, and IgE levels are low to absent.
 - Affects T cell priming and antigen-specific T cell responses, in addition to defective antibody production
 - Chronic diarrhea and failure to thrive are present.
 - In addition, can have opportunistic infections, particularly with *Pneumocystis*, *Cryptosporidium*, and *Histoplasma* organisms
 - May have lymphadenopathy and hepatosplenomegaly on exam
 - Treatment includes allogeneic hematopoietic cell transplantation.
 - Autosomal recessive hyper IgM syndromes (AR-HIGM)
 - Includes mutations in the following:
 - CD40 (HIGM3)
 - Activation-induced cytidine deaminase (AID) (HIGM2): the most common AR-HIGM, AD mutations in AID are also described
 - Uracyl-N-glycosylase (UNG) (HIGM5)
 - CD40 mutations present similarly to X-linked HIGM.
 - AID and UNG mutations have less incidence of opportunistic infections and neutropenia and are associated with lymph node hyperplasia.

Secondary Defects in Antibody Production

- Increased loss: Loss of protein can occur via the kidneys, intestinal tract, lymphatic system, or skin.
 - Protein-losing enteropathy
 - Intestinal lymphangiectasia can be congenital.
 - Post-Fontan procedures with resultant hypogammaglobulinemia
 - Nephrotic syndrome
- Decreased production

- Malignancy
 - ▢ Chronic lymphocytic leukemia
 - ▢ Lymphoma
 - ▢ Multiple myeloma
- Medications
 - ▢ Sulfasalazine
 - ▢ Systemic steroids
 - ▢ Phenytoin
 - ▢ Carbamazepine
 - ▢ Androgen replacement

TREATMENT

MEDICATION

- Appropriate antimicrobial therapy at first sign of infection. Prompt initiation of therapy is recommended.
- Select patients may benefit from prophylactic antibiotics.
- Regular replacement therapy with gammaglobulin in either IV or SC forms. Usually 300–600 mg/kg every 3–4 weeks IV or every 1–2 weeks SC.
- Trough levels of 700–800 mg/dL are now preferred compared to previous recommendations of >300 mg/dL.

ONGOING CARE

PATIENT MONITORING

Patients on immunoglobulin replacement should have trough IgG levels followed regularly as well as CBCs with differential and metabolic panels to look for hemolytic processes and side effects of replacement.

PROGNOSIS

In most cases (except transient hypogammaglobulinemia of infancy), it requires lifelong therapy.

CODES

ICD10

- D80.1 Nonfamilial hypogammaglobulinemia
- D80.0 Hereditary hypogammaglobulinemia
- D80.2 Selective deficiency of immunoglobulin A [IgA]

FAQ

- Q: When should I check immunoglobulin levels?
- A: Immunoglobulins and antibody responses to vaccinations may be considered in any patient with a history of recurrent sinopulmonary infections.
- Q: I have a 2-month-old male patient with a family history of XLA. His IgG level is normal. Do I need to recheck it in the future?
- A: At 2 months of age, most infants still have maternal IgG present. Levels tend to wane and the infant will start to produce his or her own IgG in the 3–4-month range. Rechecking after this time is recommended.

HYPOPHOSPHATEMIC DISORDERS

Erik A. Imel • Peter J. Tebben

BASICS

DESCRIPTION

Hypophosphatemia is defined by serum phosphorus values below the age-appropriate normal range.

ALERT

- Normal phosphorus concentrations in infants and children are significantly higher than in adults.
- Hypophosphatemia can be missed if an adult normal range is used for pediatric patients.

EPIDEMIOLOGY

Acute hypophosphatemia is a common laboratory finding in the hospital, especially in the intensive care unit (ICU) setting.

ETIOLOGY

- Chronic hypophosphatemia is a common etiology of rickets. It can result from multiple causes, including:
 - Vitamin D deficiency
 - Most common form of rickets
 - X-linked hypophosphatemic (XLH) rickets
 - Most common inherited cause of rickets (prevalence \approx 1 in 20,000)
 - Other genetic forms of rickets are less common.
- Isolated dietary phosphate deficiency is rare; dietary phosphate deficiency usually involves generalized malnutrition.

Genetics

Genetic forms are less common than acquired forms and occur due to mutations in:

- PHEX (XLH rickets)
- FGF23 (autosomal dominant hypophosphatemic rickets [ADHR])

- DMP1 (autosomal recessive hypophosphatemic rickets [ARHR])
- ENPP1 (ARHR, generalized arterial calcification of infancy [GACI])
- FAM20C (autosomal recessive hypophosphatemia, Raine syndrome)
- SCL34A3 (NPT2c, hereditary hypophosphatemic rickets with hypercalciuria [HHRH])
- CYP27B1 (1 α -hydroxylase deficiency)
- VDR (vitamin D receptor)
- GNAS (McCune-Albright syndrome, activating mutations of Gs α , sometimes associated with hypophosphatemia)
- Others

RISK FACTORS

- Nutritional
 - Vitamin D deficiency
 - Malnutrition/refeeding syndrome
 - Chronic diarrhea
- Medications affecting phosphate absorption
 - Antacids
 - Sevelamer
 - Lanthanum carbonate
 - Excess calcium salts
- Genetics
 - Primary renal phosphate wasting disorders (see “[Differential Diagnosis](#)”)
 - Vitamin D metabolism disorders
 - Renal Fanconi syndrome
- Other:
 - Medications affecting renal phosphate transport
 - Treatment of diabetic ketoacidosis
 - Acute respiratory alkalosis
 - Post renal transplant
 - Hungry bone syndrome after parathyroidectomy for hyperparathyroidism
 - Also causes hypocalcemia

PATHOPHYSIOLOGY

- Decreased nutritional intake or malabsorption
- Redistribution of extracellular phosphate into the intracellular compartment
- Increased renal phosphate loss (due to medications, hormonal effects, or primary renal tubulopathy)

DIAGNOSIS

HISTORY

- Family history of hypophosphatemia or rickets
- Medications
- Known disease affecting phosphate metabolism (see “[Differential Diagnosis](#)”)
- Nutritional history
 - Vitamin D intake, phosphate sources
 - Anorexia or other malnutrition
 - Parenteral or enteral nutrition formulation
- Duration of symptoms (acute vs. chronic)
- Dental abnormalities
 - Abscessed teeth associated with XLH
- Gastrointestinal symptoms
 - Chronic diarrhea
- Cardiovascular, respiratory, or neurologic symptoms (may accompany acute hypophosphatemia, usually in hospital setting)
- Myalgia or weakness
- Bowed legs, short stature
- Bone pain or stress fractures/pseudofractures
- Precocious puberty, café au lait macules, fibrous dysplasia—due to McCune-Albright syndrome

PHYSICAL EXAM

- Height, rate of growth
- Rachitic features
 - Frontal bossing
 - Delayed closure of fontanelle

- Rachitic rosary
- Harrison sulcus (groove corresponding to the rib insertion site of the diaphragm)
- Widened wrists or ankles
- Valgus, varus, or windswept deformity of the legs
- Dental abscess
- Muscle weakness
- Café au lait macules (McCune-Albright syndrome)

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Confirm laboratory diagnosis before treating (unless unstable).

- Serum phosphorus concentration—below age-appropriate normal range (ideally fasting)
- Normal ranges by age

– 0–1 month	4.8–8.2 mg/dL
– 1–4 month	4.8–8.1 mg/dL
– 4 months–1 year	4.8–6.8 mg/dL
– 1–5 years	3.6–6.5 mg/dL
– 5–10 years	3.4–5.5 mg/dL
– 10–20 years	2.6–5.2 mg/dL
– >20 years	2.5–4.9 mg/dL
- Serum calcium
 - Normal in most primary renal phosphate wasting disorders
 - Elevated in primary hyperparathyroidism
 - Low or low normal in vitamin D deficiency rickets
- Parathyroid hormone concentration
 - Can be elevated if chronic hypophosphatemia is due to vitamin D deficiency or to XLH (pre- or posttreatment). Elevations in parathyroid hormone (PTH) concurrent with hypercalcemia indicate primary hyperparathyroidism.
- Alkaline phosphatase
 - Elevated in rickets and many patients with hyperparathyroidism
- Serum creatinine

- 25-hydroxyvitamin D
 - Low in vitamin D deficiency rickets
- 1,25-dihydroxyvitamin D
 - Low in 1α -hydroxylase deficiency
 - Elevated in vitamin D receptor mutations and nutritional phosphate deficiency
 - Low or inappropriately normal in fibroblast growth factor 23 (FGF23)-mediated causes of hypophosphatemia
- Urine phosphorus and creatinine for assessment of tubular maximum phosphate reabsorption per glomerular filtration rate (TmP/GFR or TP/GFR)
 - Should be obtained at same time as serum phosphorus and creatinine
 - $TP/GFR = \text{serum phosphorus} - (\text{urine phosphorus} \times \text{serum creatinine} / \text{urine creatinine})$
 - Normal or high in vitamin D-mediated hypophosphatemia and nutritional deficiency
 - Low in renal phosphate wasting disorders
- FGF23 (a phosphaturic hormone)—may be helpful in renal phosphate wasting disorders
 - Elevated in many forms of inherited rickets (XLH, ADHR, ARHR)
 - Elevated in most patients with tumor-induced osteomalacia (TIO) due to FGF23-secreting tumors
 - Low in nutritional phosphate deficiency or malabsorption or Fanconi syndrome or HHRH

Imaging

- Radiographs to evaluate for signs of rickets
 - Knees and wrists
- Skeletal survey in patients suspected of fibrous dysplasia of bone
 - Bone scan is also very sensitive in evaluating for fibrous dysplasia.
- Rare: other imaging to identify TIO—these rare tumors can be very difficult to localize
 - PET/CT scan, MRI, CT, octreotide scan, whole body sestamibi scan

Diagnostic Procedures/Other

Genetic studies, when appropriate

DIFFERENTIAL DIAGNOSIS

- Nutritional- or absorption-related
 - Low phosphorus intake
 - Premature infants
 - Chronic diarrhea
 - Short bowel syndrome
 - Vitamin D deficiency
 - Nutritional, lack of sun exposure
 - 1α -hydroxylase deficiency
 - Vitamin D receptor mutation
 - Medications
 - Antacids
 - Sevelamer
 - Lanthanum carbonate
 - Excess calcium salts
- Redistribution of phosphate into the intracellular compartment
 - Insulin therapy for diabetic ketoacidosis
 - Acute respiratory alkalosis
 - Refeeding syndrome
 - Hungry bone syndrome (after parathyroidectomy for primary hyperparathyroidism)
- Increased renal phosphate loss
 - Medications (glucocorticoids, diuretics)
 - Primary hyperparathyroidism
 - FGF23-dependent (FGF23 excess)
 - XLH rickets
 - ADHR (may present after childhood with new-onset hypophosphatemia; consider ADHR if considering TIO)
 - ARHR
 - TIO (primarily diagnosed in adults, but cases reported in children)
 - Fibrous dysplasia of bone
 - Postrenal transplant phosphate wasting
 - FGF23-independent
 - Renal Fanconi syndrome

- Familial
- Medication-induced
- Associated with other disorders (cystinosis, multiple myeloma, and others)
- HHRH (rare—mutations impairing NPT2c)

TREATMENT

MEDICATION

- Acute
 - Oral phosphate supplementation preferred route
 - Intravenous phosphate should be used with caution:
 - High doses require central venous catheter.
 - Can cause severe hypocalcemia: Monitor calcium.
 - Telemetry recommended due to possible arrhythmias
 - Replete vitamin D if needed (this will not acutely increase serum phosphorus levels)
- Chronic
 - If dietary deficiency or malabsorption: oral phosphate and vitamin D repletion
 - If renal phosphate wasting due to an FGF23-mediated cause
 - Phosphate 20–40 mg/kg/day divided in 3–5 doses
 - Start therapy with low doses and then increase gradually to reduce risk of diarrhea.
 - Calcitriol 20–30 ng/kg/day in 2 divided doses (may require higher doses)
 - Non-FGF23-mediated renal phosphate wasting with elevated 1,25-dihydroxyvitamin D (HHRH)
 - Phosphate 20–40 mg/kg/day divided in 3–5 doses

ADDITIONAL TREATMENT

- Chronic hypophosphatemic disorders resulting in skeletal deformity (especially inherited causes) may require surgical intervention to correct valgus or varus deformities of the lower extremities.
 - Adequate medical therapy should be initiated first, as it may reduce

the need for surgical interventions.

- Routine dental care
 - Dental abscess common in some genetic forms of hypophosphatemia
- For the rare cases of TIO, complete surgical removal of the offending tumor is curative.

General Measures

- Routine dental care at least twice per year (especially for patients with inherited rickets)
- Audiology evaluation in patient with inherited hypophosphatemic rickets
 - Increased risk of hearing loss

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- For chronic hypophosphatemia
 - Frequent laboratory monitoring is mandatory if long-term phosphate and calcitriol therapy is needed (every 3–4 months)
 - Calcium
 - Phosphorus
 - Creatinine
 - Alkaline phosphatase
 - Parathyroid hormone
 - Urine calcium, creatinine, and phosphorus
 - The goal is NOT to normalize serum phosphate in chronic renal phosphate wasting disorders, as this may lead to secondary or tertiary hyperparathyroidism and/or nephrocalcinosis.
 - Periodic radiographic studies
 - Annual renal ultrasound to evaluate for nephrocalcinosis
 - Periodic x-ray of knees/wrists to evaluate response to treatment
 - Improvement in rachitic changes
 - Improvement in varus/valgus deformities

PROGNOSIS

- Hypophosphatemia due to nutritional deficiency
 - Hypophosphatemia resolves with adequate replacement of nutritional deficiencies or discontinuation of phosphate-binding agents.
- Acute hypophosphatemia (typically seen in the hospital setting) can be life-threatening and requires careful monitoring and treatment.
 - Hypophosphatemia resolves when the underlying condition is treated.
- Chronic renal phosphate wasting disorders have a variable response to treatment. Some have radiographic healing of rickets, correction of varus/valgus deformity, and normalization of alkaline phosphatase, whereas others have an incomplete response to therapy.
- Short stature is a common result of chronic hypophosphatemia.
- Hypophosphatemia resolves with removal of the offending tumor in patients with TIO, but long-term monitoring for recurrence is necessary, as hypophosphatemia may recur years later.

CODES

ICD10

- E83.39 Other disorders of phosphorus metabolism
- E72.09 Other disorders of amino-acid transport
- E83.31 Familial hypophosphatemia

FAQ

- Q: What is the most important complication of intravenous phosphate administration?
- A: Severe life-threatening hypocalcemia. Infusions of phosphate should be slow and monitored with telemetry.

- Q: Should I measure FGF23 concentrations?
- A: Generally, a diagnosis can be made without FGF23 measurement. FGF23 measurement is only useful if the TP/GFR is low.
- Q: What are dietary phosphate sources?
- A: Phosphate sources are ubiquitous; examples include processed meats, dairy, legumes, nuts, whole grains, citrus, and colas. Phosphates are used as a preservative in processed foods.

HYPOPLASTIC LEFT HEART SYNDROME

Laura Mercer-Rosa

BASICS

DESCRIPTION

Hypoplastic left heart syndrome (HLHS) is a continuum of congenital cardiac defects resulting from severe underdevelopment of the structures of the left side of the heart (left atrium, mitral valve, left ventricle, aortic valve, and ascending aorta).

EPIDEMIOLOGY

- 0.16–0.36 per 1,000 live births
- 8% of congenital heart disease (CHD); 3rd most common cause of critical CHD in the newborn
- 23% of all neonatal mortality from CHD
- Male predominance (67%)

RISK FACTORS

Genetics

- Familial inheritance: Sibling recurrence risk ranges from 8% to 21%, with higher recurrence observed when cardiovascular malformations are present in either parent. In addition, rare kinships have a frequency approaching autosomal dominant transmission.

COMMONLY ASSOCIATED CONDITIONS

- Increased mortality when associated with definable genetic disorders, which comprise 10–28% of HLHS patients:
 - Turner syndrome, Noonan syndrome, Smith-Lemli-Opitz syndrome, Holt-Oram syndrome
 - Trisomy 13, 18, 21, or microdeletion syndromes
- Major extracardiac anomalies (diaphragmatic hernia, omphalocele)

PATHOPHYSIOLOGY

- The etiology appears multifactorial, most likely resulting from an in utero reduction of left ventricular inflow or outflow (mechanisms

postulated include premature closure of the foramen ovale and fetal cardiomyopathy).

- As a result, the right ventricle (RV) must supply both the pulmonary and systemic circulations (via the ductus arteriosus) before and after birth.
- The reduction in pulmonary vascular resistance that occurs with lung expansion at birth reduces the proportion of RV output to the systemic circulation. If the ductus arteriosus closes, shock occurs.

DIAGNOSIS

HISTORY

- In the current era, HLHS is often diagnosed prenatally.
- Postnatal signs and symptoms:
 - Respiratory distress (tachypnea, grunting, flaring, retractions)
 - Cyanosis
 - Cardiovascular collapse and profound metabolic acidosis when the ductus arteriosus closes

PHYSICAL EXAM

- CHF secondary to pulmonary overcirculation (e.g., tachycardia, hepatomegaly, gallop)
- Normal S₁ and single S₂ (A₂ absent); a murmur of tricuspid regurgitation may be auscultated
- Varying degrees of cyanosis
- Decreased perfusion and weak peripheral pulses

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Chest radiograph: varying degree of cardiomegaly with increased pulmonary vascular markings (if the atrial septum is intact or highly restrictive, lungs will appear hazy with a pulmonary venous obstructive pattern)
- ECG: right axis deviation (+90 to +210 degrees), RV hypertrophy with a qR pattern in the right precordial leads, decreased left ventricular forces with an rS pattern in the left precordial leads

- Echocardiogram: varying degrees of hypoplasia or atresia of the mitral valve, left ventricle, aortic valve, ascending aorta, and aortic arch; patent ductus arteriosus with right-to-left shunt in systole and diastolic flow reversal; atrial septal defect with left-to-right flow
- Cardiac catheterization: no longer routinely performed; similar findings as with echocardiography

DIFFERENTIAL DIAGNOSIS

- Cardiac: Other causes of circulatory collapse in the neonate include critical aortic stenosis and coarctation of the aorta, cardiomyopathy (infectious, metabolic, or hypoxic), persistent supraventricular tachycardia, obstructive cardiac neoplasms, and large arteriovenous fistulae.
- Noncardiac: neonatal septicemia, respiratory distress syndrome, inborn errors of metabolism

TREATMENT

INITIAL STABILIZATION

During initial resuscitation and stabilization of a newly diagnosed infant:

- Prostaglandin E1 therapy should be initiated as soon as possible to maintain ductal patency.
- Avoid using oxygen despite low pulse oximetry saturation. Increasing FiO_2 will lower pulmonary vascular resistance, preferentially shunting cardiac output away from the systemic circulation toward the lungs, thereby worsening systemic perfusion.
- Should invasive ventilation be required, avoid hyperventilation.
 - Permissive hypercapnea is preferred due to the secondary increase in pulmonary vascular resistance and subsequent improvement in systemic perfusion.
 - Maintain mildly elevated PaCO_2 levels (40–50 mm Hg).

SUPPORTIVE CARE

- Although surgical intervention has become the medical standard, supportive measures are sometimes offered, especially when multiple noncardiac congenital anomalies exist or when severe multiorgan

system damage is present.

- The preoperative goal is to balance the systemic and pulmonary circulations provided by the RV to a Q_p/Q_s (ratio of pulmonary to systemic blood flow) of $\sim 1:1$, usually achieved with a pulse oximetry measurement of 75%.
- Prostaglandin E1 infusion: 0.05–0.1 mcg/kg/min
- Aggressive treatment of hypocalcemia with calcium boluses, avoidance of metabolic acidosis with fluid boluses, consider sodium bicarbonate
- 0.21 FiO_2 , goal PaO_2 of 35–40 mm Hg
- Careful use of small amounts of inotropic agents (in cases of sepsis or RV failure). Aggressive use of inotropic agents (alpha effect) may worsen systemic perfusion.

SURGERY/OTHER PROCEDURES

- Palliative surgery is generally performed in 3 stages:
 - Stage I Norwood palliation (performed in the first few days of life or soon after presentation): transection of the main pulmonary artery with anastomosis of the augmented aortic arch to the pulmonary valve stump to form a neo-aortic valve and arch, placement of an aorta-to-pulmonary artery shunt (modified Blalock-Taussig shunt), and often an atrial septectomy. The RV provides both systemic and pulmonary blood flows with postoperative saturations of $\sim 75\%$.
 - Stage I Sano modification: Developed in 2003 as an alternative to the Norwood procedure, the Sano modification replaces the modified Blalock-Taussig shunt with an RV to pulmonary artery conduit, with the RV continuing to supply both pulmonary and systemic circulations.
 - Hybrid procedure: An additional alternative to the Norwood procedure uses both median sternotomy (pulmonary artery banding) and interventional cardiac catheterization (PDA stenting) to provide both systemic and pulmonary blood flow while avoiding cardiopulmonary bypass.
 - Stage II/Hemi-Fontan or bidirectional Glenn (cavopulmonary anastomosis) procedure: involves anastomosis of the superior vena cava to the pulmonary artery, resulting in volume unloading of the RV. All prior shunts are usually removed. The oxygen saturations

after this procedure are usually 85–90%.

- Stage III/Modified Fontan procedure: baffling the inferior vena cava to the pulmonary artery with placement of a small fenestration in the baffle, permitting a small residual right-to-left shunt. The RV is now supplying only systemic blood flow. The oxygen saturations after this procedure are usually 90–95%.
- There are many surgical modifications to these 3 procedures. In addition, these procedures may be performed at different ages based on an institution's experience. Our approach has been to perform the hemi-Fontan operation at 4–6 months of age and the Fontan operation at 18 months to 2 years of age.
- Orthotopic heart transplantation may be performed either as an initial approach or after a stage I palliation.

FOLLOW-UP RECOMMENDATIONS

Admission Criteria

The admission for the first operation usually lasts for about 3–4 weeks after birth. Patients are watched to ensure stable oxygen saturation and weight gain. Nutritional needs often require nasogastric tube feed supplementation.

PROGNOSIS

- Fatal if untreated (95% mortality within the first month of life)
- Improved outcomes may result from early diagnosis and prevention of the presentation as neonatal shock.
- 90% early survival after stage I palliation if treated in a timely fashion at experienced institutions
- 5% mortality at stage II hemi-Fontan (bidirectional cavopulmonary anastomosis) procedure
- Recently, 1% mortality at Fontan operation (with the addition of a fenestration to allow right-to-left shunting)
- Excluding infants who die waiting for a donor organ, the 5-year actuarial survival for either staged palliation (Fontan) or heart transplantation is similar, ~75%.

COMPLICATIONS

Neonatal presentation:

- Circulatory collapse with resultant metabolic acidosis
- Multiorgan system failure (i.e., necrotizing enterocolitis, renal failure, liver failure, CNS injury)

Patient Monitoring

Interval evaluations should include careful consideration of growth parameters, cardiovascular symptoms, and developmental milestones. Examinations should focus on the presence or absence of cyanosis, edema, pleural effusions, diarrhea, ascites, and arrhythmias.

- For patients after staged palliation, frequent echocardiograms and intermittent cardiac catheterizations may be needed to assess for the following:
 - RV dysfunction
 - Residual or recurrent aortic arch obstruction
 - Branch pulmonary artery narrowing
 - Venous collateral formation causing increased cyanosis
 - Protein-losing enteropathy
 - Sinus node dysfunction
 - Atrial arrhythmias
- For patients treated alternatively with heart transplantation, other lifelong issues should be addressed:
 - Graft rejection and/or coronary vasculopathy
 - Infection
 - Hypertension
 - Lymphoproliferative disease
- Follow-up medications:
 - Lifelong subacute bacterial endocarditis (SBE) prophylaxis
 - Furosemide is generally administered until the hemi-Fontan.
 - Afterload reduction (i.e., angiotensin-converting enzyme inhibitors) may be used to reduce the workload on the heart at any stage.
 - Antiplatelet (aspirin) and anticoagulant (Coumadin) therapies are used by most physicians after stage 1 and later in the setting of the low-flow state of the cavopulmonary connection.
- For transplant patients, immunosuppressive regimens are managed differently according to institution preferences.

CODES

ICD10

- Q24.8 Other specified congenital malformations of heart

- Q96.9 Turner's syndrome, unspecified
- Q87.1 Congenital malform syndromes predominately associated with short stature

FAQ

- Q: What should the differential diagnosis include when an infant with HLHS who's undergone stage I palliation presents with cyanosis and respiratory distress?
- A: Modified Blalock-Taussig shunt thrombosis, anemia, intercurrent lower respiratory tract infection leading to V/Q mismatch, low cardiac output state, sepsis
- Infants with HLHS status post stage I palliation are solely dependent on the modified Blalock-Taussig shunt for pulmonary blood flow. This synthetic tube graft ranges from 3.5 to 4 mm in diameter and is prone to thrombosis, especially during periods of illness, which lead to dehydration (gastroenteritis), poor nutrition, or systemic inflammation.
- Q: Should there be a specific concern if a patient with HLHS who's completed the 3-stage palliation with Fontan procedure presents with complaints of unremitting diarrhea, crampy abdominal pain, ascites, and peripheral edema?
- A: Yes. Protein-losing enteropathy (PLE) is a poorly understood disease process affecting patients with single ventricle after Fontan operation associated with significant morbidity and mortality. PLE is defined as the abnormal loss of serum proteins into the lumen of the gastrointestinal tract and occurs in up to 11% of patients after Fontan palliation. Diuretic therapy and nutritional supplementation are often insufficient management strategies, often requiring the addition of somatostatic analogs (octreotide), sildenafil, and/or the creation of a fenestration in the Fontan circuit to palliate potentially elevated Fontan pressures.

HYPOSPADIAS

Natasha Gupta • Ming-Hsien Wang

BASICS

DESCRIPTION

Hypospadias is one of the most common congenital anomalies of the male external genitalia. It is characterized by a urethral meatus that opens proximally on the ventral surface of the penis or in the scrotum or perineum instead of at the tip of the glans. Classification is based on the position of the external meatus relative to the penile shaft or surrounding structures (distal, middle, proximal). Although the ventral foreskin is incomplete in the vast majority of cases, the megameatus variant is characterized by an intact foreskin.

EPIDEMIOLOGY

- 1/200–1/300 live male births
- Concordance rates among twins: 18–77%
- Megameatus variant: 5% of cases
- Incidence is likely not increasing over time. Although there have been some data suggesting an increasing incidence over time, the majority of published studies in the U.S. population indicate a stable incidence.

RISK FACTORS

- In vitro fertilization
- Maternal exposures to substances such as pesticides, hormones, phthalates, and phytoestrogens that can act as endocrine disruptors during penile development
- Associated with maternal preexisting diabetes mellitus, placental insufficiency, and low birth weight
- More common among Caucasians

Genetics

- Likely polygenic
- Familial clustering: 7% of affected boys have an affected 1st- or 2nd-degree relative.

- Equally maternally and paternally transmitted
- Associated with genetic mutations in several genes involved in the androgen pathway and external genitalia development, including homeobox, fibroblast growth factor, and sonic hedgehog genes

ETIOLOGY

- Due to incomplete fusion of the urethral folds during penile development, which is an androgen-driven process that occurs during weeks 8–16 of gestation
- Likely multifactorial with environmental and genetic interplay
- Defects in urethral development are usually accompanied by foreskin developmental defects (an incomplete ventral foreskin and dorsal hooded foreskin), except in the megameatus variant

COMMONLY ASSOCIATED CONDITIONS

- Usually idiopathic and isolated
- Less commonly associated with some chromosomal abnormalities and ~200 syndromes, including disorders of sexual differentiation (DSD)
- Hypospadias, particularly proximal hypospadias, can be associated with an increased risk of other genitourinary (GU) malformations.
- The most commonly associated GU malformations include the following:
 - Chordee
 - Cryptorchidism
 - Inguinal hernia

DIAGNOSIS

HISTORY

- Important to inquire about the following:
 - Family history of hypospadias, congenital anomalies, or genetic disorders
 - Patient history of genetic disorder and/or DSD
 - GU symptoms
 - Maternal history of fertility treatments
 - Maternal exposures during pregnancy

- Birth history
- For older patients
 - Painful erections
 - Infertility or difficulties with intercourse
 - Difficulty urinating while standing
 - Deflected urinary stream

PHYSICAL EXAM

- Assess for hypospadias in all male newborns with complete GU exam, paying particular attention to the following:
 - Any sign of incompletely formed foreskin or dorsal hooded foreskin
 - Any phallus curvature
 - Location of the meatus
 - Presence of rugated scrotum
 - Impalpable testes

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- No tests are needed for isolated hypospadias.
- If testes are impalpable bilaterally with proximal hypospadias, consider workup for DSD.
- Additional workup for DSD as needed based on level of concern

Imaging

- Not usually indicated
- Renal ultrasound or voiding cystourethrogram in cases of proximal hypospadias
- Ultrasound of urinary tract and internal genitalia if hypospadias is present in conjunction with cryptorchidism or nonpalpable testicle(s)

DIFFERENTIAL DIAGNOSIS

DSD such as congenital adrenal hyperplasia or partial androgen insensitivity syndrome

TREATMENT

GENERAL MEASURES

- Preferably refer to pediatric urologist within the first few weeks of life.
- Preoperative stimulation with parenteral testosterone may be required to increase penis size in cases of micropenis to improve surgical outcomes.
- Cases of mild, distal hypospadias may be observed.

ALERT

- For newborn circumcision, retract the foreskin (megameatus variant requires foreskin retraction for detection). If any abnormalities noted, abort the circumcision and refer to a pediatric urologist.
- In cases of hypospadias, circumcision is absolutely contraindicated because foreskin is used in hypospadias repair.
- Bilateral impalpable testes and hypospadias during newborn period must be worked-up to rule out DSD.

SURGERY/OTHER PROCEDURES

- Surgical repair
 - Outpatient procedure
 - May be accompanied by chordee repair if needed
 - Performed at age 6 months–1 year to minimize psychological trauma of surgery
 - Complex cases may require staged repair, with stage 1 generally performed at 6 months of age and stage 2 at 1 year of age.
 - Perioperative care may include the following:
 - Antibiotics (no standard course duration)
 - Pain management (generally with a caudal nerve block and acetaminophen with opioid analgesic or ketorolac as needed)
 - Type of repair performed is based on patient's anatomy.
 - Some types of repair may involve temporary urethral stent placement.
- Types of repair include the following:
 - Urethromeatoplasty
 - Meatal advancement and glanuloplasty (MAGPI)
 - Meatal inverted V flap
 - Sleeve technique
 - Flip-flap technique (local flap)

- Adjacent tissue transfer
- Glans approximation procedure
- Thiersch-Duplay
- Transverse incised plate or Snodgrass procedure
- Most common complications include the following:
 - Urethrocutaneous fistula
 - Urethral diverticulum
 - Urethral or meatal stenosis
 - Dehiscence

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Surgical dressings are variable and surgeon dependent.
- Postoperative clinic visit (surgeon-dependent)
- If urethral stent is placed, removal usually occurs on postoperative days 5–14 at clinic visit.
- Antibiotics may be continued postoperatively.

PROGNOSIS

Success rate is generally high, although dependent on the type of repair, degree of hypospadias, and patient's overall medical condition.

CODES

ICD10

- Q54.9 Hypospadias, unspecified
- Q54.1 Hypospadias, penile
- Q54.3 Hypospadias, perineal

FAQ

- Q: Does the patient with hypospadias routinely have other urinary tract abnormalities?
- A: No. Hypospadias is usually an isolated anomaly, and most patients have no other anatomic problems.
- Q: Should a newborn circumcision be performed if there are concerns with the meatal opening?
- A: Circumcision should be delayed, and the patient should be evaluated by a pediatric urologist.
- Q: Are there any medical alternatives to surgical repair?
- A: No. Surgery is the only treatment of hypospadias, but very mild cases may not warrant surgical repair.

HYPOTHYROIDISM, CONGENITAL

Adda Grimberg

For issues related to acquired hypothyroidism, please see the separate chapter on [page 16](#).

BASICS

DESCRIPTION

Primary thyroid failure present at birth

EPIDEMIOLOGY

- Increasing trend in the United States
 - Unclear etiology (definitional issues related to newborn screening vs. true increase from unidentified risk factors)
 - Had been 1 in 3,000–4,000 births, United States and worldwide
 - In 2007, U.S. incidence 1 in 2,370 births
- Male-to-female ratio is 1:2–1:3.
- 80% dysgenesis or agenesis; 20% dyshormonogenesis
- Racial differences: prevalence in African American infants ~1/3 that in whites
- Higher prevalence of congenital hypothyroidism in low-birth-weight (<2,000 g) and macrosomic ($\geq 4,500$ g) babies

RISK FACTORS

Genetics

- Dysgenesis is usually sporadic.
 - Familial occurrence in 2%
 - Mutations have been found in the TSH-receptor gene and in the transcription factors PAX-8, TTF-1, and TTF-2 (FOXE1).
- Dyshormonogenesis is inherited in an autosomal recessive pattern.
Most commonly
 - Chromosome 2p: Mutations in the thyroid peroxidase gene result in partial or complete loss of iodide organification.
 - Chromosome 19p: Mutations in the sodium-iodide symporter gene

result in an inability to maintain the normal thyroid-to-plasma iodine concentration difference.

- Pendred syndrome (chromosome 7q): Mutations in PDS gene cause the most common syndromal form of deafness; a mild organification defect leads to goiter, usually in childhood.

ETIOLOGY

- Thyroid gland malformation
 - Agenesis: absent thyroid gland
 - Dysgenesis: ectopic (e.g., sublingual) or incorrectly formed (e.g., hemigland) thyroid
- Dyshormonogenesis
 - 15 known defects of thyroxine (T_4) synthesis, including those in iodide transport and iodide organification
- Transient hypothyroidism
 - Maternal ingestion of antithyroid drugs
 - Transplacental transfer of maternal antithyroid antibodies (transient or permanent damage)
 - Exposure to high levels of iodine-povidone, (i.e., Pyodine, Betadine) in neonatal period

COMMONLY ASSOCIATED CONDITIONS

- Down syndrome neonates have lower T_4 (left-shifted normal distribution) and mildly elevated TSH, suggesting a mild hypothyroid state.
- Newborns with congenital hypothyroidism have an increased risk for congenital heart defects, and vice versa (common embryologic developmental program).

DIAGNOSIS

HISTORY

- Symptoms that may relate to hypothyroidism:
 - Prolonged jaundice
 - Poor feeding
 - Constipation

- Sedate or placid child
- Poor linear growth
- Family history of thyroid disorders
 - Autoimmune thyroid disease
 - Vague histories of “mild hypothyroidism” not requiring treatment are often found in families with thyroid-binding globulin deficiency.
- Maternal medications
- Birth history
- Results of the newborn screen
- Signs and symptoms:
 - Most children are diagnosed by the neonatal screening program:
 - 5–10% false-negative rate
 - Neonatal screening protocols differ state to state (i.e., may screen TSH, T₄, or both).
 - In severely ill neonates transferred from 1 unit or hospital to another, be sure the state screen has been performed and not overlooked. If missed by the state screening procedure, the symptoms above are seen within the 1st 2 months of life.

PHYSICAL EXAM

- Signs that may relate to hypothyroidism:
 - Hypothermia
 - Large fontanelles (especially posterior) with wide cranial sutures
 - Coarse facial features, including macroglossia
 - Hoarse cry
 - Hypotonia
 - Delayed deep tendon reflex release
 - Distended abdomen
 - Umbilical hernia
- Examine for possible goiter; helpful pearls
 - Inspect the base of tongue for ectopic gland.
 - While supporting the posterior neck and occiput, allow the infant’s head to hang back over a parent’s arm or exam table. This will extend the neck and allow better visualization of the anterior region.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Neonatal screening program (filter card)
 - Methods vary from state to state (screen for T_4 or TSH); primary TSH screening plus serial testing for infants at risk for later rising TSH shown to outperform other strategies.
 - Abnormal results on state screen should prompt immediate examination and confirmatory tests.
 - Because of delayed TSH elevations, very low-birth-weight babies and those with congenital cardiac anomalies may need rescreening for diagnosis.
- Confirmatory tests:
 - Serum T_4 and TSH are preferable to a repeated filter screen, which may result in delayed diagnosis and treatment.
 - If abnormalities in binding are suspected, also check thyroid-binding globulin level and free T_4 concentration or triiodothyronine (T_3) resin uptake.
 - Free T_4 is the most sensitive indicator of secondary or tertiary hypothyroidism (hypopituitarism).
- Antenatal tests
 - Fetal goiter can be detected by prenatal ultrasound.
- Reference ranges for 3rd trimester amniotic fluid concentrations of TSH and total and free T_4 are established for diagnosis of fetal hypothyroidism among those with goiters. Otherwise, cordocentesis is needed.

Imaging

- ^{123}I or technetium thyroid scan to define gland anatomy (agenesis, dysgenesis, ectopic gland)
- ^{123}I scan with perchlorate washout to help identify dysmorphogenesis
- ^{123}I scan must be obtained before beginning thyroxine replacement therapy. If this delays treatment, defer scanning until brain growth is complete (2 years of age), when a period off medication is safer.
- Ultrasonography can also evaluate thyroid anatomy (but not dysmorphogenesis) and does not require deferral of treatment.

DIFFERENTIAL DIAGNOSIS

- Developmental
 - Transient hypothyroxinemia in the 1st weeks of life in premature babies
- Metabolic
 - Sick euthyroid syndrome in severely ill neonates
- Secondary or tertiary
 - Panhypopituitarism
 - Congenital isolated central hypothyroidism (a “hot spot” mutation in the TSH- β gene)
 - Central congenital hypothyroidism due to maternal Graves disease during pregnancy (estimated incidence 1:35,000; thought to indicate impaired maturation of the fetal hypothalamic–pituitary–thyroid system from a hyperthyroid fetal environment)
- Genetic
 - Thyroid-binding globulin deficiency (X-linked recessive)
- Environmental
 - Iodine exposure (e.g., delivery by cesarean section, surgery in the neonatal period)
 - Maternal iodine deficiency (American Thyroid Association recommends pregnant and lactating women to take prenatal vitamins containing 150 mcg of iodine daily.)
 - Maternal use of antithyroid drugs or lithium
- Immunologic
 - Transfer of maternal antithyroid and TSH receptor–blocking antibodies

ALERT

False positives

- X-linked thyroid-binding globulin deficiency: low total T_4 , normal TSH, and normal free T_4 . Diagnose with low thyroid-binding globulin level or high T_3 resin uptake. No treatment is necessary!
- Panhypopituitarism: low T_4 and low or low-normal TSH (i.e., loss of the negative feedback loop). Screen with free T_4 . Treat with L-thyroxine as for primary hypothyroidism, and investigate for other pituitary hormone deficiencies.

- Blood specimens obtained before 48 hours of life may have “elevated” TSH as a result of the normal postnatal surge.

False negatives

- Normal newborn screening can be falsely reassuring in babies with congenital central hypothyroidism.

TREATMENT

MEDICATION

Levothyroxine

- Start at 10–15 mcg/kg/24 hr PO once a day. Titer dose to keep T_4 in the upper range of normal.
- TSH levels may not normalize for several weeks even with good T_4 values.
- Starting dose of 50 mcg PO daily (12–17 mcg/kg/24 hr) may provide more rapid normalization (free T_4 by 3 days and TSH by 2 weeks).
- A minority of infants have variable pituitary–thyroid hormone resistance, with relatively elevated serum levels of TSH for their free T_4 that improves with age.
- Duration: lifelong
 - If medication is started without imaging studies and diagnosis is not clear, can stop levothyroxine after completion of early brain growth (2–3 years of age). Reevaluate need for supplementation after a 6-week trial off therapy.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- When to expect improvement:
 - Most children are asymptomatic at diagnosis.
 - Parents may note an increase in activity, improvement in feeding, and increase in urination and bowel movements soon after starting treatment.
- Signs to watch for: Poor growth and low T_4 and elevated TSH values

suggest poor compliance or undertreatment.

- Neuropsychological sequelae:
 - IQ scores are predominantly in the normal range, but subtle impairments in language and motor skills and specific learning disabilities may occur despite early treatment.
 - Neurocognitive evaluation and rehabilitation should be provided.
 - Maternal hypothyroxinemia during early gestation can lead to neurodevelopmental delays if not corrected during pregnancy.

DIET

- No restrictions
- Soybean flour (as in some formulas) and iron can decrease gastrointestinal absorption of levothyroxine.
- Pharmacies in recent years have been recommending that levothyroxine be administered on an empty stomach. The Drugs and Therapeutics Committee of the Pediatric Endocrine Society recommended that consistency in administration, coupled with regular dose titration to thyroid function tests, is more important than improving absorption by restricting intake to only times of empty stomach.

PATIENT EDUCATION

- Whether the child has learning disabilities related to hypothyroidism depends on when the diagnosis was made and how quickly treatment was started. There may be an increase in learning disabilities when compared with siblings, even in patients treated within the 1st 4 weeks of life.
- If a dose of levothyroxine is forgotten, it should be given as soon as it is remembered. If it is the next day, 2 doses should be given.
- Levothyroxine is available only in tablet form. The tablet should be crushed between 2 spoons and the powder dissolved in a small amount of formula or breast milk and offered to the baby at the start of a feeding to ensure complete ingestion.
- There are no side effects from the medication. The tablet contains only the hormone that the child's thyroid is not making. It is synthetically produced, so there are no infectious risks.

PROGNOSIS

- Excellent, if treatment is started within the 1st 2 weeks of life
- Level of T₄ at birth is an important indicator of long-term sequelae.

COMPLICATIONS

- If untreated:
 - Severe mental retardation (cretinism)
 - Poor motor development
 - Poor growth
- Children with hypothyroidism as part of hypopituitarism do not seem to be as significantly affected by their low thyroid hormone levels as do those with primary hypothyroidism.

CODES

ICD10

- E03.1 Congenital hypothyroidism without goiter
- E03.0 Congenital hypothyroidism with diffuse goiter

FAQ

- Q: What are some of the reasons that a normal newborn may have an abnormal thyroid screen?
- A: Blood tests obtained prior to 48 hours of age may have an elevated TSH from newborn surge; some states (for quality control) will ask to have a certain percentage of tests repeated, even though they are normal.

IDIOPATHIC INTRACRANIAL HYPERTENSION (PSEUDOTUMOR CEREBRI)

Daphne M. Hasbani • Sabrina E. Smith

BASICS

DESCRIPTION

Diagnostic criteria of idiopathic intracranial hypertension (IIH) include the following:

- Signs and symptoms of increased intracranial pressure (e.g., headache, vomiting, ocular manifestations, and papilledema)
- Elevated cerebrocranial fluid pressure but otherwise normal CSF
- Normal neurologic exam except for papilledema (occasional abducens or other motor cranial neuropathy)
- Normal neuroimaging study (or incidental findings only)

EPIDEMIOLOGY

- Boys and girls are affected equally in childhood; in adulthood, more women than men are affected.
- IIH has been reported in patients as young as 4 months of age, with a median age of 9 years.

Incidence

Estimated to be 0.5/100,000 cases/year for children younger than 18 years old

RISK FACTORS

Genetics

Sporadic, no clear genetic predisposition, unless related to an underlying hormonal, toxic, or inflammatory condition; no data are available in children.

PATHOPHYSIOLOGY

Pathogenesis unknown but may involve decreased CSF absorption owing

to arachnoid villi dysfunction or elevated intracranial venous pressure. For example, obesity may lead to increased intra-abdominal, intrathoracic, and cardiac filling pressure, leading to elevated intracranial venous pressure.

ETIOLOGY

- Numerous precipitants of IIH have been reported. In adolescents, it is clearly associated with obesity and weight gain but not clearly linked to obesity in children <11 years of age. Many weaker associations may be due to chance.
- IIH is often linked to minocycline, tetracycline, sulfonamides, isotretinoin, and thyroid replacements and to corticosteroid withdrawal. It is also linked to vitamin A deficiency or intoxication, chronic anemia, and hypothyroidism.

COMMONLY ASSOCIATED CONDITIONS

- Visual loss due to optic nerve pressure
- Endocrinopathies, exogenous steroids, lead exposure, and therapy involving tetracycline and several other antibiotics may be associated with IIH.

DIAGNOSIS

HISTORY

- Headache
- Blurred vision
- Transient visual darkening
- Stiff neck
- Pulsatile tinnitus
- Dizziness
- Infants and young children may present with irritability, somnolence, or ataxia.
- IIH should be considered in any child with chronic headache or unexplained visual changes.
- Directed history for signs of associated endocrinopathy, exposure to antibiotics or steroids, sinus infection, abnormal clotting, or familial tendency for thrombosis or visual disturbance

PHYSICAL EXAM

- Examination of the fundi is essential.
- Recording baseline visual acuity and visual fields in older children is essential.
- Papilledema is almost always present in older children with IIH.
- Most infants have some degree of papilledema, even with open fontanelles and split sutures.
- 6th cranial nerve (abducens) palsies are common in children with IIH; they were found in 29 of 68 patients in 1 series.
- Facial or other cranial nerve deficits rare

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CSF exam including opening pressure; cell count, glucose, and protein are essential and should be normal in IIH.
- CBC and thyroid function tests should be obtained because anemia, hypothyroidism, and hyperthyroidism have rarely been associated with IIH.
- The following may be useful in selected cases:
 - ANA test
 - ESR
 - Urine cortisol
 - Serum lead level
 - Serologic testing for Lyme disease

Imaging

Cranial CT or MRI should be normal. MRI is recommended because of superior imaging of brainstem, posterior fossa, and venous sinuses.

Magnetic resonance venography is strongly suggested to evaluate for venous sinus thrombosis, which can be difficult to distinguish from IIH.

Diagnostic Procedures/Other

- Lumbar puncture manometry, with the patient in a relaxed lateral decubitus position, should show an opening pressure >280 mm H₂O.
- Goldmann perimeter visual field testing or computerized visual fields are useful in children >5 years of age to document field deficits and monitor response to therapy.

DIFFERENTIAL DIAGNOSIS

Some conditions may cause increased intracranial pressure and be confused with IIH, but the clinical picture and CSF analysis usually permit their distinction.

- Chronic meningitis (e.g., CNS Lyme disease), encephalitis, or cerebral edema (may show minimal changes on neuroimaging with elevated CSF protein levels and little evidence of pleocytosis)
- Cerebral venous sinus thrombosis
- Chronic headache (common) with pseudopapilledema (optic nerve disc drusen)

TREATMENT

MEDICATION

First Line

- For patients with mild to moderate visual loss, acetazolamide, a carbonic anhydrase inhibitor that decreases CSF production, is the drug of choice.
 - The pediatric dosage is 25–100 mg/kg/24 h divided b.i.d.–q.i.d. for the standard form and b.i.d. for the long-acting form (Diamox sequels).
 - The initial adult dose is 250 mg q.i.d. or 500 mg b.i.d., increased to 750 mg q.i.d. or 1,500 mg b.i.d. if tolerated.
- If visual loss, papilledema, and symptoms of pressure resolve, acetazolamide dosage can be tapered after 2 months of therapy.

Second Line

Furosemide can be used if acetazolamide is ineffective or has intolerable adverse effects.

ISSUES FOR REFERRAL

Follow-up and tapering of acetazolamide should be done in conjunction with a neurologist or neuro-ophthalmologist.

SURGERY/OTHER PROCEDURES

- Serial lumbar punctures are not recommended as standard therapy,

although the initial puncture can be useful to relieve symptoms quickly.

- Surgical therapy (e.g., optic nerve sheath fenestration, lumboperitoneal shunt) is indicated for progressive visual loss despite medical therapy and may also be considered as an urgent intervention at presentation depending on degree of visual loss. Optic nerve sheath fenestration may be the preferred surgical treatment, especially in children, because of the high failure rates of lumboperitoneal shunting. High-dose IV steroids and acetazolamide therapy may be used while awaiting surgical therapy.
- Recent studies of stenting in adults with transverse sinus stenosis and a pressure gradient on angiography demonstrated some improvement in visual symptoms and papilledema with variable effects on headache. However, this intervention is controversial and may not be technically feasible in children because of the smaller caliber of their vasculature.

INPATIENT CONSIDERATIONS

Initial Stabilization

- The urgency of diagnosis and treatment depends on the severity of visual loss. Recent reports suggest that severe visual loss may progress rapidly, warranting close initial (weekly) tracking of vision and prompt consideration of surgical treatment (see below).
- For patients with no visual loss, removal of possible causative agents may be the only intervention needed, along with treatment of associated conditions (e.g., obesity, anemia, thyroid disease). Consider treatment with acetazolamide (Diamox; see later comment). Headache can be treated symptomatically if needed.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Initially, patients should have visual acuity, visual fields, and fundi evaluated weekly or biweekly.
- If vision is stable, monthly visits may be adequate for 3–6 months.

- More frequent follow-up is required for any signs of progressive visual loss.
- IIH can recur. In one pediatric series, nearly 1/4 of patients had recurrence.
- Pitfalls: Children are not exempt from permanent visual loss as a consequence of IIH. Ophthalmologic follow-up is important. Occasional patients, especially adolescents, may experience headache weeks or months after resolution of objective signs of IIH (i.e., even though intracranial pressure has returned to normal).
- IIH may be diagnosed erroneously if
 - Pseudopapilledema is mistaken for papilledema. (Pseudopapilledema is apparent optic disc swelling that simulates papilledema but is usually secondary to an underlying benign process. It can be differentiated by an experienced ophthalmologist or neurologist.)
 - CSF abnormalities (i.e., isolated increase in protein) are overlooked.
 - Clinician fails to identify underlying cerebral venous sinus thrombosis.

FAQ

- Q: What are the side effects of acetazolamide?
- A: Side effects of acetazolamide include GI upset, paresthesias, loss of appetite, drowsiness, metabolic acidosis, and renal stones. An alternative is furosemide.
- Q: If IIH occurs on tetracycline, can the patient take penicillin?
- A: Penicillins/cephalosporins have not been reported as a significant cause of IIH.
- Q: Are there any limitations on physical activity?
- A: Activity can be graded entirely according to the child's symptoms.

IDIOPATHIC THROMBOCYTOPENIC PURPURA

Charles Bailey

BASICS

DESCRIPTION

- Idiopathic or immune thrombocytopenic purpura (ITP) is an autoimmune syndrome characterized by the following:
 - Isolated thrombocytopenia (platelet count formally $<100,000/\text{mm}^3$, typically $<20,000/\text{mm}^3$)
 - Shortened platelet survival
 - Platelet autoantibodies
 - Increased number of megakaryocytes in the bone marrow
- Primary ITP implies absence of other causes for thrombocytopenia; secondary ITP indicates another diagnosis associated with autoimmune thrombocytopenia.
- Phases of ITP
 - Newly diagnosed (acute) ITP: within 3 months of initial diagnosis
 - Persistent ITP: transient improvement or continued thrombocytopenia for 3–12 months
 - Chronic ITP: persistent thrombocytopenia >12 months after initial presentation

EPIDEMIOLOGY

- Most common acquired platelet disorder in childhood
- Often follows viral syndrome by a few weeks; this may be associated with higher likelihood of spontaneous recovery.
- Males and females are equally affected in childhood ITP (mild male predominance in younger children; female-to-male ratio is 3:1 in adult and chronic ITP).
- Median age at diagnosis is 4 years. Children <1 year or >10 years are more likely to develop chronic ITP.
- $>70\%$ of childhood ITP resolves within 6–12 months.

- Risk of severe bleeding is <5% and of intracranial bleeding is ~0.5%.

Incidence

Incidence is 1–10/100,000 children per year (<15 years of age).

PATHOPHYSIOLOGY

- Thrombocytopenia due to increased destruction of antibody-coated platelets in the reticuloendothelial system, particularly the spleen
- Hypothesized that antibodies generated in response to foreign antigen or drug cross-react with platelet membrane glycoproteins (most commonly IIb/IIIa and Ib/IX)
- Other mechanisms of immune dysregulation have been implicated, including possible inhibition of thrombocytopoiesis, limiting ability to compensate for destruction.
- Typical bone marrow aspirate shows increased numbers of immature megakaryocytes.

COMMONLY ASSOCIATED CONDITIONS

- In younger children, primary ITP is the most common presentation of ITP.
- Secondary ITP is seen with autoimmune disorders (e.g., systemic lupus erythematosus [SLE], autoimmune lymphoproliferative syndrome [ALPS]).
- HIV

DIAGNOSIS

HISTORY

- Presents with unusual bruising (with minor or no trauma, or in uncommon locations such as torso, neck, face), petechiae, epistaxis, prolonged bleeding with minor trauma, gingival bleeding, hematuria, or hematochezia
- Acute onset in an otherwise well child
- Not associated with pallor, fatigue, weight loss, or persistent fevers
- A majority of cases are preceded by a viral infection 1–3 weeks before onset (particularly varicella; also Epstein-Barr virus, cytomegalovirus).

- Associated with recent MMR in younger children; possibly hepatitis A vaccine, Tdap in older children
- Ascertain history of other autoimmune diseases (e.g., rheumatologic disorders, thyroid disease, hemolytic anemia).
- Obtain medication history, focusing on drugs with antiplatelet effects or associated with thrombocytopenia (e.g., valproate, heparin).
- Family history is usually negative for bleeding disorders. Ask about family autoimmune disease.
- Screen for bleeding, headache, abdominal or back pain, and any focal neurologic change.

PHYSICAL EXAM

- Clusters of petechiae or large or purple bruises readily apparent on skin or mucosae
- Hematomas or persistent slow bleeding on mucosal surfaces or from minor trauma
- Absence of lymphadenopathy (LAD), hepatosplenomegaly (HSM), masses, bone pain
- Screen for nonobvious bleeding (neurologic and funduscopic exam, abdominal or muscular tenderness); these events are rare.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Thrombocytopenia (typically $<20,000/\text{mm}^3$) with normal WBC and hemoglobin (or mild anemia in proportion to amount of blood loss)
- Mean platelet volume may be increased.
- Peripheral blood smear will be otherwise normal, with no red cell fragmentation, no spherocytes, and no blasts. Review also rules out pseudothrombocytopenia from platelet aggregation.
- Prothrombin time/INR and partial thromboplastin time are normal. Bleeding time will be prolonged, but testing is unnecessary.
- Direct antiglobulin (Coombs) test to exclude coexisting autoimmune hemolysis (Evans syndrome)
- Limited role for antinuclear antibody (ANA) and other immunologic tests in subset of patients at higher risk for other autoimmune disease
- HIV testing if risk factors are identified

- Bone marrow aspirate is needed only if unexplained anemia, abnormal WBC, blasts on peripheral smear, organomegaly, jaundice, or lymphadenopathy is present. It is safe to perform with a low platelet count.
- There is controversy over whether to obtain a marrow aspirate before giving corticosteroids and little evidence to support it.
- Marrow shows normal to increased numbers of megakaryocytes with otherwise normal morphology and cellularity.
- Assays for platelet-associated antibodies (either direct or indirect) are not sensitive and are not routinely indicated.
- Demonstration of platelet-associated IgG may be useful in more complicated patients in whom chronic ITP is a possible diagnosis.

Imaging

As indicated by symptoms, particularly abdominal pain, headache, vision, or focal neurologic change

DIFFERENTIAL DIAGNOSIS

- Consider malignancy if persistent fever, weight loss, adenopathy, bone pain, or organomegaly is present (mild splenomegaly seen in 5–10% of patients with ITP).
- Other destructive thrombocytopenias
 - Secondary ITP: infection, drug induced, posttransfusion purpura, autoimmune hemolytic anemia (when coexistent with ITP is called Evans syndrome), lymphoproliferative disorders, SLE
 - Nonimmunologic: microangiopathic hemolytic anemia (including TTP, HUS), disseminated intravascular coagulation (DIC), Kasabach-Merritt syndrome (hemangioma), cardiac defects (left ventricular outflow obstruction, prosthetic heart valves), malignant hypertension
- Impaired or ineffective production
 - Marrow-infiltrative processes (leukemias, other tumor metastases, myelofibrosis, osteopetrosis, storage diseases)
 - Drug- or radiation-induced thrombocytopenia or aplastic anemia, nutritional deficiency states (iron, folate, vitamin B₁₂)
 - Infection-associated suppression: typically viral (e.g., hepatitis,

Epstein-Barr virus, HIV, parvovirus B19), also severe or neonatal sepsis

- Congenital disorders: thrombocytopenia absent radii (TAR) syndrome, dyskeratosis congenita, Fanconi anemia, trisomies 13 and 18, Bernard-Soulier syndrome, Wiskott-Aldrich syndrome, May-Hegglin anomaly, other inherited thrombocytopenias (X linked or autosomal dominant), metabolic disorders (e.g., methylmalonic acidemia)

TREATMENT

- Because severe hemorrhage is rare and ITP resolves spontaneously in 90% of pediatric cases, most patients without severe bleeding will not require treatment.
- Treatment slows antibody-mediated platelet clearance and raises platelet counts acutely but does not alter the long-term course.
- Patients with a platelet count $<10,000/\text{mm}^3$ are at higher risk for bleeding, but platelet count alone is not an indication for treatment.
- Active toddlers or children at risk for trauma may require treatment when platelet count is $<20,000\text{--}30,000/\text{mm}^3$.
- Observation alone is acceptable for older children without serious bleeding and with adequate supervision and assured follow-up; may be preferable to repeated treatment in clinically well children with chronic ITP

MEDICATION

First Line

- IVIG: 94–97% will have an increase in platelet count $>20,000/\text{mm}^3$ by 72 hours. The usual dose is 0.8–1 g/kg. Response typically peaks after 1 week and lasts 3–4 weeks.
 - Advantages: faster time to platelet increase (24 hours), helps confirm diagnosis
 - Disadvantages: high cost, long infusion time, allergic reactions; 10–30% have evidence of aseptic meningitis with severe headache and stiff neck; headache, nausea, vomiting, or fever more common

- Scheduled acetaminophen and diphenhydramine for 24 hours after infusion may reduce acute side effects.
- Subcutaneous administration has been used successfully as an alternative to IV.
- Corticosteroids: 80% respond with platelet counts $>20,000/\text{mm}^3$ by 72 hours (faster with high-dose pulse therapy). Oral prednisone at 2 mg/kg/24 h tapered over 1–4 weeks is typical.
 - Advantages: ease of dosing, low cost, often longer duration of response
 - Disadvantages: short-term side effects: mood changes, increased appetite and weight gain, hypertension, insulin resistance. Long-term side effects with chronic use: adrenal suppression, osteopenia, growth delay
- Anti-Rh D immunoglobulin—WinRho-SDF (patient must be Rh[+], nonsplenectomized, and not have hemolysis or hemorrhage): 80% respond with platelet counts $>20,000/\text{mm}^3$ after 72 hours. Dose is 50–75 mcg/kg IV over 3–5 minutes. If hemoglobin (Hb) <10 mg/dL, give 25–40 mcg/kg. 1 mcg = 5 IU of drug. Response lasts ~5 weeks.
 - Advantages: less expensive than IVIG but more costly than steroids; lower rate of allergic side effects (10%) than with IVIG and does not cause aseptic meningitis; amenable to outpatient administration
 - Disadvantages: fever/chills, mild hemolysis (Hb decrease of 1–3 g/dL) in all patients; rare reports of catastrophic hemolysis; subcutaneous route may ameliorate risk.
- Any of these therapies may be repeated if responsive patient later develops recurrent thrombocytopenia.

Second Line

- Rituximab (anti-CD20 monoclonal antibody) induces response in many refractory patients (after median 5 weeks), but duration is often limited (median 12 months).
- Thrombopoietin receptor agonists (e.g., eltrombopag, romiplostim) have been shown in trials to improve platelet counts and bleeding risk in patients with chronic ITP. Cost, concerns about adverse effects including myelofibrosis and thrombosis, and paucity of long-term follow-up data limit use.

- Cytotoxic drugs (e.g., vincristine) or immunosuppression (e.g., cyclosporine A or mycophenolate mofetil) is effective in some patients refractory to other therapy and splenectomy.

ADDITIONAL TREATMENT

General Measures

- Platelet transfusions are generally ineffective because transfused platelets are rapidly destroyed. Role is limited to emergent support for critical hemorrhage.
- Avoid medications that affect platelet function, such as aspirin, ibuprofen, most other NSAIDs, and anticoagulants.
- Educate parents about signs and symptoms of intracranial hemorrhage and GI bleeding.
- Avoid activities with significant fall, collision, or other trauma risk while thrombocytopenic.

SURGERY/OTHER PROCEDURES

Splenectomy: 70–80% respond with complete remission. No reliable presurgical predictors of response have been found; generally deferred until >12 months from diagnosis to allow for spontaneous remission or medical response

- Advantages: response in patients refractory to medical therapy
- Disadvantages: surgical morbidity; risk of sepsis with encapsulated organisms (immunize preoperatively against *Haemophilus influenzae*, pneumococcus, and meningococcus and consider penicillin prophylaxis)

INPATIENT CONSIDERATIONS

Initial Stabilization

Life-threatening hemorrhage: The goal is to stop bleeding rapidly. Platelet transfusion, IVIG, and steroids (after emergent marrow exam, if indicated) should be given concomitantly.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Platelet count twice weekly when $<20,000/\text{mm}^3$, weekly when $<50,000/\text{mm}^3$ or after treatment, except in stable chronic ITP. Increase interval if no symptoms and platelet count $>50,000/\text{mm}^3$.
- Platelet counts may fall transiently with intercurrent illnesses prior to resolution of ITP.
- Discontinue monitoring when no symptoms and normal platelet count for >3 months.

PROGNOSIS

- Acute ITP: In 3 months, 60% of children will have a platelet count $>100,000/\text{mm}^3$; at 1 year from diagnosis, 90%. Recurrence is rare.
- Chronic ITP: Platelet count tends to be higher, at $40,000\text{--}80,000/\text{mm}^3$. Remissions can occur many years after diagnosis (predicted spontaneous remission rate 61% after 15 years).
- Not yet possible to prospectively distinguish patients with self-limited ITP from those who will persist with chronic ITP
- Patients with chronic ITP should be periodically reevaluated for secondary ITP.

COMPLICATIONS

- The incidence of significant bleeding-related morbidity and mortality is low ($<5\%$).
 - Intracranial hemorrhage is rare ($<0.5\%$).
 - May occur without prior trauma
- Retinal hemorrhage is rare.
- Mucosal bleeding from nose, gums, lower GI tract, or kidneys is not uncommon. Hematemesis and melena are rare.
- Significant menorrhagia may occur.

- D69.41 Evans syndrome

IMMUNE DEFICIENCY

Kathleen E. Sullivan

BASICS

DESCRIPTION

Immunodeficiencies generally represent a defect in host defense. Less common deficiencies represent defects in the regulation of immune function. Congenital and acquired forms exist.

- Defects in antibody production: often characterized by frequent sinopulmonary infections with typical organisms
 - X-linked agammaglobulinemia
 - Onset of symptoms after 6 months of age; sinopulmonary infections with typical bacterial pathogens
 - Markedly decreased immunoglobulins (Ig) and B cells. Tonsils are absent.
 - Hyper-IgM syndromes: several forms
 - Usually present with recurrent bacterial infections in infancy; *Pneumocystis jiroveci* is seen; intermittent neutropenia is common.
 - Decreased IgG, IgE, IgA with normal or increased IgM
 - Common variable immunodeficiency (CVID)
 - Usually presents with recurrent bacterial infections; most commonly arises in the 2nd or 3rd decade (but seen at all ages)
 - Ig levels and function gradually decline; autoimmunity is common.
 - IgA deficiency
 - Most common congenital immunodeficiency (1:500); most are asymptomatic.
 - Symptoms seen at any age; typically sinopulmonary infections; increased risk of allergy, autoimmune disease, and anaphylaxis from blood products
 - Transient hypogammaglobulinemia of infancy
 - A developmental delay of Ig production; function is intact;

- typically resolves between 1 and 2 years of age
- T-cell defects: most often characterized by persistent viral infections or opportunistic infections
 - Severe combined immunodeficiency (SCID)
 - Most common presentation is a respiratory virus that fails to clear or chronic diarrhea.
 - Failure to thrive, thrush, and *P. jiroveci* pneumonia are also common.
 - Many states now have SCID newborn screening; patients identified have no symptoms.
 - Combined immune deficiencies
 - Several forms
 - Children exhibit increased severity of a broad range of infections, opportunistic infections, and unusual autoimmunity.
 - Chromosome 22q11.2 deletion syndrome
 - See “DiGeorge Syndrome.”
 - Chronic mucocutaneous candidiasis
 - Multiple forms of this disorder
 - One form is also called autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) and has an association with polyendocrinopathies and ectodermal dysplasia.
 - The other types are more likely to have an associated T-cell defect. Infants have extensive or recurrent *Candida* infection; modest predisposition to other infections.
 - IPEX (immunodeficiency, polyendocrinopathy, enteropathy, X-linked syndrome)
 - Diarrhea associated with villous atrophy and a T-cell infiltrate, progressive autoimmune destruction of endocrine organs
 - Infections can be severe but the autoimmune manifestations predominate.
 - Neutrophil defects: *Staphylococcus*, *Pseudomonas*; unusual bacterial or fungal infections are characteristic.
 - Autoimmune neutropenia of infancy
 - Most common neutrophil defect of childhood; usually detected at ~6–12 months of age

- Often resolves by 2 years of age
- Congenital neutropenia
 - Infections may be skin infections or sinopulmonary.
 - Patients have either persistently absent or markedly low neutrophil counts.
 - Some patients will have 21-day cycles of neutropenia—cyclic neutropenia.
- Leukocyte adhesion deficiency
 - 10% have delayed separation of the umbilical cord.
 - Most common presentations are recurrent skin ulcers and periodontitis.
 - Spontaneous peritonitis occurs.
- Chronic granulomatous disease (CGD)
 - Recurrent skin abscesses common, deep hepatic abscesses, and pulmonary infections
 - Typical organisms are *Staphylococcus aureus*, *Burkholderia*, *Serratia*, *Nocardia*, mycobacteria, *Aspergillus*, and *Candida*.
 - Age of onset is usually 1–3 years.
- Innate defects in signaling: typically present with severe bacterial or viral infections in early infancy
 - IRAK4 and MyD88 deficiencies
 - Associated with staphylococcal, streptococcal, or pseudomonal sepsis/meningitis
 - Clostridial infections are also seen.
 - Herpes simplex encephalitis is associated with several gene defects.
- Macrophage activation defects
 - Universally associated with atypical mycobacteria. *Salmonella* is also seen.
 - Biopsies may reveal poorly formed granulomas.
- Complement deficiency
 - Deficiencies of C5–C9 are associated with *Neisseria* infections.
 - Deficiencies of C1, C2, and C4 are associated with lupus and recurrent bacterial infections.
 - C3 deficiency associated with glomerulonephritis and severe recurrent infections.

- Defects in complement regulatory proteins are associated with atypical hemolytic uremic syndrome (HUS) or hereditary angioedema.
- Immunodeficiency syndromes
 - Ataxia telangiectasia
 - Progressive cerebellar ataxia during infancy; ocular telangiectasias at about 5–15 years of age
 - Recurrent sinopulmonary infections; α -fetoprotein is elevated, IgA and IgG2 are diminished.
 - Wiskott-Aldrich syndrome
 - Clinical triad of eczema, thrombocytopenia, and recurrent infections
 - Ig levels are variable but responses to vaccines often poor; small platelets and thrombocytopenia
 - Hyper-IgE syndrome
 - Recurrent infections of the skin and lungs; *S. aureus* is a major cause of infection, and pulmonary infections typically heal with pneumatoceles.
 - X-linked lymphoproliferative syndrome
 - 4 main types of presentation and 2 genetic types: acute Epstein-Barr virus infection with hemophagocytosis, lymphoma, hypogammaglobulinemia, and aplastic anemia
 - Family history is key to diagnosis.
 - Chédiak-Higashi syndrome
 - Pigmentary dilution, progressive neuropathy, and frequent infections; associated with a hemophagocytic process
 - Neutrophil counts are low and neutrophils have giant inclusions.
 - Familial hemophagocytic lymphohistiocytosis
 - Defect in cytotoxic function; presents with fever, pancytopenia, and hepatosplenomegaly; usually <5 years of age
 - Ectodermal dysplasia with immune deficiency
 - Two forms. Variable ectodermal dysplasia and variable immune deficiency. Ig levels are variable as are responses to vaccines.
 - Susceptibility to mycobacteria, *Pneumocystis*, and common bacterial pathogens

- Secondary immunodeficiencies include the following:
 - HIV infection
 - Malignancy
 - Viral suppression
 - Nephrotic syndrome
 - Protein-losing enteropathy
 - Malnutrition
 - Medications
 - Splenectomy

EPIDEMIOLOGY

Primary immune deficiencies range from the common (1:600) to the very rare (1:1,000,000).

- 1:600 for IgA deficiency in Caucasians
- 1:3,000 for chromosome 22q11.2 deletion syndrome (DiGeorge syndrome)
- 1:20,000 for common variable immune deficiency
- 1:50,000 for SCID
- 1:200,000 for CGD

RISK FACTORS

Genetics

- The immunodeficiencies are generally autosomal recessive, although there are several important exceptions.
- X-linked
 - Properdin deficiency, X-linked agammaglobulinemia, X-linked hyper-IgM, X-linked SCID, X-linked CGD, X-linked lymphoproliferative syndrome (2 types), IPEX, Wiskott-Aldrich syndrome, NEMO deficiency. All of these have autosomal recessive phenocopies or may be seen in females with altered X inactivation.
- Autosomal dominant
 - Hyper-IgE syndrome, chromosome 22q11.2 deletion syndrome, some macrophage activation defects
- Polygenic
 - IgA deficiency and CVID

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Chronic inflammation of mucous membranes such as that due to reflux or allergies can lead to recurrent infections.
- Immunocompromised status due to chemotherapy and immunosuppressive drugs
- Malnutrition
- Intercurrent viral infections such as Epstein-Barr virus and cytomegalovirus
- Medications such as antiseizure drugs and corticosteroids can cause IgA deficiency or hypogammaglobulinemia.
- Inborn errors of metabolism
- Chromosomal syndromes
- Protein loss can be associated with hypogammaglobulinemia.
- HIV infection

HISTORY

- **Question:** Family history?
- Significance: X-linked disorders are common.
- **Question:** Number and duration of infections?
- Significance: To determine whether the problem is one of clearance or frequency
- **Question:** Types of infections?
- Significance: Infections of skin are frequently due to neutrophil problems, whereas recurrent infections of a single site imply an anatomic problem. Opportunistic infections are associated with both neutrophil defects (unusual bacteria and fungi) and T-cell defects (opportunistic viruses).
- HIV risk factors

PHYSICAL EXAM

Examination should be directed at defining organ damage as a result of infection, the presence of any current infections, syndromic features, signs of autoimmune disease, and the characterization of accessible lymphoid organs, liver, and spleen.

DIAGNOSTIC TESTS & INTERPRETATION

- **Test:** IgG, IgA, IgM, IgE levels, and responses to vaccines such as diphtheria and tetanus
- **Significance:** Recurrent sinopulmonary infections with typical organisms are associated with defects in antibody production.
- **Test:** Evaluation of T-cell production and function—T-cell enumeration and lymphocyte proliferation studies
- **Significance:** T-cell defects will often have low T-cell numbers.
- **Test:** Evaluation of neutrophil numbers and function—a CBC with differential, morphologic exam of neutrophils, and a measure of respiratory burst
- **Significance:** Neutrophil disorders typically present with skin abscesses or ulcers or deep infections with *Staphylococcus* or fungi.
- **Test:** Special studies designed to test the function of the toll-like receptor signaling complex
- **Significance:** Innate defects, such as IRAK4, MyD88, and NEMO deficiencies, can be detected.
- **Test:** A CH50
- **Significance:** A CH50 will detect most of the structural component deficiencies. Special studies are needed for defects of the alternative pathway and the regulatory proteins.
- **Test:** CBC with differential; IgG, IgA, and IgM levels; and diphtheria and tetanus titers
- **Significance:** In certain patients, it may be difficult to differentiate between viral processes and bacterial processes. In these cases, a CBC with differential; IgG, IgA, and IgM levels; and diphtheria and tetanus titers are a useful screen to evaluate for the most common immunodeficiencies.

TREATMENT

- Prophylactic antimicrobials
 - Chronic mucocutaneous candidiasis
 - Hyper-IgE syndrome
 - CGD

ADDITIONAL TREATMENT

General Measures

- Suspected SCID requires isolation, cytomegalovirus-negative/irradiated blood products, and a prompt evaluation for hematopoietic stem cell transplant.
- Ig replacement (either IV or SC)
 - X-linked agammaglobulinemia
 - Hyper-IgM
 - CVID
- Probiotics may be useful for antibiotic-associated diarrhea.
- Hand washing to prevent infections
- Prophylactic antibiotics can be useful.

SURGERY/OTHER PROCEDURES

- Hematopoietic stem cell transplantation
 - SCID
 - Wiskott-Aldrich syndrome
 - X-linked lymphoproliferative syndrome
 - Chédiak-Higashi syndrome
 - Familial hemophagocytic lymphohistiocytosis
 - Selected cases of hyper-IgM, CGD, macrophage activation defects
- Thymus transplantation
 - Severe chromosome 22q11.2 deletion syndrome (DiGeorge syndrome)

ONGOING CARE

PROGNOSIS

- Most antibody deficiencies have an excellent prognosis. Transient or developmental deficiencies of IgG or IgG subclasses typically resolve by 2 years of age.
- Some patients with CVID can develop malignancy or autoimmune disease and this defines the prognosis.
- The treatment of neutrophil disorders remains problematic; most children with CGD will not have full life expectancy.

- Patients with T-cell disorders for whom bone marrow transplantation is not performed can do well if the defect is mild and if they do not suffer from autoimmune disease, malignancy, or recurrent infections.

COMPLICATIONS

- Bronchiectasis
- Deafness
- Autoimmune disease
- Lymphoreticular malignancies occur in patients with T-cell disorders.
- Live viral vaccines administered to patients with significant T-cell dysfunction can result in unchecked viremia.
- Oral polio vaccine administered to patients with agammaglobulinemia can cause meningoencephalitis.

- D80.9 Immunodeficiency with predominantly antibody defects, unspecified
- D83.9 Common variable immunodeficiency, unspecified

FAQ

- Q: Does a child with thrush require evaluation?
- A: A child with severe thrush in the absence of risk factors should have an evaluation for T-cell dysfunction, HIV, and the possibility of chronic mucocutaneous candidiasis of childhood. Moderate thrush or recurrent simple thrush does not require evaluation unless it is occurring in an older child.
- Q: A newborn in my practice still has his umbilical cord attached at 6 weeks of age. Is that abnormal, and does it require an evaluation for leukocyte adhesion deficiency?
- A: A completely healthy-appearing cord at 6 weeks of age does not require any evaluation. If there is clinical suspicion of leukocyte adhesion deficiency, a CBC can be performed to identify neutrophilia.
- Q: Which immunodeficiencies are associated with absent tonsils and adenoids?
- A: Boys with X-linked agammaglobulinemia and X-linked hyper-IgM have absent tonsils and adenoids.
- Q: Which immunodeficiency is associated with abscesses that are not painful?
- A: Children and adults with hyper-IgE syndrome develop abscesses that are not painful.

IMMUNOGLOBULIN A DEFICIENCY

Nashmia Qamar • Ramsay L. Fuleihan

BASICS

DESCRIPTION

Serum IgA <7 mg/dL and a normal serum IgG and IgM in patients >4 years of age

RISK FACTORS

Genetics

- Exact pattern of inheritance remains unclear; however, the following associations may occur:
 - 22q11 deletion syndrome
 - 18q syndrome
 - Partial deletions in the long or short arm and ring forms of chromosome 18
 - Also associated with HLA-A1, HLA-A2, B8, DR3, DQ2 (8.1), and Dw3
 - Also associated with non-MHC-associated genes involved in autoimmunity including IFIH1 on chromosome 2q24, CLEC16A on chromosome 16

PATHOPHYSIOLOGY

- Failure of B lymphocyte differentiation into plasma cells producing IgA
- Block may be due to
 - Defect in T-helper cells
 - Antigen-presenting cells
 - B cells
 - Lack of effects from various cytokines, including IL-21, IL-4, IL-6, IL-7, or IL-10

COMMONLY ASSOCIATED CONDITIONS

Increased association with the following:

- Atopy
- Sinopulmonary infections
- GI infections (especially *Giardia lamblia*)
- Inflammatory bowel disease (Crohn disease and ulcerative colitis)
- Celiac disease
- Nodular lymphoid hyperplasia
- Malignancy
- Autoimmune illnesses
 - Systemic lupus erythematosus
 - Immune endocrinopathies (e.g., Graves disease, type 1 diabetes)
 - Autoimmune hematologic conditions
 - Chronic active hepatitis

DIAGNOSIS

HISTORY

- Patients with IgA deficiency
 - Can have frequent sinopulmonary infections
 - Can have frequent GI infections
 - Tend to be allergic
 - Have an increased incidence of autoimmune diseases
- ~30% of patients with IgA deficiency are completely healthy.
- Patients with low switched memory B cells exhibit more severe clinical features including pneumonia, autoimmune disease, and bronchiectasis.

PHYSICAL EXAM

- Look for signs of recurrent infection and atopy.
- Allergies are associated with IgA deficiency. Signs include the following:
 - Cobblestoning of the conjunctiva
 - Allergic shiners
- Serous otitis media may be the result of recurrent ear infections or persistent fluid:
 - Increased ear infections can be seen in IgA deficiency.

- Persistent fluid can be secondary to allergies.
- Pain on palpation of the sinuses
 - Recurrent sinus infections are associated with IgA deficiency.
- Lung examination
 - An increased frequency of pneumonia is associated with IgA deficiency.
- Swollen joints:
 - An increased frequency of autoimmune disease is associated with IgA deficiency.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

The general goal is to decide whether the patient's complaints are consistent with IgA deficiency (frequent upper respiratory and GI infections or allergies).

- Measure serum IgA level:
 - If the patient is IgA deficient, exclude other conditions associated with IgA deficiency.
 - Serum IgA level: Patient is considered deficient if the serum IgA level is <7 mg/dL.
- Total immunoglobulins
 - If normal, helps rule out X-linked agammaglobulinemia (Bruton), common variable immunodeficiency, and severe combined immunodeficiency
- IgG subclasses:
 - Helps rule out an associated IgG subclass deficiency
- Lymphocyte stimulation to mitogens
 - A functional lymphocyte study
 - If normal, helps rule out common variable immunodeficiency, severe combined immunodeficiency, ataxia telangiectasia, DiGeorge syndrome, and Nezelof syndrome
- Lymphocyte stimulation to Candida antigen
 - No response to Candida in vivo is consistent with chronic mucocutaneous candidiasis.
- Specific antibody responses to polysaccharide and protein antigens: to evaluate for an associated specific antibody deficiency

- Screening for celiac disease
 - Should include IgG antibodies against gliadin and tissue transglutaminase because IgA isotype may not be detected

DIFFERENTIAL DIAGNOSIS

- Toxic, environmental, drugs
 - Penicillamine and anticonvulsants can induce IgA deficiency.
- Cyclosporine A has been reported to cause permanent IgA deficiency.
- Genetic/metabolic
 - X-linked agammaglobulinemia (Bruton)
 - Common variable immunodeficiency (CVID)
 - Severe combined immunodeficiency
 - Ataxia telangiectasia
 - DiGeorge syndrome
 - Chronic mucocutaneous candidiasis
 - Nezelof syndrome
 - Selective IgG2 deficiency
- Miscellaneous: Patients may be completely healthy, and IgA deficiency may be an incidental finding.

ALERT

Factors that may alert you to request a referral include the following:

- Suggestion that IgA deficiency may be part of a more complex immune deficiency: An allergist/immunologist can assist with an appropriate immunologic evaluation.
- Suggestion of associated autoimmune disease: Evaluation and treatment by a rheumatologist is indicated.
- Patient likely to need a blood transfusion: An allergist/immunologist can help select appropriate blood products.

TREATMENT

ADDITIONAL TREATMENT

General Measures

- There is no specific drug therapy.
- Recurrent infections should be treated aggressively with broad-

spectrum antibiotics.

- Antibiotic prophylaxis to prevent recurrent sinopulmonary infections is often indicated.
- IV gammaglobulin is generally not indicated unless there is evidence of an associated specific antibody deficiency.

ALERT

Patients with no detectable IgA may develop antibodies against IgA in transfused blood products. These patients are at risk for allergic reactions including anaphylactic (or anaphylactoid) transfusion reactions on subsequent exposure. It should be noted, however, that life-saving products should not be withheld in emergent situations. In the nonurgent setting, to avoid potential allergic reactions, patients may receive the following:

- Packed RBCs (only if these cells have been washed 3 times)
- Plasma products from IgA-deficient donors
- Autologous banked blood

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Patients should be observed for the following:
 - Sinopulmonary infections
 - GI infections
 - Autoimmune diseases
 - Inflammatory bowel disease
 - Malignancy typically of lymphoid origin
- It is important to manage infectious complications aggressively and to intervene promptly if associated conditions develop.
- It is also known that IgA deficiency may progress to CVID in some cases.

PATIENT EDUCATION

- IgA deficiency can be induced by some anticonvulsants and by penicillamine.
- IgA-deficient patients should wear medical alert bracelets. These

patients can have anaphylaxis if administered blood products containing IgA. In an emergency situation, this is important information for the caregivers to know. However, this is not very common and does not occur with the first blood product infusion/transfusion.

PROGNOSIS

Survival into the 7th decade is common. However it is also known that some patients may progress to CVID.

COMPLICATIONS

Increased incidence of the following:

- Sinopulmonary infections
- GI tract infections
- Atopy
- Autoimmune diseases
- Malignancy

CODES

ICD10

D80.2 Selective deficiency of immunoglobulin A [IgA]

FAQ

- Q: Should patients with IgA deficiency be monitored for the development of progressive immunodeficiency?
- A: Patients with IgA deficiency should be monitored for progression to CVID, as this is associated with a poorer prognosis and would require treatment with IV gammaglobulin.
- Q: Should IgA-deficient patients wear medical alert bracelets?
- A: Yes. These patients can have anaphylaxis if they are given blood products containing IgA. In an emergency situation, this is important information for the caregivers to know.

IMMUNOGLOBULIN A NEPHROPATHY

Maha N. Haddad • Lavjay Butani

BASICS

DESCRIPTION

Primary immune complex–mediated glomerulonephritis

EPIDEMIOLOGY

- Most common chronic glomerulonephritis worldwide
- Prevalence varies considerably across countries; more common in Caucasians and Asians compared to African Americans.
- Because reported prevalence is based on biopsy-confirmed diagnosis and therefore does not account for mild or asymptomatic cases, data grossly underestimate “true” prevalence.
- Represents 2–10% of all biopsy-confirmed primary glomerular diseases in adults in the United States
- No robust epidemiologic data in children

RISK FACTORS

- Typically sporadic
- Familial cases have been described suggesting that genetic factors influence susceptibility to and severity of disease.
- Reported in children with history of perinatal HIV-1 infection
- Increased risk of IgA nephropathy in adult patients with celiac disease, cirrhosis, and HIV infection

PATHOPHYSIOLOGY

- Etiology and pathogenesis remain uncertain.
- Substantial evidence that IgA nephropathy is a systemic immune complex–mediated disease as it recurs after transplantation
- Multiple studies have found abnormal glycosylation patterns of the IgA1 molecule (galactose deficiency), suggesting the following hypotheses:
 - Glycan-specific IgG antibodies form immune complexes with

galactose-deficient IgA1.

- Complexes deposit in the glomerular mesangium.
- Activated mesangial cells proliferate and excrete extracellular matrix, cytokines, and chemokines with resulting renal injury.
- Majority of patients have elevated galactose-deficient IgA1 in the serum.

DIAGNOSIS

HISTORY

- Clinical presentation varies widely in constellation of signs and symptoms and also in severity.
- Patients may be completely asymptomatic.
- In children, the most common presentation is recurrent gross hematuria.
 - Triggered by acute upper respiratory tract infection in about half of the patients
 - In IgA nephropathy, in contrast to postinfectious glomerulonephritis, the hematuria presents at the same time (“synpharyngitic”) or within a few days after the onset of the respiratory illness.
- Other presentations include the following:
 - Microscopic hematuria found on routine urinalysis
 - Hematuria (gross or microscopic) and proteinuria
 - Acute nephritic syndrome (hematuria, proteinuria, edema, impaired renal function, and hypertension). Rarely, this may be rapidly progressive.
 - Nephrotic syndrome: edema, hypoalbuminemia, and nephrotic range proteinuria
- Variable levels of proteinuria are seen.

PHYSICAL EXAM

- Hypertension: usually absent in mild disease; variably present depending on severity
- Edema: found in patients with high levels of proteinuria

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Urinalysis: RBCs, RBC casts, and protein
- Spot urine protein/creatinine ratio or 24-hour urine collection to quantify proteinuria
- Comprehensive metabolic panel
 - Kidney function tests (blood urea nitrogen and serum creatinine), serum electrolytes, and albumin are normal in mild disease.
 - Variably affected depending on severity
- In patients presenting with rapidly progressive glomerulonephritis, check complement levels, antinuclear antibody (ANA), antineutrophil cytoplasmic antibody (ANCA), and anti-glomerular basement membrane (GBM) antibodies to rule out other diseases.
- Serum IgA levels have very low sensitivity and specificity and are not recommended.

Imaging

Kidney ultrasound findings are nonspecific and either normal or, in more severe cases, may demonstrate increased echogenicity of the renal parenchyma.

Diagnostic Procedures/Other

- Kidney biopsy is required for a definitive diagnosis.
- Hallmark of the diagnosis is the presence, on immunofluorescence staining, of IgA deposits in the mesangium, either alone or with C3 (in children), IgM and IgG, or both (in adults).
- Biopsy is generally not required in mild cases as it does not affect the management or prognosis in the absence of proteinuria.
- Biopsy findings are variable on light microscopy:
 - Main finding is diffuse or focal mesangial proliferation with mesangial expansion.
 - Other possible findings include segmental or global endocapillary hypercellularity with segmental crescents and segmental necrosis.
 - Glomerulosclerosis in advance disease
 - Tubulointerstitium is usually normal with varying degree of atrophy and fibrosis in chronic cases.
 - Electron microscopy: immune complex deposits in the mesangium

- Several histologic classifications have been developed with the purpose of predicting clinical course, prognosticating, and in guiding therapy.
- The Oxford classification is one such example, based on a constellation of findings such as mesangial cellularity score, segmental glomerulosclerosis, endocapillary hypercellularity, and tubular atrophy/fibrosis.

DIFFERENTIAL DIAGNOSIS

- Thin basement membrane disease, Alport syndrome, or idiopathic hypercalciuria in mild cases presenting with hematuria
- Other forms of glomerulonephritis must be considered in the setting of a more acute presentation, including the following:
 - Postinfectious glomerulonephritis
 - Lupus nephritis
 - Membranoproliferative glomerulonephritis (MPGN)
 - Pauci-immune glomerulonephritis
 - Other vasculitides
- Henoch-Schönlein purpura nephritis has similar biopsy findings as IgA nephropathy but has additional nonrenal manifestations such as skin rash, abdominal pain, and periarthrititis.

ALERT

May be progressive and lead to end-stage renal disease in moderate to severe cases. Refer to a nephrologist if persistent proteinuria, abnormal creatinine, gross hematuria, or hypertension.

TREATMENT

- Weak evidence base and mostly derived from expert opinion
- Varies based on severity of renal impairment, amount of proteinuria, and whether or not the course is rapidly progressive with associated crescents on biopsy. Higher amounts and persistence of proteinuria are associated with greater risk of disease progression.

MEDICATION

- Control of proteinuria and blood pressure
 - Protein excretion 0.5–1 g/1.73 m²/day: angiotensin-converting enzyme inhibitor (ACEI) or angiotensin receptor blockers (ARBs). Increase dose to effect as long as symptomatic hypotension or hyperkalemia do not develop.
 - Protein excretion >1 g/1.73 m²/day despite optimum blood pressure control and the use of ACEI or ARB and when GFR is >50 mL/min/1.73 m²: Consider alternate day oral glucocorticoids for 6 months.
- Rapidly progressive glomerulonephritis and/or crescents on biopsy: intravenous (followed by oral) glucocorticoids, and consider additional immunosuppression such as cyclophosphamide or azathioprine (strength of evidence is poor for immunosuppression other than ACEI/ARB and glucocorticoids)

ADDITIONAL THERAPIES

- Fish oil suggested when proteinuria is persistent >1 g/1.73 m²/day despite optimal supportive care.
- Mycophenolate mofetil: multiple studies with conflicting conclusions

GENERAL MEASURES

- Clinical presentation: Treat hypercholesterolemia associated with nephrotic syndrome. Address factors that modulate progression of chronic kidney disease—obesity, smoking, hypertension.
- Optimize blood pressure control.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- IgA nephropathy may be a progressive disease. Patients should be monitored periodically for the following:
 - Kidney function tests
 - Level of proteinuria
 - Blood pressure
 - Intensity and frequency of monitoring depends on severity. Patients presenting with microscopic hematuria and minimal proteinuria

should be monitored with UA every 6 months to assess for progression of proteinuria.

PROGNOSIS

- Variable depending on severity of clinical presentation and renal histopathologic score
- 15–40% of adult patients with IgA nephropathy eventually progress to end-stage renal disease (ESRD).
- Although some reports suggest that children are more likely to have a benign course and have better prognosis than adults, other studies have reported similar outcomes for adults and children.
- In one series, renal survival rates in Japanese children were 95% at 10 years and 80% at 20 years.
- Patients who present with microscopic hematuria and minimal proteinuria have an excellent prognosis.
- Clinical predictors associated with poor outcome include severe persistent proteinuria, hypertension, and impaired renal function at presentation.
- The strongest predictive factor is the amount of proteinuria.
- Histopathologic features associated with poor outcome include mesangial hypercellularity score, endocapillary hypercellularity, tubular atrophy, and glomerular crescents.

CODES

ICD10

- N02.8 Recurrent and persistent hematuria with morphologic changes
- N02.5 Recurrent and persistent hematuria with diffuse mesangiocapillary glomerulonephritis
- N02.2 Recurrent and persistent hematuria with diffuse membranous glomerulonephritis

FAQ

- Q: Will my child ever outgrow IgA nephropathy?
- A: No. The etiology and pathogenesis of IgA nephropathy remain uncertain. IgA nephropathy is a chronic condition, but sometimes it can go into spontaneous remission. Spontaneous remission is reported to occur in 59% of children with mild disease. More severe cases can also go into remission with medications.

- Q: My child has had a kidney transplant. Can IgA nephropathy recur in the graft?
- A: Yes. Recurrence of the condition can develop in 33% of patients. Depending on the published series, recurrence rates vary between 9 and 66%. However, even if it does come back, it can be controlled/treated with medications.
- Q: My child has microscopic hematuria and proteinuria. He has normal kidney function and blood pressure. His kidney biopsy was consistent with the diagnosis of IgA nephropathy. What is the strongest predictor for progression?
- A: The amount of proteinuria. Children with no or mild proteinuria usually have good long-term prognosis, whereas those with high amounts of protein in the urine are more likely to progress and develop long-term kidney damage.

IMPERFORATE ANUS

Lusine Ambartsumyan

BASICS

DESCRIPTION

- Imperforate anus (IA) is a congenital abnormality in which the bowel fails to perforate or only partially perforates the pelvic muscular floor.
- IA may also perforate the epidermal covering of the pelvic muscular floor (anal membrane).
- Spectrum of anorectal malformations that range in severity from imperforate anal membrane to complete caudal regression
- IA has been classically described as low and high anomalies.
 - In a low lesion, the colon remains close to the skin and there may be a stenosis of the anus, or the anus may be missing altogether, with the rectum ending in a blind pouch.
 - In a high lesion, the colon is higher up in the pelvis, with a fistula connecting the rectum and the bladder, urethra, or the vagina.
- More recently, classification of IA is by type of associated fistula: rectal, bladder, urethra, or vaginal.

EPIDEMIOLOGY

- Prevalence is estimated to be in the range of 1:3,000–1:5,000.
- High lesions are more common in males (2:1).
- Low lesions occur with equal frequency in both sexes.

RISK FACTORS

Genetics

- Can be an isolated defect or part of a syndrome or association
- Syndromic disorders that contain IA are associated with defects on chromosomes 6, 7, 10, and 16.
- Can be associated with trisomy 21 (typically IA without fistula)
- Can be part of omphalocele-exstrophy of the bladder-IA-spinal defects (OEIS) complex or cloacal exstrophy (EC)

PATHOPHYSIOLOGY

- During the 6th week of fetal development, the hindgut comes into contact with the cloacal membrane. The hindgut is divided into a ventral urogenital and dorsal rectal component. By the 8th week, the dorsal 1/2 perforates to the exterior. In IA, the process is arrested during this critical period.
- There is a wide spectrum of anatomic variants of IA; commonly associated with urologic and spinal defects
- Classification of anatomic variants is based on the relationship between the rectum and the puborectalis muscle: supralelevator (high) and translevator (low) malformations
- Cloaca is a complex defect, where the rectum, urethra, and the vagina drain into a common channel that communicates with the perineum.
 - A fistula communicating from the rectum to the external opening (perineal fistula) or to the urogenital system is present in 90% of cases.
 - Females: Most common defect is a recto-vestibular fistula where the rectum opens into the vestibule.
 - Males: Most common defect is a rectourethral fistula from the rectum to lower posterior urethra (bulbar) or upper posterior urethra (prostatic).

COMMONLY ASSOCIATED CONDITIONS

- Other anomalies are present up to 50% of patients with an IA.
- IA can be associated with vertebral, cardiac, tracheoesophageal fistula, renal, and limb anomalies (VATER or VACTERL).
- Other associated anomalies include urologic, spine/sacrum (hypoplastic sacrum, sacral agenesis, presacral mass, myelomeningocele, tethered cord), gastrointestinal (esophageal/intestinal atresia, malrotation, omphalocele, annular pancreas), gynecologic (duplicate uterus, septate vagina, vaginal atresia), and cardiovascular defects (septal defects).

DIAGNOSIS

HISTORY

- Most children are diagnosed during a routine neonatal examination.
- Failure to pass meconium, a history of constipation, and signs of low intestinal obstruction (abdominal distention and vomiting) should mandate reexam of perianal area.
- Approximately 13–25% may present beyond the neonatal period and have higher morbidity (19–35%) and mortality (4–10%).

PHYSICAL EXAM

- Placement of the anus: lack of or anterior/lateral malposition
- Decreased or abnormal radial corrugations of the anus
- Abnormal rectal caliber
- Poor anal tone or patulous anal opening
- Absent or asymmetric anal wink
- Spinal dimples or tufts
- Flat buttocks, abnormal gluteal crease, lack of midline groove
- Abnormal genitourinary or neurologic examination
- Associated renal, cardiac, vertebral, or limb anomalies.

DIAGNOSTIC TESTS & INTERPRETATION

- Exclusion of associated anomalies
- Classification of the malformation (established after 18–24 hours)

Imaging

- Prone cross-table lateral and invertogram: After sufficient time for a transit of gas (>12 hours after birth), the child is placed in an upside-down position for 5 minutes, after which a lateral view of the pelvis is obtained to identify level of obstruction.
- Lumbosacral films to evaluate for vertebral anomalies and sacral integrity
- MRI of the spine and pelvis should be considered to look for a tethered cord and evaluate the pelvic anatomy.
- Water contrast enema to evaluate the anatomy: rectosigmoid caliber and genitourinary fistulas
- Renal and pelvic ultrasound to evaluate for hydronephrosis, megaureters, and hydrocolpos
- Voiding cystoureterogram and IV pyelogram can be used if urinary tract anomalies are highly suspected.

- Echocardiogram

DIFFERENTIAL DIAGNOSIS

- No disorders can mimic IA.
- Task is to define the location of the termination of the bowel and the opening of the fistula.

TREATMENT

SURGERY/OTHER PROCEDURES

- Surgery should be performed by an experienced surgeon.
- High lesions require an emergent and protective diverting colostomy, followed by pull-through procedure with posterior sagittal anorectoplasty (PSARP) at 3–9 months of age. Colostomy is closed after the anoplasty has healed and any necessary secondary dilations have been completed.
- Laparoscopy-assisted PSARP in conjunction with muscle electrostimulation may be performed in those with complex and high lesions.
- Transanal anorectoplasty was recently shown to have sphincter sparing and results in accurate placement of anus in external canal with good neurologic function.
- After surgery, follow-up with anal dilatation helps minimize the risk of stricture formation and helps the newly constructed canal to become functional.
- Complications of surgery include stricture of the anocutaneous anastomosis, rectourinary fistula, mucosal prolapse, constipation, and incontinence.

ONGOING CARE

PATIENT EDUCATION

- Prognosis for bowel and urine continence depends on type of malformation and sacral integrity.
- Low malformations have greater bowel control, increased incidence of

megacolon with subsequent constipation, and “overflow” incontinence.

- High malformations have increased associated defects and poor bowel and urinary control.

PROGNOSIS

- Prognostic factors: type of malformation, sacral integrity, and length of the cloaca common channel
- Sacral integrity is the most important prognostic indicator of bowel control.
- Good prognostic indicators of bowel control:
 - Normal sacral integrity
 - No presacral mass
 - Two well-formed buttocks and midline groove
 - Low anorectal malformations (rectal atresia, rectoperineal fistula, rectobulbar urethral fistula, cloaca with common channel <3 cm, and IA without fistula)
- Poor prognostic indicators of bowel control:
 - Abnormal sacral integrity
 - Myelomeningocele
 - High anorectal malformations (rectoprostatic urethral fistula, rectobladder neck fistula, cloacal exstrophy cloaca, >3 cm common channel, complex defects)
- Experienced centers report
 - ~75% have voluntary bowel movements after age 3 years, of which 50% continue to have intermittent fecal incontinence.
 - In their cohort, ~25% have fecal incontinence despite treatment.
- Continence can be attained in 80–90% of patients who have low lesions.
- <50% of patients with high lesions are continent before school age, but most continue to improve and achieve continence by adolescence.
- Many patients will need regular enemas or comprehensive bowel management program for years to prevent or reduce constipation and fecal incontinence.

CODES

ICD10

- Q42.3 Congenital absence, atresia and stenosis of anus without fistula
- Q42.2 Congenital absence, atresia and stenosis of anus with fistula

FAQ

- Q: Is IA an isolated defect in my child?
- A: IA is often associated with multiple other anomalies. In particular, renal and vertebral anomalies must be excluded.
- Q: What is the genetic basis for this defect?
- A: IA can be associated with chromosomal anomalies or can be an isolated problem.
- Q: How likely is it that my child will ever be able to be toilet trained successfully?
- A: Successful toilet training will depend on what type of IA defect your child has: Children with high lesions may have more difficulty becoming toilet trained than children with low lesions. All children should improve over time but will need specialist treatment and a comprehensive bowel management program for many years to prevent or reduce constipation and fecal incontinence.

IMPETIGO

Maribeth Chitkara

BASICS

DESCRIPTION

- Impetigo is a superficial skin infection seen frequently in children.
 - It is one of the most common skin and soft tissue infections observed in pediatrics.
 - Pyoderma and impetigo contagiosa are synonyms for impetigo.
- Classification
 - Primary impetigo: direct bacterial invasion of previously normal skin
 - Secondary impetigo: infection at sites of minor skin trauma or underlying conditions
- Types of impetigo
 - Nonbullous impetigo
 - Most common form
 - Lesions begin as papules that progress to vesicles surrounded by erythema.
 - Subsequently, the papules mature into pustules that enlarge and break down to form thick, adherent, golden crusts.
 - Bullous impetigo
 - Vesicles enlarge to form bullae containing clear yellow fluid, which become darker and more turbid.
 - Ruptured bullae leave a honey-colored crust.
 - Ecthyma
 - An ulcerative form of impetigo
 - Lesions extend through the epidermis and deep into the dermis.

EPIDEMIOLOGY

- Location: most frequently in tropical or subtropical regions but also prevalent in northern climates during summer months
- Age: found most commonly in children aged 2–5 years and can spread rapidly through child care centers and schools

RISK FACTORS

- Poverty, overcrowding
- Poor hygiene
- Underlying scabies infection
- Eczema

ETIOLOGY

- Staphylococcus aureus: most common etiologic agent. Toxin-producing strains cause cleavage in superficial skin layer.
- Impetigo due to community-associated methicillin-resistant Staphylococcus aureus (CA-MRSA) has occurred in a minority of cases.
- Beta-hemolytic streptococci (primarily group A, but serogroups C and G have been implicated in some cases)

DIAGNOSIS

HISTORY

- Patients with impetigo may report a history of minor trauma, insect bites, scabies, herpes simplex virus infection, varicella infection, or eczema before the development of the infection. Lesions are usually present for a few days to weeks before the patient seeks medical attention.
- Lesions may be described as itchy but are usually painless.
- Additional symptoms such as fever, respiratory distress, vomiting, or diarrhea are rare and perhaps indicative of another diagnosis.
- Outbreaks commonly occur in families and child care centers as well as among sports team members.

PHYSICAL EXAM

- Nonbullous impetigo
 - Usually occurs on exposed areas of body, most frequently the face and extremities
 - Lesions first begin as papules or thin-walled vesicles on an erythematous base. The lesions gradually enlarge, may coalesce, and break down over the course of 4–6 days. After rupture, their

serum is released, which dries and forms a thick brown, “honey-colored” crust.

- As the lesions resolve with treatment, the crusts slough from the affected areas and may leave hypopigmented areas.
- Lymphadenopathy is rare.
- Bullous impetigo
 - Lesions may form on grossly normal or previously traumatized skin.
 - Appear initially as superficial vesicles that rapidly enlarge to form flaccid bullae, filled with clear yellow liquid that gradually becomes more turbid and sometimes purulent.
 - After the lesions rupture, a thin, light brown crust remains.
 - Lymphadenopathy is rare.
- Ecthyma
 - The lesion is a vesicle or pustule overlying an inflamed area of skin that deepens into a dermal ulceration. “Punched-out” ulcers are covered with yellow crust, surrounded by raised violaceous margins.
 - Ecthyma heals slowly and commonly produces a scar.
 - Regional lymphadenopathy may occur, but systemic symptoms are usually absent.

Lab

- Impetigo is a clinical diagnosis, and no laboratory workup is routinely indicated.
- Culture of bullae or purulent fluid may be useful in patients who have failed empiric treatment. Swabs of intact skin are not helpful.
- If MRSA is suspected, a Gram stain and culture of lesion should be considered.
- If systemic symptoms are present, a CBC and blood culture should be considered to evaluate for other possible causes of infection.
- Skin biopsy may be useful if diagnosis is unclear.

DIFFERENTIAL DIAGNOSIS

- Varicella
- Staphylococcal scalded-skin syndrome
- Erythema multiforme
- Herpes simplex virus infection

- Burns (thermal and chemical)
- Contact dermatitis
- Atopic dermatitis
- Tinea corporis
- Insect bites
- Scabies
- Lice

TREATMENT

MEDICATION

- Topical therapy
 - Topical therapy is preferred when there are a limited number of lesions without bullae.
 - Mupirocin
 - 2% ointment or cream
 - Children >2 months old
 - Applied to affected areas three times daily for 5 days
 - Retapamulin
 - 1% ointment
 - Children >9 months old
 - Applied to affected area (up to 2% body surface area [BSA]) twice daily for 5 days
 - Although the components of over-the-counter triple antibiotic ointments (bacitracin, neomycin, polymyxin B) have some activity against the organisms causing impetigo, they are not considered effective for treatment.
- Oral therapy
 - Oral antibiotic therapy should be used for impetigo when the lesions are bullous or when topical therapy is impractical due to the extent or location of lesions.
 - Methicillin-sensitive *Staphylococcus aureus* (MSSA) or beta-hemolytic streptococci
 - Amoxicillin/clavulanic acid 40 mg/kg/24 h PO in 2 divided doses
 - Cephalexin 25 mg/kg/24 h PO in 4 divided doses

- Dicloxacillin 12.5 mg/kg/24 h PO in 4 divided doses
- Clindamycin 15–25 mg/kg/24 h PO in 3 divided doses
- Erythromycin 40 mg/kg/24 h PO in 4 divided doses
- When MRSA is suspected
 - Clindamycin 15–25 mg/kg/24 h PO in 3 divided doses
 - Trimethoprim-sulfamethoxazole: trimethoprim 8 mg/kg and sulfamethoxazole 40 mg/kg daily PO in 2 divided doses (has activity against MRSA but not against streptococci)

ADDITIONAL TREATMENT

General Measures

- Clipping fingernails short to minimize effects of scratching is recommended.
- Hand washing is important for reducing spread among children, as is covering the lesions.
- Treatment is important for reducing spread of infection to self and others.
- Cleansing and debriding the lesions are unnecessary.
- Crusted lesions can be cleansed gently with soap and water.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Duration of therapy
 - The duration of antimicrobial therapy should be tailored to clinical improvement; 7 days of treatment is usually adequate.
 - Children should be excluded from out-of-home child care until 24 hours after treatment has been initiated.
- Signs of incomplete therapy
 - Recurrent infection may indicate incomplete therapy, reinfection, or an *S. aureus* carrier state.
 - Development of fever is unusual and may indicate a more serious infection and/or the presence of cellulitis or an abscess.
- Prevention of recurrence
 - Impetigo frequently spreads among close contacts and family

members.

- Patients and family members should wash their hands frequently.
- Keep clothes and bedding clean.
- Do not share towels and other personal care items.
- Underlying skin conditions (e.g., eczema) and infestations (e.g., scabies) should be treated appropriately to decrease the likelihood of the development of impetigo.

COMPLICATIONS

- Cellulitis
- Lymphangitis
- Suppurative lymphadenitis
- Staphylococcal scalded-skin syndrome
- Poststreptococcal glomerulonephritis
 - Most cases are believed to be caused by a preceding streptococcal impetigo rather than streptococcal pharyngitis.
 - Deposition of group A beta-hemolytic streptococci (GABHS) nephrogenic antigens induce immune complex formation in kidneys.
 - Latent period is 3–6 weeks following skin infection.
- Scarlet fever, osteomyelitis, septic arthritis, pneumonia, septicemia, and rheumatic fever have also been observed in patients with impetigo.

PROGNOSIS

The lesions of impetigo usually heal without significant scarring. Overall, the infection is highly curable, but the condition often recurs in young children.

- L01.01 Non-bullous impetigo
- L01.09 Other impetigo

FAQ

- Q: Which is the more effective treatment for impetigo—oral or topical antibiotics?
- A: In general, if there are a few localized lesions, topical therapy is preferred. If there is more diffuse involvement, or systemic symptoms, a course of oral antibiotics is recommended.
- Q: Can a child with impetigo attend school or child care?
- A: The child should be excluded from child care until 24 hours after treatment has been initiated. Once the lesions begin to improve, the child may resume his or her activities without restrictions.
- Q: How does one help prevent impetigo from spreading?
- A: Gently wash the affected areas with mild soap and running water, use the antibiotics (topical or oral) as directed, and then cover lesions with bandages. Wear gloves when applying any antibiotic ointment to the patient's lesions and endorse thorough hand washing afterward. Do not share clothes, linens, or towels used by the affected individual until the infection has cleared.

INFANTILE SPASMS

John R. Mytinger

BASICS

DESCRIPTION

- Infantile spasms (IS) are seizures commonly associated with West syndrome—a severe infantile epileptic encephalopathy often with poor developmental outcome.
 - IS are characterized by sudden flexion, extension, or mixed flexion-extension of the neck, trunk, arms, and/or legs.
 - IS can be subtle such as a mild contraction of the abdominal muscles or subtle movements of the head, shoulder, or eyes.
 - IS can occur singly, but the clustering (often on awakening) is a key diagnostic feature.
- IS are commonly dismissed as “normal” movements or misdiagnosed as reflux/colic.
- West syndrome is classically the triad of (1) IS, (2) developmental delay, and (3) hypsarrhythmia—a chaotic, high amplitude EEG background typically associated with multifocal spikes.

EPIDEMIOLOGY

- The onset occurs in the 1st year of life in >90%, typically 3–12 months of age (peak onset 4–8 months, mean 6 months).
- Rarely occurs after 18 months of age

Incidence

The incidence is 2–3.5/10,000 live births.

PATHOPHYSIOLOGY

- Unknown
- In 70–80% of cases, a specific condition is associated with IS; however, this does not necessarily suggest a direct cause-and-effect relationship with IS.

ASSOCIATED CONDITIONS

- Hypoxic-ischemic encephalopathy (HIE)
- Chromosomal disorders such as trisomy 21
- Brain malformation such as holoprosencephaly, malformations of cortical development (such as pachygyria or lissencephaly [including Miller-Dieker syndrome with deletion of 17p13.3], hemimegalencephaly, schizencephaly, heterotopia, and focal cortical dysplasia)
- Stroke
- Intraventricular/intraparenchymal hemorrhage
- Periventricular leukomalacia
- Tuberous sclerosis complex (TSC)
- Other neurocutaneous conditions such as neurofibromatosis type 1 (NF1), incontinentia pigmenti achromians (Hypomelanosis of Ito)
- Disorders of X-linked inheritance such as Aicardi syndrome (consider in girls with agenesis of the corpus callosum and chorioretinal lacunae)
- Hydrocephalus of various causes
- There is an expanding list of IS-associated genes: ARX, CDKL5, FOXG1, GRIN1, GIN2A, MAGI2, SPTAN1, MEF2C, SLC25A22, STXBP1, SCN1A, SCN2A, GABRB3, and ALG13.
- Trauma (any but often nonaccidental)
- Progressive encephalopathy with edema, hypsarrhythmia, and optic atrophy syndrome
- Infections: meningitis/encephalitis, TORCH
- Inborn errors of metabolism such as Menkes disease, disorders of amino acid metabolism (such as phenylketonuria and maple syrup urine disease), pyruvate dehydrogenase complex deficiency, mitochondrial disorders (such as Leigh syndrome), pyridoxine-dependent seizures, glucose transporter protein type 1 (GLUT1) deficiency, and uncommonly, organic acidurias (such as methylmalonic aciduria)

DIAGNOSIS

HISTORY

- A description of spells including the timing of onset (single IS can

precede clustering)

- Prenatal and perinatal history including complications of pregnancy or delivery, gestational and maternal ages, place of birth (for access to newborn screening)
- History of HIE (perinatal, cardiac arrest, near drowning, near-miss SIDS)
- History of miscarriages, early infant death, family members with birth marks or seizures (a family history of IS is rare but can occur)
- Developmental history including any loss of skills (loss of visual tracking or social smile)

PHYSICAL EXAM

- Head circumference, dysmorphisms (such as Down syndrome or Miller-Dieker syndrome), cardiac murmur (rhabdomyoma in TSC), skin abnormalities (hypopigmented macules [may be present at birth in TSC and highlighted by the Wood's lamp] and café au lait spots [in NF1]), hepatomegaly (inborn errors of metabolism)
- Retinal evaluation (for metabolic disease and chorioretinal lacunae in Aicardi syndrome)
- Social smile, tracking, strength (head lag and axial slipping with the child held underarm in vertical suspension), tone, and reflexes

DIAGNOSTIC TESTS & INTERPRETATION

- Although nearly all children with IS have an abnormal EEG background, only 60% have hypsarrhythmia (or one of its variants). Thus, the presence of hypsarrhythmia is not required for the diagnosis or treatment of IS.
- The diagnosis is made with a video-EEG to characterize the spell and EEG background.
- An epilepsy protocol brain MRI to determine the etiology is strongly recommended.
- Early diagnosis and effective treatment can improve developmental outcome.
- The diagnostic and posttreatment EEG should include sleep, as the abnormal background is most often present during non-REM sleep.
 - IS begins with an initial phasic contraction lasting 1–2 seconds,

sometimes followed by a tonic contraction that can last 2–10 seconds.

- Most IS are clinically symmetric, but asymmetric spasms can occur and may indicate a focal brain lesion.
- The EEG background is typically high voltage and disorganized with multifocal spikes.
- The EEG correlate of IS is often a slow wave or sharp then slow wave followed by an electrodecreeement (i.e., voltage attenuation).
- A 100-mg pyridoxine infusion during the EEG to assess for background improvement may help diagnose pyridoxine-dependent seizures.

Lab

- Testing should emphasize those conditions with a specific treatment:
 - Ammonia level
 - Serum lactic acid
 - Biotinidase assay (assess newborn screen)
 - Serum amino acids (assess newborn screen)
 - Copper/ceruloplasmin (for Menkes disease)
 - Consider lumbar puncture (LP) for GLUT1 deficiency (compare CSF to serum glucose).
 - Urine organic acids (uncommon etiology, assess new born screen)
- Any metabolic, chromosomal, genetic, and CSF studies must be considered on an individual basis: karyotype and or microarray analysis (especially with dysmorphisms), IS-associated gene/panel testing, whole exome sequencing.

Imaging

- Epilepsy protocol, brain MRI is recommended.
- Consider PET to assess for or better define a lesion that may be correctable with surgery.

Diagnostic Procedures/Other

Consider LP for neurotransmitter and folate metabolites, tetrahydrobiopterin, and lactic acid.

DIFFERENTIAL DIAGNOSIS

- Normal movements confused with IS: Moro reflex and similar-

appearing startle/arousal responses; normal sleep myoclonus and hypnagogic/hypnic jerks

- Nonepileptic movement disorders confused with IS: benign myoclonus of early infancy; posturing; hyperekplexia; colic and gastroesophageal reflux (Sandifer syndrome)
- Epileptic syndrome confused with IS: benign myoclonic epilepsy of infancy
- Neonatal epileptic encephalopathies that may include or evolve to IS: early infantile epileptic encephalopathy (Ohtahara syndrome); early myoclonic epilepsy
- Childhood epileptic encephalopathy that may include or evolve from IS: Lennox-Gastaut syndrome (LGS)

TREATMENT

MEDICATION

First Line

- Generally accepted 1st-line medical treatments include adrenocorticotrophic hormone (ACTH), high-dose oral corticosteroids (HOC), and vigabatrin.
- The etiology may determine the initial treatment: epilepsy surgery (such as tumor, hydrocephalus), ketogenic diet (such as GLUT1 deficiency, pyruvate dehydrogenase complex deficiency), vigabatrin (TSC).
- The approach should focus on an early “all or none” electroclinical remission with early changes in treatment if needed.
 - If no clinical remission by 2 weeks, consider changing treatment.
 - If there is clinical remission, confirm absence of spasms with EEG (at various durations).
 - If spasms noted on EEG, consider modification of treatment.
- ACTH
 - High rates of electroclinical remission have been reported with high-dose regimens (see Baram et al, 1996 for published regimen).
 - However, one study of high-dose (150 U/m²/day) versus low-dose (20–30 U/day) found no difference in electroclinical remission.

- Short-course ACTH may limit side effects.
 - Common: weight gain (increased appetite/fluid retention), irritability, poor sleep, hypertension
 - Less common: hyperglycemia, electrolyte abnormalities (hypokalemia), hypertrophic cardiomyopathy, immunosuppression, gastritis/gastric ulcer, reduced bone mineral density, adrenal insufficiency/failure
 - Rare: death most commonly due to immunosuppression with infection
- Inpatient admission is typically performed for initiation of treatment and caregiver education.
 - Gastric acid suppression to avoid gastritis/gastric ulceration is typical.
 - ≥ 1 time weekly during treatment: blood pressure, urine glucose, and stool guaiac
 - One time weekly during treatment: electrolytes
 - Treatment of hypertension may be needed (e.g., enalapril or a reduced dose of ACTH).
- High-dose oral corticosteroids
 - High-dose regimens are recommended (see Lux et al, 2004 for published regimen)
 - The side effects, initial hospital admittance, and monitoring are the same as for ACTH.
- Vigabatrin
 - Initially, 50 mg/kg/24 h (divided twice daily) and increased by 50 mg/kg/24 h every 3 days to a maximum dose of 150–200 mg/kg/24 h (divided twice daily)
 - If there is no response in 2 weeks, use an alternative and taper vigabatrin off.
 - With electroclinical remission, the dose can be continued for 6 months and then weaned.
 - Risk of permanent peripheral visual field loss
 - The incidence and degree of retinal injury with short courses of vigabatrin (e.g., 6 months) are unknown but appear to be low.
 - The short-term rates of clinical remission appear to be superior with

hormone treatment (ACTH or HOC) compared to vigabatrin, and this may impact later developmental outcome (at least for those with an unknown etiology).

Second Line

- Ketogenic diet: treatment of choice for some conditions and can be effective for others
- Zonisamide (5–15 mg/kg/day divided twice daily)
- Valproic acid: Consider POLG mutation analysis before starting (15–45 mg/kg/day in 2–3 divided doses).
- Oral pyridoxine: Some cases of pyridoxine-dependent seizures require longer treatment trials (e.g., 10 mg/kg/day for several weeks).
- Topiramate: not a 1st-line treatment due to the low-response rates, but commonly used and occasionally effective (10–30 mg/kg/day once daily or divided twice daily)

SURGERY/OTHER PROCEDURES

- Can be effective and should be considered early (generally after failed 1st-line treatment)
 - Examples: functional hemispherectomy for stroke and hemimegalencephaly, shunting of hydrocephalus, and resection of a tumor for focal cortical dysplasia

INPATIENT CONSIDERATIONS

Initial Stabilization

After the ABCs, consider metabolic stabilization and treatment of convulsive seizures if presenting with IS (IS themselves are typically not life-threatening.).

ONGOING CARE

PROGNOSIS

- Prognosis depends on the underlying etiology and associated conditions.
- Best prognosis in those with unknown etiology and normal development before diagnosis

- About 1/3 die early (most from underlying disease and uncommonly from treatment).
- Spontaneous remission of IS can occur (cumulative rate of 25%, 1 year from onset).
- Regardless of treatment, IS typically remits (persisting beyond 7 years of age in only 8%).
- Early, successful, and sustained electroclinical remission, as well as a short time-lag to treatment, is necessary for optimal outcome
- About 1/3 with electroclinical remission will experience a relapse requiring treatment.
- About 1/2 have other seizure types (occurring before, after, or at the time of IS onset).
- 1/5–1/2 will evolve to LGS.
- 1/5–1/4 will have a favorable outcome (normal or slightly impaired intelligence).
- About 1/3 will have autism (common in TSC).
- About 2/5 will have cerebral palsy.

COMPLICATIONS

For hormone treatment: Hold non-live vaccines for 2 months and live vaccines for 6 months.

CODES

ICD10

- G40.822 Epileptic spasms, not intractable, w/o status epilepticus
- G40.824 Epileptic spasms, intractable, without status epilepticus

FAQ

- Q: Should I prescribe an abortive medication for longer clusters of IS?
- A: Generally, No. IS do not typically respond acutely to benzodiazepines.
- Q: My patient has IS and an abnormal EEG but no hypsarrhythmia. Should I treat him?
- A: Yes. Treat the seizures with 1st-line therapy; only 60% will have hypsarrhythmia.
- Q: Caregivers report that IS has resolved with treatment. Do I need the EEG?
- A: Yes. IS can be subtle making them difficult to detect. In addition, you must have evidence of EEG background improvement.

INFLUENZA

Kristen A. Feemster

BASICS

DESCRIPTION

An acute febrile illness characterized by fever, malaise, and respiratory symptoms

EPIDEMIOLOGY

- Although influenza affects people of all ages, the highest morbidity and mortality occur in young children <2 years old, the geriatric population, and those with high-risk conditions.
- Influenza epidemics occur almost exclusively during winter months, peak ~2 weeks after the index case, and last 4–8 weeks.
- Attack rates are highest among school-aged children (range 10–40%).
- An estimated 10–20% outpatient visits among children <5 years old attributable to influenza
- Transmission of influenza virus occurs via large respiratory droplets or contact with contaminated surfaces.
- After an incubation period of 1–4 days, viral shedding starts 24 hours before symptom onset and usually continues for 7 days.
 - Prolonged shedding in young children and immunocompromised individuals

RISK FACTORS

High-risk conditions for severe disease include the following:

- Chronic pulmonary disease (i.e., asthma)
- Hemodynamically significant cardiac disease
- HIV and other immunodeficiencies
- Chronic immunosuppressive therapy
- Hemoglobinopathies (i.e., sickle cell disease)
- Long-term salicylate use
- Chronic renal dysfunction
- Chronic metabolic disease, morbid obesity

- Neuromuscular disorders

GENERAL PREVENTION

- Vaccination
 - Routine influenza vaccination for ALL individuals ≥ 6 months old
- Prioritize vaccination for those at highest risk for influenza complications and their close contacts, including young children ages 6–59 months, older adults ≥ 50 years, adults and children with certain chronic diseases and high-risk conditions, long-term care facility residents, American Indians/Alaska Natives, pregnant women, health care professionals, out-of-home caregivers and household contacts of all children < 5 years old OR children 5–18 years old with high-risk conditions (see “[Risk Factors](#)”).
- Vaccine types
 - Trivalent inactivated influenza vaccine (TIV) approved for ages ≥ 6 months; administered as an intradermal injection
- Quadrivalent influenza vaccines newly available for 2013–2014 season and beyond; include second influenza B strain
 - Inactivated: Fluarix (GlaxoSmithKline) for ages ≥ 3 years and Fluzone (Sanofi Pasteur) for ages ≥ 6 months
 - Live-attenuated influenza vaccine (LAIV); for healthy nonpregnant 2–49-year-olds; administered as an intranasal spray
- Trivalent cell culture-based inactivated vaccine (Flucelvax, Novartis) for ages ≥ 18 years
- Recombinant hemagglutinin vaccine (FluBlok, Protein Sciences) for ages 18–49 years; egg-free
- Special vaccination considerations:
 - There is no preferential recommendation for one vaccine product over another for children who can receive more than one of the available vaccines.
 - Children ≤ 8 years old receiving seasonal influenza vaccination for the first time should receive 2 doses of vaccine at least 4 weeks apart.
- LAIV not recommended for individuals with high-risk conditions, young children (ages 2–4 years) with history of wheezing in past year, contacts of severely immunocompromised persons (such as contacts of

BMT patients in a protected environment), or children receiving chronic aspirin therapy

- LAIV can be given simultaneously with other live or inactivated vaccines. However, after administration of any live vaccines, a minimum of 4 weeks should pass before administering another live vaccine.
- Contraindications to vaccination: history of severe allergic reaction to any vaccine component or after previous influenza vaccine dose
 - Precautions: Those with history of Guillain-Barré syndrome within 6 weeks of previous influenza vaccination should consult a physician before receiving the vaccine.
- Influenza vaccines can be safely administered to children with history of egg allergy (see <http://www.cdc.gov/flu/professionals/acip/> for specific recommendations).
- Postexposure chemoprophylaxis
 - Indicated for high-risk children who are unvaccinated or were vaccinated within 2 weeks of exposure, immunocompromised patients who have a poor vaccine response, or to control outbreaks in institutions housing high-risk people
 - Chemoprophylaxis should begin within 48 hours of exposure to be most effective.

ETIOLOGY

- Orthomyxoviruses influenza types A, B, and C. Influenza C virus has not been reported as a cause of influenza epidemics.
- Influenza A subtypes defined by 2 surface antigens: hemagglutinin and neuraminidase.
 - Currently circulating subtypes include pH1N1 (pmd09) and H3N2.
- Mild variation, or antigenic drift, for both A and B viruses results in seasonal epidemics; antigenic shift occurs only with A viruses and results in pandemics.

DIAGNOSIS

Clinical case definition of influenza-like illness is fever ($\geq 100^{\circ}\text{F}$) AND

cough and/or sore throat but may look similar to other respiratory illnesses.

- Positive predictive value of these symptoms for influenza lower (~65%) among children <5 years old
- Clinical presentation varies with age:
 - Infants and young children are less likely to present with typical symptoms but may have higher fever and more severe respiratory symptoms.

HISTORY

- Abrupt onset of illness, beginning with chills, headache, malaise, and dry cough
- Subsequent increase in respiratory tract symptoms that can range from mild cough to severe respiratory distress (infants)
- Other symptoms: fever, anorexia, myalgias, sore throat, irritability
- Younger children may have GI complaints including vomiting, diarrhea, and severe abdominal pain.
- Children may also present with otitis media.

PHYSICAL EXAM

- Cough is the predominant respiratory sign. Infants and small children may exhibit a “barky” cough (croup).
- Nasal congestion with conjunctival and pharyngeal injection
- Cervical adenopathy, especially in children
- Neonates may appear septic with apnea, circulatory collapse, or petechiae.
- A generalized macular or maculopapular rash is sometimes observed.

DIAGNOSTIC TESTS & INTERPRETATION

Laboratory testing can confirm diagnosis, provide surveillance data, and help guide treatment and infection control decisions because clinical symptoms alone may not accurately identify all influenza cases. However, during periods of high influenza activity when the likelihood of infection is high and a child has symptoms consistent with influenza, testing may not be indicated.

- Gold standard: RT-PCR or viral culture
 - RT-PCR preferred: most accurate and sensitive; results within 3–8 hours

- Only viral culture can be used to measure subtype and antiviral resistance of circulating strains but requires 3–10 days.
- Direct immunofluorescent antibody (DFA) and indirect immunofluorescence antibody (IFA) tests have moderate sensitivity (60–70%) and excellent specificity (>95%) and are completed within 2–4 hours.
 - Predictive value greatly affected by prevalence of circulating influenza.
- Rapid antigen testing (RIDT) available for diagnosing influenza A and influenza B. Results available in ~15 minutes but with wide range of sensitivities (22–77% in community settings) which may limit their usefulness.
- A negative test result should not guide management, especially when community prevalence is high.
- Serology: Look for 4-fold rise in serum antibody titers between acute and convalescent samples (at least 10–14 days apart); not helpful for clinical decision making
- Special considerations for laboratory testing:
 - The false-positive rate for DFA, IFA, and rapid antigen testing may be as high as 20% (influenza A) and 40% (influenza B).
 - Nasopharyngeal aspirates rather than swabs may reduce false-positive rate by 5–10%.
 - Tests most sensitive <4 days of symptom onset

Imaging

Chest x-ray

- May be normal despite significant respiratory involvement
- X-rays of patients with lower airway disease are indistinguishable from those in patients with other viral lower respiratory infections.

Ancillary Laboratory Data

- Leukocyte count may be high, low, or normal with a variable differential.
- Arterial blood gas analysis or pulse oximetry to evaluate oxygenation in severe cases of influenza infection. Infants without radiologic evidence of lower respiratory tract infection can experience apnea or rapid decrements in pulmonary function.

- May see elevated creatine phosphokinase (CPK) with benign acute viral myositis. If with myoglobinuria, consider acute viral rhabdomyolysis, which can damage the kidneys. May require hospitalization and hydration.

DIFFERENTIAL DIAGNOSIS

- Viral infections including but not limited to respiratory syncytial virus, parainfluenza, adenovirus
- Streptococcus pyogenes, Mycoplasma pneumoniae, or Legionella spp infection
- Bacterial sepsis in young infants

TREATMENT

MEDICATION

- Antiviral treatment is recommended for any patient who is
 - Hospitalized
 - Has severe or progressive illness
 - At high risk for complications
- Treatment most effective when initiated <2 days after symptom onset but may still reduce morbidity and mortality for hospitalized patients or patients with severe disease if started up to 5 days after symptom onset.
- Treatment of healthy children with suspected or confirmed influenza in the outpatient setting is at the clinician's discretion but should be initiated <2 days after symptom onset.
- Neuraminidase inhibitors: the recommended antiviral medications for both treatment of and chemoprophylaxis against influenza A and B
- Dosage recommendations:
 - Zanamivir is approved for treatment in children ≥ 7 years and prophylaxis in children ≥ 5 years of age.
 - ▢ Treatment: two 10-mg inhalations b.i.d. \times 5 days
 - ▢ Prophylaxis: two 10-mg inhalations once per day \times 10 days
 - ▢ Can cause bronchospasm so should not be used in patients with history of chronic pulmonary diseases such as asthma

- Oseltamivir is approved for treatment in children ≥ 2 weeks of age and prophylaxis in children ≥ 1 year of age.
 - Dose depends on age and weight (<1 year: 3 mg/kg/dose; >1 year and <15 kg: 30 mg; 15–23 kg: 45 mg; >23–40 kg: 60 mg; >40 kg: 75 mg), twice per day \times 5 days for treatment and once daily \times 10 days for prophylaxis
 - May cause nausea and vomiting
- Amantadine hydrochloride and rimantadine: approved for treatment of influenza A in children >1 year of age but NOT recommended for either treatment or prophylaxis due to increasing resistance. Neither effective against influenza B.
- Resistance to neuraminidase inhibitors <1% among currently circulating influenza strains
- Investigational parenteral medications: peramivir and zanamivir
 - For severely ill high-risk patients with suspected or confirmed oseltamivir-resistant infection
 - Available through emergency investigational new drug protocol only
- Consider longer course of therapy if patient remains severely ill after 5 days.
- Preexposure prophylaxis can be considered for very high-risk patients who cannot be protected through other means when there is high risk of exposure to influenza cases.
 - Duration depends on expected duration of exposure, but 4–6 weeks has been well tolerated.
- Chemoprophylaxis should not be given within 14 days after LAIV receipt as the vaccine strains are susceptible to the antiviral medications.

ADDITIONAL TREATMENT

General Measures

- Most patients with influenza infection require supportive oral hydration, antipyresis, and routine decongestant therapy.
- With the exception of young infants, previously healthy children with influenza infection rarely require emergency treatment.
- Humidified air, with oxygen as needed, is helpful to most patients with

respiratory symptoms.

- Airway maneuvers, including endotracheal intubation, may be required for severe laryngotracheitis or patients with hypoxia that is unresponsive to high-flow oxygen administration.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

When to expect improvement:

- Fever associated with influenza infection usually lasts up to 5 days. Recrudescence of fever does not necessarily signify the onset of a secondary bacterial infection.
- Cough may last up to 2 weeks.
- Lethargy or malaise may persist for up to 2 weeks.
- Influenza A infection usually lasts longer than influenza B or influenza C infection.

COMPLICATIONS

- Secondary bacterial infections including pneumonia (pneumococcal or staphylococcal)
- Otitis media (24%)
- Sinusitis
- Primary progressive viral pneumonia
- Pulmonary hemorrhage
- Acute myositis during convalescence
 - More common with influenza B
 - Marked by extreme muscle tenderness, especially in the calf muscles
- Rhabdomyolysis/myoglobinuria
- Elevated transaminase levels
- Reye syndrome: fatty degeneration of the liver and diffuse encephalopathy; associated with aspirin use during acute illness
 - More commonly associated with influenza B but may also occur with influenza A
- Febrile convulsions

- Drug toxicity: Influenza infection may result in increased serum levels of certain medications that are metabolized by the liver.
- Rare sequelae in severe cases of influenza infection:
 - Focal and diffuse myocarditis
 - Diffuse cerebral edema
 - Mediastinal lymph node necrosis
 - Sudden death
 - Guillain-Barré syndrome
 - Encephalitis

Patient Monitoring

Signs to watch for:

- Clinical signs of secondary bacterial infection
- Deteriorating mental or respiratory status after initial improvement
- Myoglobinuria in the face of muscle pain

FAQ

- Q: When is it safe for a child with influenza to return to day care or school?
- A: Older children with influenza may shed the virus in nasal secretions for up to 7 days from onset of symptoms and younger children even longer. Therefore, older children with influenza may return to school 1 week after onset of symptoms, and infants and toddlers should remain home for 10–14 days.
- Q: Can a child on chronic steroid therapy be immunized against influenza?
- A: In general, children who require maintenance steroid therapy for their underlying illness should still receive influenza immunization. If possible, immunize while the child is on the lowest possible dose of steroids.
- Q: Is chemoprophylaxis an acceptable alternative for protecting children against influenza?
- A: In general, chemoprophylaxis should not be used as a substitute for vaccination. Specific recommendations and indications for chemoprophylaxis can be found at www.cdc.gov/flu/professionals/antivirals/summary-clinicians.htm.

INGUINAL HERNIA

Nora M. Fullington • Jeremy T. Aidlen

BASICS

DESCRIPTION

Inguinal hernia is a protrusion of abdominal contents (intestine, omentum) into, and often through, the inguinal canal.

EPIDEMIOLOGY

- Inguinal hernia is the most frequent problem requiring elective surgical intervention in children.
- Significantly more common in boys (90% of cases)
- Has a familial tendency
- Because of later descent of right testis and subsequently delayed obliteration of right processus vaginalis, inguinal hernia presents more frequently on the right side.
 - Clinical presentation is on the right side in 60% of cases, on the left side in 30%, and bilateral in 10%.
- Frequency varies with age and ranges from 3–5% in full-term babies to 10–30% in preterm infants.

RISK FACTORS

- Prematurity
- Urologic conditions: cryptorchidism, hypospadias, epispadias, bladder exstrophy
- Abdominal wall defects: gastroschisis, omphalocele, Eagle-Barrett syndrome
- Conditions that increase intra-abdominal pressure (e.g., ascites, peritoneal dialysis, ventriculoperitoneal shunt)
- Cystic fibrosis
- Connective tissue disease: Marfan syndrome, Ehlers-Danlos syndrome
- Mucopolysaccharidoses
- Family history

PATHOPHYSIOLOGY

Indirect inguinal hernia

- During the 7th month of male gestation, the testes begin their descent from the peritoneal cavity through the inguinal canal into the scrotum.
- Between the 7th and 9th months of gestation, after the testes reach the scrotum, the path of peritoneum through which the testicle passed (processus vaginalis) begins to obliterate spontaneously, leaving only a small potential space adjacent to the testes (tunica vaginalis).
- In girls, although the ovaries do not leave the abdomen, the round ligament (part of the gubernaculum) travels through the inguinal ring into labium majus. When the processus vaginalis remains open, it is called the canal of Nuck.
- Incomplete obliteration of the processus vaginalis leaves a sac of peritoneum extending all the way from the internal inguinal ring to the scrotum or labium majus, through which an inguinal hernia may develop.

Direct inguinal hernia

- Uncommon in children
- Results from either a congenital or acquired/traumatic weakness or tear in abdominal wall fascia

Other types of inguinal hernias

- Sliding hernia occurs when one wall of the hernia is composed of abdominal viscera (bladder, colon, adnexa).
- Richter hernia results from the herniation of only a part of the bowel wall. If this hernia is incarcerated/strangulated, it may progress to bowel perforation without obstruction.
- Hernia of Littre includes a Meckel diverticulum within the hernia sac.
- Amyand hernia is an inguinal hernia in which the appendix is included within the hernia sac.

DIAGNOSIS

HISTORY

- Most common presentation is complaint of swelling or bulge in the inguinal area.

- Intermittently appearing
 - Present during times of increased intra-abdominal pressure such as crying or straining
 - A picture taken by the caregiver while the hernia is out may be helpful.
- Reducible hernias are not generally painful.
- If bulge is painful, incarcerated inguinal hernia must be suspected, and other etiologies (e.g., testicular torsion) should be excluded.

PHYSICAL EXAM

- Examine the child in the supine and upright positions.
- If the bulge is apparent in the standing position but disappears when the child is supine, presence of a hernia is strongly suggested.
 - Reduction of hernia contents through the inguinal ring is confirmatory.
 - If the bulge is not readily apparent, perform maneuvers that increase intra-abdominal pressure (gently press on his or her abdomen, have him or her cough, or strain or jump around).
- Transillumination
 - Can be an unreliable finding, particularly in babies
 - Some inguinal hernias (which usually do not transilluminate) can be differentiated from hydroceles (which usually do transilluminate).
- Silk glove sign
 - When empty hernia sac is palpated over the cord structures, sensation is similar to rubbing 2 layers of silk together: thick tissue that slides over cord structures
- Tender scrotal mass: Consider incarcerated hernia, testicular torsion, epididymitis, orchitis, or trauma.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- In cases where incarceration is suspected, such as presentation with a hard, painful, swelling in the groin, CBC and chemistry should be checked. Leukocytosis or acidosis should increase concern for compromised bowel.
- Genetic testing

- Karyotype is necessary when a testis is discovered during hernia repair in a phenotypic female. Biopsy of the gonad is also typically performed.
- 1% of full-term females with bilateral inguinal hernias have a disorder of sexual development—complete androgen insensitivity.

Imaging

Diagnosis is usually made with history and physical exam. However, use of scrotal or inguinal ultrasonography is indicated in cases involving:

- Scrotal tenderness
 - Suggestion of torsion (use duplex ultrasound to evaluate blood flow)
 - Scrotal trauma and concern for testicular rupture
- Mass along the spermatic cord or testicular tumor

DIFFERENTIAL DIAGNOSIS

- Lymphadenopathy
- Hydrocele
- Retractable testis
- Undescended testis
- Varicocele
- Testicular tumor

TREATMENT

GENERAL MEASURES

- Try to reduce the hernia with the child in the supine and/or head-down position so that gravity assists the maneuver.
- Many suggest application of pressure to hernia that is directed toward the inguinal canal.
- Gentle traction of the sac away from the canal and toward the contralateral knee is sometimes more effective if constant pressure is applied to the hernia sac contents.
 - The neck of the hernia is elongated by the traction and placed in line with the inguinal canal.
 - As edema is squeezed out, contents slip back into the abdomen.

- It is typical to feel a “pop” at the internal ring once the hernia is completely reduced. This can lead to immediate relief of symptoms.

SURGERY/OTHER PROCEDURES

Inguinal hernia will not resolve spontaneously and must be treated surgically to avoid incarceration.

- Complication rate after elective inguinal hernia repair is low (1–2%).
- Hernia incarceration commonly occurs in the 1st year of life and is associated with markedly increased complication rate at repair (20%). To avoid this risk, repair is recommended soon after diagnosis of an inguinal hernia.
- Surgeons will often wait 24–48 hours after reduction of an incarcerated hernia to operate in order to allow edema to resolve.
- Routine contralateral inguinal exploration in children with unilateral hernia continues to be a topic of debate. Some surgeons perform diagnostic laparoscopy to evaluate for a contralateral patent processus vaginalis at the time of unilateral herniorrhaphy.
- Laparoscopic inguinal hernia repair can be performed safely in children of all ages, with a variety of techniques.

INPATIENT CONSIDERATIONS

There is no consensus regarding the optimal timing for hernia repair in hospitalized infants. The risk of incarceration must be balanced against the potential risks of operative and anesthetic complications.

ONGOING CARE

PATIENT EDUCATION

- Preoperative: Parents should consult a physician immediately if signs of incarceration are present (firm or tender lump, pain, or emesis).
- Postoperative: Avoidance of major physical activity for 1 week is recommended.

COMPLICATIONS

- Incarceration: >50% of cases occur within the first 6 months of life.
- Bowel obstruction secondary to incarcerated loop of small intestine

- Strangulation: incarceration with progression to ischemia
- Intestinal infarction can lead to perforation and peritonitis.
- Testicular/ovarian ischemia or infarction. Ovaries are less likely to suffer ischemic insult given narrow vascular pedicle.

CODES

ICD10

- K40.90 Unil inguinal hernia, w/o obst or gangr, not spcf as recur
- K40.20 Bi inguinal hernia, w/o obst or gangrene, not spcf as recur
- K40.30 Unil inguinal hernia, w obst, w/o gangr, not spcf as recur

FAQ

- Q: When should a pediatric surgeon be consulted for a suspected inguinal hernia?
- A: Inguinal hernias do not resolve and require repair to avoid the complications associated with incarceration and strangulation. A pediatric surgeon should be consulted at the time of diagnosis in order to plan for herniorrhaphy. Additionally, findings suspicious for incarceration or strangulation such as a painful, swollen mass in the inguinal area should result in immediate pediatric surgical consultation as urgent intervention may be required.

- Q: At what age is a patient most at risk for incarceration of an inguinal hernia?
- A: Incarceration of an inguinal hernia most often occurs within the first 6 months of life.

INTELLECTUAL DISABILITY

Rita Panoscha

BASICS

DESCRIPTION

- Intellectual disability (formerly called mental retardation) is characterized by a slow rate of learning or slow cognitive-processing abilities. By definition, there are significant cognitive and adaptive delays first evident in childhood. Significant cognitive delays are defined as 2 standard deviations below the population mean on a standard cognitive or IQ test.
 - Usually indicates an IQ score of <70 –75
- Adaptive skills are the functional skills of everyday life, including communication, social skills, daily living/self-care skills, and the ability to safely move about the home and community.
- Intellectual disability is typically subdivided into mild, moderate, severe, and profound categories, depending on the severity of the delays. A more recent definition by the American Association on Mental Retardation (AAMR) puts more emphasis on the level of functioning and the amount of support required by an individual.

ALERT

- Children with behavioral problems may also be masking cognitive delays.
- Hearing impairment may present as a delay in development.
- Children with mild intellectual disability may not be diagnosed as having a problem until they are having difficulties keeping up in elementary school.

EPIDEMIOLOGY

Found in both sexes and all racial and socioeconomic groups

Prevalence

- Prevalence of intellectual disability is generally listed as 2–3% of the population.

- Of the different subcategories of intellectual disability, the mild form is the most prevalent, at 85% of those with intellectual disability.
 - Profound intellectual disability is least prevalent, at ~1% of this group.

GENERAL PREVENTION

- There is no specific prevention, but prevention of some underlying causes may be possible.
- Immunization programs, early detection of metabolic disorders, and education programs for head injury/asphyxia prevention may be useful in some cases.
- Avoidance of alcohol and some drugs during pregnancy may also decrease the likelihood of some specific brain insults.

ETIOLOGY

- The cause of the intellectual disability is usually an insult to the brain or abnormal development of the CNS but is not evident in many cases. The following represent potential causes.
- Genetic/familial/metabolic
 - Fragile X syndrome
 - Trisomy 21 (Down syndrome) and other chromosomal abnormalities
 - Tuberous sclerosis
 - Neurofibromatosis
 - Phenylketonuria (PKU)
 - Other inborn errors of metabolism
- Nervous system anomalies
 - Hydrocephalus
 - Lissencephaly
 - Seizures
- Endocrinologic
 - Congenital hypothyroidism
- Infectious
 - Prenatal cytomegalovirus, rubella, toxoplasmosis, HIV
 - Postnatal bacterial meningitis, neonatal herpes simplex
- Environmental toxins

- Heavy metal poisoning such as lead
- In utero drug or alcohol exposure, including fetal alcohol syndrome
- Traumatic
 - Closed-head trauma
 - Asphyxia

COMMONLY ASSOCIATED CONDITIONS

- Associated findings are more common in the more severe forms of intellectual disability.
- Intellectual disability has many associated findings, including seizures, autism, cerebral palsy, communication disorders, failure to thrive, sensory impairments, and psychiatric disorders.
- Behavioral disorders can be seen, including attention-deficit/hyperactivity disorder and self-injurious and self-stimulating behaviors.
- Families often face additional stressors when caring for a child with intellectual disability.

DIAGNOSIS

HISTORY

Complete information regarding the following:

- Pregnancy history
 - Maternal age and parity
 - Maternal complications (including infections and exposures)
 - Medications/drugs used
 - Tobacco or alcohol used, along with quantities
 - Fetal activity
- Birth history
 - Gestational age
 - Birth weight
 - Route of delivery
 - Maternal or fetal complications/distress
 - Apgar scores
- General health

- Significant illnesses, hospitalizations, or surgeries
- Accidents or injuries
- Hearing and vision status
- Medications used
- Known exposures to toxins
- Any new or unusual symptoms
- Developmental history
 - Current developmental achievement in each stream of development
 - Age when developmental milestones were achieved
 - Any loss of skills
 - Where parents think their child is functioning developmentally
- Educational history
 - Type of schooling and services received, if any
 - Any previous educational/developmental testing
- Behavioral history
 - Any perseverative or stereotypical behaviors
 - Interaction skills
 - Attention and activity levels
- Family history
 - Family members with developmental delays, neurologic disorders, syndromes, inherited disorders, or consanguinity

PHYSICAL EXAM

A complete physical exam including growth parameters is needed looking for etiology. Key features to include are the following:

- Observation of interactions and behavior
 - Atypical behaviors and general impressions
- Head circumference
 - Macro- or microcephaly
- Skin exam
 - Neurocutaneous lesions
- Major or minor dysmorphic features
 - Indication of a syndrome or anatomic malformation
- Neurologic exam
 - Assess for cranial nerve deficits, neuromuscular status, reflexes, balance and coordination, and any soft signs.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab test

- There is no specific laboratory test battery for intellectual disability.
- Testing must be tailored to the individual situation based on history and physical exam. A high index of suspicion should be maintained for any associated findings and delays in the other streams of development. Listed below are some of the more common studies.
- Genetic testing
 - For any dysmorphic features or a family history of delays or genetic disorder, a karyotype and fragile X DNA testing should be considered, particularly for significant cognitive delays, although the comparative genomic hybridization (CGH) microarray is increasingly recommended as a 1st-line genetic test.
- Metabolic tests
 - Quantitative plasma amino acid, quantitative urine organic acid, lactate, pyruvate, or ammonia levels should be considered if there is any loss of skills or indication of a metabolic disorder.
 - Additional metabolic tests may be indicated depending on symptoms.
- Thyroid function tests
 - Most infants will have had screening for hypothyroidism shortly after birth. This should be rechecked if symptoms indicate.

Imaging

Head MRI: Consider for head abnormalities, significant neurologic findings, loss of skills, or for workup of a specific disorder, such as trauma or leukodystrophy.

Diagnostic Procedures/Other

- When developmental delays are present and intellectual disability is suspected, more formal developmental screening or testing should be done.
- The pediatrician can do some in office developmental screening, but the diagnosis needs to be made based on standardized tests, usually done by a clinical psychologist. Such standardized testing might involve the Stanford-Binet Intelligence Scale, the Wechsler scales, and

the Vineland Adaptive Behavior Scales.

- Audiologic testing
 - For any child with speech and language and/or cognitive delays
- EEG
 - An EEG should be considered if there is any concern about seizures.

DIFFERENTIAL DIAGNOSIS

The differential can include several other developmental diagnoses, including the following:

- Borderline cognitive abilities
- Developmental language disorder
- Autism
- Learning disability
- Cerebral palsy
- Significant visual or hearing impairment
- Degenerative disorders

TREATMENT

GENERAL MEASURES

- There is no specific cure for intellectual disability. The ultimate goal of all therapies is to help the child reach his or her full potential.
- Therapy should consist of appropriate treatment for any underlying or associated medical condition.
- Early intervention and special education programs are available for an individualized education program based on the child's needs and abilities.
- Behavior management programs or selected use of medications is available for patients with severe behavioral problems.

ISSUES FOR REFERRAL

- A referral is made to a clinical psychologist for the formal diagnosis.
- Subspecialists
 - Referral to other medical specialists may also be indicated.
 - These specialists may include developmental pediatrics, neurology, genetics, or ophthalmology.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Children with intellectual disability will need regular pediatric preventive care in addition to management of any underlying medical conditions.
- Ongoing monitoring of the educational programs, to ensure that it is still meeting the child's needs, is important.
- The family will also need ongoing counseling and support in dealing with a child having special needs.

PROGNOSIS

- The prognosis for longevity varies with the associated findings and overall health, but individuals with intellectual disability can live to adulthood and old age.
- An individual's level of functioning is variable depending on the level of retardation, special individual skills, and family or community supports. In general, the following applies:
 - Mild intellectual disability (IQ 55–70): formerly called educable. May be in school with extra help and may achieve roughly a 4th–6th grade level in reading and math. May be employed in an unskilled to semiskilled job. May live in a group home or independently.
 - Moderate intellectual disability (IQ 40–54): may learn to recognize basic words and learn basic skills. May work in a sheltered workshop or with supported employment in an unskilled job. May live with family or in a group home doing much of their own care.
 - Severe intellectual disability (IQ 25–39): may live with family or in a group home or institution. Some may be in a sheltered workshop. May be able to do some daily self-care or chores with supervision.
 - Profound intellectual disability (IQ <25): live with family, in a group home, or in institution. Usually require full-time care.

CODES

ICD10

- F79 Unspecified intellectual disabilities
- F70 Mild intellectual disabilities
- F71 Moderate intellectual disabilities

FAQ

- Q: Will my child be “normal” by adulthood?
- A: Generally, intellectual disability is considered a lifelong condition.

Some individuals, usually with the milder form of intellectual disability, can function well in the community, especially when given added supports.

- Q: Can my child learn?
- A: Except for the most severe forms of intellectual disability, children do learn. This learning may not be as rapid or as extensive as that of a typically developing child.
- Q: But my child looks fine and has had appropriate motor development. How can he be mentally retarded?
- A: Mental retardation or intellectual disability is a slowed rate of cognitive development. Many children with intellectual disability do not have obvious dysmorphic features. Other streams of development, such as gross motor skills, may be reached on time or nearly so, yet the cognitive developmental streams can be significantly delayed.

INTESTINAL OBSTRUCTION

Nora M. Fullington • Jeremy T. Aidlen

BASICS

DESCRIPTION

- Blockage of normal flow of air and other contents through the intestine
 - May be partial or complete, mechanical or functional
 - May arise from intrinsic abnormalities (e.g., meconium ileus, intestinal atresia) or extrinsic abnormalities (e.g., adhesions, bands, or volvulus)
 - May also be caused by neuromotor dysfunction of the gastrointestinal tract (i.e. hypomotility or paralysis of the intestine)
 - Most commonly involves the small bowel
- Untreated, obstruction can lead to intestinal ischemia.

PATHOPHYSIOLOGY

- Pathophysiology depends on the mechanism of the obstruction.
- Functional obstruction (paralytic ileus)
 - Failure of intestinal motor function without mechanical obstruction
 - Common after abdominal surgery, following extensive manipulation of the bowel
 - Other causes: infection (pneumonia, gastroenteritis, urinary tract infection, peritonitis, systemic sepsis), drugs (e.g., opiates, loperamide, vincristine), metabolic abnormalities (hypokalemia, hypomagnesemia, uremia, myxedema, and diabetic ketoacidosis)
- Mechanical obstruction
 - Intestinal dilation proximal to site of obstruction as the bowel fills with intestinal contents and air
 - Common after abdominal surgery following extensive manipulation of the bowel
 - Buildup of intestinal contents results in further distention, nausea, and vomiting.
 - Internal and external losses result in hypovolemia, oliguria, and azotemia.

- Bacteria proliferate in the small bowel and its contents can become feculent.
- “Closed loop” obstruction occurs when contents cannot get in or out of an intestinal segment.
- Ischemic obstruction
 - Occurs secondary to occlusion of intestinal blood supply
 - Causes
 - Twisting/kink of feeding blood vessels
 - Increased intramural pressure in the setting of bowel distention can result in decreased perfusion to the affected area.
 - With progression, gangrene, peritonitis, and perforation may occur.
 - Damage to the normal gut barrier may enable bacteria, bacterial toxins, and inflammatory mediators to enter the circulation, causing sepsis.

ETIOLOGY

May be congenital (e.g., atresia, duplication), acquired (e.g., neoplastic, inflammatory), or iatrogenic (e.g., adhesions, radiation stricture)

Etiology varies by age:

- Neonates
 - Intestinal atresia (most common cause in neonates)
 - Obstructive meconium disorders (associated with cystic fibrosis)
 - Meconium ileus
 - Meconium plug syndrome
 - Meconium peritonitis
 - Duodenal atresia (associated with Down syndrome)
 - Annular pancreas
 - Anorectal malformation/Imperforate anus
 - Necrotizing enterocolitis
 - Hirschsprung disease
- Infants
 - Pyloric stenosis (age: 1–2 months)
 - Intussusception (age: 2 months to 2 years)
 - Postoperative adhesions
 - Incarcerated inguinal hernia
 - Hirschsprung disease

- Duplications
- Meckel diverticulum
- Older children
 - Postoperative or postinfectious intestinal adhesions (e.g., perforated appendicitis)
 - Inflammatory bowel disease
 - Malrotation with or without midgut volvulus
 - Annular pancreas
 - Meckel diverticulum
 - Superior mesenteric artery syndrome
 - Corrosive injury
 - Foreign body ingestion
 - Juvenile polyposis and related syndromes
 - Distal intestinal obstruction syndrome (cystic fibrosis)
 - Roundworm (*Ascaris lumbricoides*)
 - Gastric and intestinal bezoars
 - Colonic volvulus secondary to aerophagia and constipation (more common in neurodevelopmentally impaired)
 - Cancer-related intestinal obstruction and radiotherapy-induced adhesions

DIAGNOSIS

- Presentation may be acute and dramatic or chronic and subtle. Chronic or intermittent obstruction can be more challenging to diagnose.
- Careful history, physical examination, and consideration of age-related etiology will usually identify the specific cause.

HISTORY

- The classic symptoms of intestinal obstruction include vomiting, abdominal distention, colicky abdominal pain, and failure to pass flatus/stool (vomiting will be bilious if obstruction is distal to ampulla of Vater). Closed loop obstruction may present with pain and retching without emesis.
- Neonates

- History of maternal polyhydramnios and aspiration of >20 mL gastric fluid after birth may suggest high intestinal obstruction.
- Failure to pass meconium within 48 hours of birth is suggestive of a distal obstruction.
- Older children
 - Commonly present with pain which can be poorly localized, colicky visceral pain or sharp peritoneal pain
 - Nausea and vomiting: High intestinal obstruction results in bilious emesis; distal obstruction may lead to feculent emesis.
 - Passage of blood or mucus per rectum may be a sign of intestinal ischemia or mucosal sloughing (e.g., intussusception and volvulus).

ALERT

Due to potentially delayed diagnosis and reduced functional reserve, neonates with unrecognized intestinal obstruction deteriorate rapidly, with increased morbidity, mortality, and surgical complications.

PHYSICAL EXAM

- General assessment and vital signs, signs of dehydration, sepsis, or malnutrition
- Palpation typically reveals abdominal distention. It may also reveal the presence of a hernia, a mass suggestive of stool, or intussusception.
- Tenderness denotes inflammation, significant distention, or ischemia and should raise concern for bowel compromise. Guarding and rigidity result from full-thickness bowel wall involvement or perforation/peritonitis.
- Bowel sounds are unreliable. They may be initially increased in hyperperistaltic obstructed loops. They may also become decreased, occasional, or even absent; typically absent sounds with ileus
- Anal inspection excludes anorectal malformation. Rectal examination reveals, at times, a palpable polyp or intussusceptum and blood (overt, occult, or “currant jelly,” typical of intussusception).
- Fever, tachycardia, signs of peritonitis, and severe pain that persists after nasogastric decompression may indicate a need for surgical intervention.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- No laboratory studies are diagnostic, but CBC, electrolytes, and blood gas should be obtained to help optimize supportive treatment.
- Assess for hypochloremic, hypokalemic metabolic alkalosis.
- Bowel infarction may lead to marked leukocytosis, thrombocytopenia, and metabolic acidosis.
- Serum amylase and lipase should be determined to rule out pancreatitis (may be mildly elevated in intestinal obstruction).

Imaging

- Plain abdominal x-rays: supine and erect or decubitus views may identify the classic features: gasless abdomen or air–fluid levels and distended loops of intestine
 - In small bowel obstruction: dilated small bowel, air–fluid levels without gas in the colon
 - Paralytic ileus: distended loops of bowel throughout.
 - Duodenal obstruction: “double-bubble” sign
 - Pneumoperitoneum in perforation
 - Peritoneal calcifications in meconium peritonitis
 - Right lower quadrant ground-glass appearance in meconium ileus
 - High small bowel obstruction or ischemic obstruction (midgut volvulus) may present with normal or nearly normal X-rays.
- Ultrasonography: may identify a mass or phlegmon (e.g., perforated appendix), pyloric stenosis, malrotation (orientation of vessels), intussusception (“target sign” or “Doughnut sign”), or pelvic pathology in adolescents
- CT or MRI: localize the obstruction “transition zone”; diagnosis of strangulation-ischemic segment does not perfuse with contrast; may demonstrate ileus—absence of transition zone, Crohn disease—terminal ileitis or stricture, and neoplasms
- Contrast enema: to confirm/treat intussusception or to evaluate for Hirschsprung; may show “microcolon” of disuse in neonatal small bowel obstruction
- Upper GI series: for malrotation with or without volvulus.
- Water-soluble, low osmolarity materials should be preferred (risk of perforation). Effort should be made to minimize radiation exposure.

ALERT

Evaluation for associated congenital anomalies is mandatory in some surgical conditions, as some are life threatening. The most frequent are cardiac and renal abnormalities.

DIFFERENTIAL DIAGNOSIS

Other causes of abdominal pain and vomiting should be considered and ruled out by history and physical examination:

- Appendicitis
- Torsion of testis or ovary
- Lower lobe pneumonia
- Pancreatitis
- Sick cell crisis
- Henoch-Schönlein purpura
- Biliary colic
- Lead poisoning
- Acute adrenal insufficiency
- Diabetic ketoacidosis
- Acute intermittent porphyria

ALERT

There is no spontaneous resolution of inguinal hernia. Surgery should be scheduled before incarceration occurs. Inguinal hernias have 10–28% risk for incarceration.

TREATMENT

INITIAL STABILIZATION

- Hold oral intake.
- Decompress the stomach by nasogastric tube.
- Administer IV fluids, correct electrolyte imbalance, and ensure adequate urine output.
- Cultures and broad-spectrum antibiotics (covering gram-negative aerobes and anaerobes) for sepsis or perforation/peritonitis
- Identify etiology of obstruction.

GENERAL MEASURES

- Paralytic ileus is usually self-limiting and resolves with supportive treatment.
- Nasogastric decompression and fluids alone initially for adhesions. Adhesive postoperative obstruction is less likely to resolve without surgery in a child younger than age 1 year old.
- In intussusception, hydrostatic or air enema reduction is successful in 90% of cases.
- Anti-inflammatory medication/steroids for inflammatory obstruction of IBD; persistent strictures may require resection
- Contrast enemas and direct enteral installation of N-acetylcysteine for uncomplicated meconium ileus
- Manual reduction of incarcerated inguinal hernias followed by repair
- Colonic volvulus may be treated with endoscopic decompression followed by elective surgery.
- Endoscopic removal of foreign bodies

SPECIAL THERAPY

- Nonoperative management with decompression by nasogastric tube and IV fluids is the 1st-line approach in
 - Early postoperative, partial, and recurrent adhesive obstructions
 - Necrotizing enterocolitis
 - Meconium ileus
 - Duodenal hematomas
 - Superior mesenteric artery syndrome
 - Crohn disease

SURGERY/OTHER PROCEDURES

- Surgery may be required for definitive correction of bowel obstruction.
- Exceptions to this rule may include the above-mentioned conditions managed conservatively.
- In all situations: If no improvement within 12–24 hours, surgery is advisable.
- Additionally, bowel obstruction without a definitive causal diagnosis requires surgery.
- The surgical procedure is individualized according to the specific type,

site, anatomy of the obstruction, and associated conditions.

- Laparoscopic surgery can be used for the diagnosis and repair of select intestinal obstructions and for adhesiolysis.

ONGOING CARE

PROGNOSIS

- Varies with different causes of intestinal obstruction, age of the patient, and associated conditions
- Extensive bowel resection or multiple repeat bowel resections can lead to short bowel syndrome, in which a requirement for long-term central access and parenteral nutrition is associated with significant morbidity and mortality.

COMPLICATIONS

- May result from delayed operation
 - Dehydration, azotemia, renal failure
 - Intestinal ischemia with sepsis and shock
 - Bowel perforation and peritonitis
 - Short-gut syndrome

CODES

ICD10

- K56.60 Unspecified intestinal obstruction
- P76.0 Meconium plug syndrome
- Q41.9 Congen absence, atresia and stenosis of sm int, part unsp

FAQ

- Q: When should I consult a pediatric surgeon?
- A: If there is concern for bowel obstruction, a pediatric surgical consultation should be obtained early. In some cases, emergency surgery is necessary, whereas other times, it is more reasonable to place an NGT, administer IV fluids, and monitor for gradual resolution of the obstruction by clinical exam and radiographs.
- Q: Why are nasogastric tubes used in the treatment of intestinal obstruction?
- A: Tube decompression of the stomach allows for some symptomatic relief of nausea. In addition, it decreases the amount of fluid in obstructed intestine which may speed recovery. NGT output volume and character can guide management.
- Q: Is my child likely to have recurrent episodes of intestinal obstruction?
- A: It depends on the cause of the obstruction. Conditions associated with recurrence include intussusception, inflammatory conditions, and postoperative adhesions.

INTOEING–TIBIAL TORSION

George D. Gantsoudes

BASICS

DESCRIPTION

- Intoeing, as a presumptive diagnosis, results in numerous orthopedic consultations.
- Causes of intoeing are most frequently one or more of the following: metatarsus adductus, internal tibial torsion, and femoral anteversion.
- Definitions:
 - Version: normal variation in axial alignment
 - Torsion: any variation beyond two standard deviations of normal
- Clear explanation of the difference between physiologic variations and pathologic anatomy will allow the treating physician to effectively manage expectations.

EPIDEMIOLOGY

Very common; one the most common reasons for a “well child” to visit an orthopedist

RISK FACTORS

Genetics

No strong evidence of familial links

PATHOPHYSIOLOGY

- Most are self-limiting issues but when paired together, can cause significant issues.
- Excessive femoral anteversion and external tibial torsion can result in the so-called “miserable malalignment,” known to cause significant patellofemoral issues.

ETIOLOGY

- In utero, fetuses are subjected to forces that mold feet and tibiae into adductus and internal torsion, respectively.
- Most children are born with a relatively increased femoral anteversion

(approximately 45 degrees).

- Tends to resolve and “unwind” as the child develops
- Usually resolves by age 8–10 years to the normal adult anteversion of 10–20 degrees

ASSOCIATED CONDITIONS

May be more common in first-born children (especially metatarsus adductus) as part of the “packaging disorders” such as developmental dysplasia of the hip and torticollis

DIAGNOSIS

HISTORY

- Varies based on age of presentation
- The most common reasons for malalignment visits in the preambulatory infant are either intoeing due to metatarsus adductus, or due to an external hip rotation contracture that all children have, which results in an obligatory and physiologic outtoeing.
- The ambulatory toddler will commonly come in with either intoeing or “bowleggedness” as a complaint.
 - The bowleggedness is almost always physiologic or related to the illusion of genu varum due to the child externally rotating their hips to prevent tripping over their internally rotated feet.
- Intoeing in an older child is most often due to femoral anteversion, which is slightly slow to “unwind.”
- The most common complaints are as follows:
 - Frequent tripping
 - Motor delay that is slower than peers or other relatives
 - Family member observation (e.g., an older relative who insists “something is wrong”)
- There may be also be an adult family member with similar issues who did not “grow out of it,” prompting an early evaluation.

ALERT

Functional limitations (such as tripping and falling frequently) may suggest other diagnoses, such as mild cerebral palsy, especially if

abnormal birth history, abnormal developmental milestones, and physical findings consistent with cerebral palsy.

PHYSICAL EXAM

- Goal to rule out significant pathologies that could cause the relatively benign complaints
 - For example, any male child with a history of clumsiness must get a Gower test and deep tendon reflexes to rule out muscular dystrophy.
- If possible, observe the child exploring the room before starting the physical exam. The examiner may gain more information here than at any other point in your exam.
- Watch the child walk and run in the hallway.
 - Ask the child to toe walk, heel walk, and use tandem gait (walk in a straight line touching the heel of one foot to the toes of the other foot) to further explore levels of coordination and function.
 - Look at the foot progression angle (angle formed between axis of foot and axis of forward progression of gait); normally 6–10 degrees of external rotation. An abnormal angle should be explainable by looking at rotation of other parts of leg during gait (hip rotation, thigh-foot angle, and/or foot abnormalities). If something does not add up, ask the child to walk again.
 - Gait can be too complex to observe all at once. If necessary, focus on one level (hips, knees, feet) at a time and have the child walk back and forth numerous times.
 - A “quick hint” is to watch the patella when evaluating the knees; they should always be roughly collinear with the feet.
- All children should have a thorough hip exam to rule out hip dysplasia as a cause.
 - All children have their hip abduction checked; any asymmetry is further evaluated with pelvis x-rays.
 - Children younger than 2 years: Get a Barlow/Ortolani to check for hip instability.
 - Barlow: Adduct hip (thigh toward midline) applying light pressure on knee and direct force posteriorly. Positive sign if femoral head dislocates.
 - Ortolani: Flex hip to 90 degrees, use index fingers to place

anterior pressure on greater trochanters, and abduct the legs using thumbs. Positive sign is “clunk” as femoral head relocates in acetabulum.

- The usefulness of a prone hip rotation exam far outweighs that of the supine exam.
- When examining for tibial torsion, there are a few different methods to evaluate the angle.
 - Thigh-foot axis
 - With the patient prone and the knee flexed 90 degrees, measure the difference between the axis of the foot and the axis of the femur.
 - The angle of the foot should be approximately 15 degrees externally rotated.
 - Transmalleolar axis
 - With the patella facing the ceiling, the axis between the floor and a line drawn through the malleoli is measured.
 - Twenty degrees external is normal.
 - 2nd toe test
 - With the patient prone, the second toe is rotated until it is perpendicular to the floor.
 - The femur is then held in place and the knee is flexed 90 degrees.
 - The angle of the tibia to the vertical should be roughly 20 degrees.
- Metatarsus adductus is assessed by looking at the sole of the foot and drawing a bisecting line from the center of the heel distal. The line should travel through the 2nd and 3rd webspace. The further lateral the bisector line exits the foot, the more severe the adductus.
 - Spontaneous correction of the adducted forefoot is a positive sign and is assessed by gently stroking the lateral border of the foot.
- Assess for limb length differences.
- Assess deep tendon reflexes.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Never useful for simple torsion

Imaging

- Almost never ordered for run-of-the-mill torsional exams
- Order AP and frog pelvis films if there is a high suspicion of hip dysplasia.
- A standing (or supine) AP limb alignment x-ray can be a useful tool to examine for frontal plane abnormalities; taken from pelvis to ankles
 - Should be standardized at each institution with patellae facing the beam
- In the event of significant torsion, advanced imaging (e.g., CT or MRI) can be ordered to discover the true anatomic axes. This is almost always obtained exclusively as a preoperative tool.

DIFFERENTIAL DIAGNOSIS

- Almost always the diagnosis is that of physiologic alignment.
- The examiner must rule out cerebral palsy, muscular dystrophy, hip dysplasia, etc.

TREATMENT

- The younger child (younger than 8 years) should spontaneously resolve minor internal torsion of the tibia and femur.
- Corrective shoes, Denis-Brown bars, twister cables, stretching, and formal physical therapy no more effective than observation. In addition, there has been some correlation of poor self-esteem in those patients prescribed with braces.
- Observation is the rule.
 - There are no restrictions to activity, in fact the children should be encouraged to be active.
- Recalcitrant torsion in the older patient may be an indication for osteotomy to derotate the limbs, only very rarely recommended.
- Managing family expectations is crucial.
 - It may be helpful to have a handout to give to families, to both explain the issues and to show the frequency with which the diagnosis shows up in the office.
 - Get comfortable with a standard explanation of the normal

physiology; use terms that are easy to understand.

- Families may be reassured by data suggesting positive correlation with intoeing and elite-level sprinting.

ONGOING CARE

PROGNOSIS

- Most patients are discharged with follow-up “as needed” with instructions to return if the problem hasn’t improved over a period of 2 years or if the problem acutely worsens.
- Patience is strongly encouraged, as the “unwinding” of the limbs takes years to occur.
- The overall prognosis is excellent.
 - This is a very common reason for an orthopedic visit and a very rare reason to go the operating room.

COMPLICATIONS

Many patients will come in already having seen practitioners (podiatry, physical therapy, chiropractic, orthotists) who will associate torsion with degenerative arthritis and as a cause of more proximal issues (hips, spine). The evidence for this is anecdotal at best.

CODES

ICD10

Q68.4 Congenital bowing of tibia and fibula

FAQ

- Q: Are special shoes or braces ever indicated for tibial torsion?
- A: Almost never. There is no convincing evidence that any of these treatments truly alter the natural history of the condition. The situation will improve without treatment in most children.
- Q: Why do patients with torsional pathology occasionally have knee pain?
- A: Children may have increased femoral anteversion with associated external tibial torsion (i.e., an external rotation of the tibia that matches and, in effect, balances the internal rotation of the femur). This can be diagnosed by observing the rotational profile and by noting an increased Q-angle of the knee. This situation is sometimes a “setup” for patellofemoral pain.

INTRACRANIAL HEMORRHAGE

Jorina Elbers

BASICS

DESCRIPTION

The pathologic accumulation of blood into the epidural, subdural, subarachnoid, intraparenchymal, or intraventricular space within the cranium due to loss of blood vessel integrity or coagulopathy

EPIDEMIOLOGY

- Intraventricular hemorrhage is rare beyond the newborn period.
- Trauma: common cause of ICH in children
- Arteriovenous malformations (AVMs): most common cause of nontraumatic ICH in children

Incidence

Incidence of hemorrhagic (nontraumatic) stroke is 1.1 per 100,000 person years.

RISK FACTORS

Increased frequency with hereditary disorders of coagulation, congenital heart disease, and polycystic kidney disease associated with intracranial aneurysms

Genetics

Multiple cerebral cavernomas may be associated with autosomal dominant trait with CCM1, CCM2, and CCM3.

GENERAL PREVENTION

- Automobile seat belts
- Bicycle, skating, and skateboarding helmets
- Child abuse prevention
- Diving safety practices
- Preventing falls
- Maintaining safe driving speeds
- Keeping children away from firearms

- Hematologic monitoring for those at risk for hemorrhage due to bleeding disorders

PATHOPHYSIOLOGY

- Epidural hematoma (blood between the dura mater and the skull) is frequently arterial, related to skull fracture; typically middle meningeal artery bleeding following temporal bone fracture; may also arise from dural venous sinus laceration.
- Subdural hematoma (blood between the dura mater and the arachnoid membrane) is frequently venous from trauma causing stretching and tearing of bridging cortical veins or coagulopathy.
- Subarachnoid hemorrhage (blood between the arachnoid membrane and brain): ruptured intracranial aneurysm, AVM, or trauma
- Intraparenchymal hemorrhage: trauma, infections (herpes simplex encephalitis, bacterial endocarditis), coagulopathy, brain tumor, Moyamoya arteriopathy, venous sinus thrombosis, or cerebral infarction (occurs mostly with rupture of medium or smaller branches of major cerebral arteries)
- Intraventricular hemorrhage: may occur in isolation (more frequent in preterm infants <36 weeks gestation) or in a mixed pattern with intraparenchymal or subarachnoid hemorrhage. In term infants, rule out venous sinus thrombosis (especially in patients with accompanying thalamic hemorrhage).
- 4 grades of intraventricular hemorrhage:
 - Grade I: isolated to 1 or both germinal matrices
 - Grade II: intraventricular hemorrhage without ventricular dilatation
 - Grade III: intraventricular hemorrhage with ventricular dilatation (hydrocephalus)
 - Grade IV: intraventricular hemorrhage with ventricular dilatation and extension into the periventricular white matter

ETIOLOGY

- Vascular
 - Congenital vascular anomalies: aneurysm, AVM, cavernous hemangioma, arteriovenous fistula, vein of Galen malformation
 - Developmental/acquired vasculopathy: Ehlers-Danlos syndrome

type IV, Moyamoya arteriopathy, sickle cell disease, hypertension (posterior reversible encephalopathy syndrome [PRES]), infective aneurysm, vasculitis (cocaine, inflammatory diseases), cerebral venous sinus thrombosis, hemorrhagic conversion of ischemic stroke, brain tumor

- Hematologic abnormalities: thrombocytopenia, hemophilia, sickle cell disease, liver failure, disseminated intravascular coagulation, iatrogenic (ECMO or anticoagulation therapy)
- Traumatic
 - Accidental injury
 - Nonaccidental injury

ALERT

ICH, especially in young infants and children without an obvious etiology, should raise the suspicion of nonaccidental trauma.

COMMONLY ASSOCIATED CONDITIONS

- Prematurity
- Hemophilia (prevalence of ICH 3–12%)
- Sickle cell disease (250-fold increased risk of ICH)
- Bacterial endocarditis
- Venous infarction
- Arterial infarction
- Alcohol, cocaine, and other sympathomimetics

DIAGNOSIS

HISTORY

- Delivery complications
- Head trauma
- Infection
- Cardiac disease
- High-output cardiac failure
- Patient or family history of coagulopathy
- Drug use
- Cerebral venous sinus thrombosis: dehydration, coagulopathy,

polycythemia, sepsis, asphyxia (especially in newborns)

- Arterial aneurysms: polycystic kidney disease, coarctation of the aorta, fibromuscular dysplasia, connective tissue disease
- Vein of Galen malformation: presents as failure to thrive, hydrocephalus, seizures, high-output cardiac failure
- Clinical presentation of ICH: headache (severity, quality, onset, location), neck pain or stiffness, vomiting, irritability, altered level of consciousness (“lucid interval” with epidural hematoma), seizures, visual problems (diplopia, blurred vision), focal neurologic deficits, epistaxis (may occur if skull fracture is present)
 - Posterior fossa bleed: disconjugate gaze, ataxia, and rapid deterioration to coma

ALERT

Increasing intracranial pressure from hemorrhage or hydrocephalus is life threatening.

PHYSICAL EXAM

- Signs of increased intracranial pressure or herniation, such as Cushing triad (hypertension, bradycardia, abnormal respiratory pattern); papilledema; fixed, dilated pupil; ophthalmoparesis
- In infants, increased intracranial pressure may result in a bulging fontanelle, splayed sutures, and increasing head circumference.
- Low-grade fever
- Meningeal signs
- In setting of trauma:
 - Leakage of CSF from the ear or nose
 - Battle sign: bruising over the mastoid process suggestive of basilar skull fracture
 - Raccoon eyes: periorbital ecchymosis suggestive of basilar skull fracture
 - Retinal hemorrhages

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
- Metabolic profile

- INR, prothrombin time, activated partial thromboplastin time (PT/aPTT)
- Fibrinogen
- Factors VIII, IX, XI
- Von Willebrand factor antigen
- Urine toxicology screen
- Electrocardiogram (for evaluation of cardiac disease or endocarditis)
- Lumbar puncture: Lumbar puncture will show RBCs, reduced glucose, and xanthochromia. Consider spinal fluid evaluation if CT negative.

Imaging

Initial approach

- Rapid CT of the head
 - The most important study to obtain when considering ICH in the differential diagnosis because of its relative convenience, speed, and low false-negative rate
 - Acute intracerebral blood demonstrates increased density; between 1 and 6 weeks becomes isodense with adjacent brain parenchyma. Acute ICH may appear isodense if hemoglobin <8–10 g/dL.
 - Epidural hemorrhage: biconvex, lens-shaped hemorrhage, displacing gray–white matter
 - Subdural hemorrhage: crescent-shaped hemorrhage; bilateral subdural hemorrhage frequent in nonaccidental injury
- Contrast-enhanced CT: Contrast extravasation within the hematoma may identify patients at high risk of ICH expansion.
- MRI gradient echo and T2 susceptibility-weighted imaging are helpful for acute and remote hemorrhage.

Follow-Up Tests & Special Considerations

- CT/MRI/conventional cerebral angiography and venography: for evaluation of vascular lesions, including congenital vascular anomalies, vasculopathies, venous sinus thrombosis
- Head ultrasound: Intraventricular hemorrhage in infants warrants serial head ultrasound exams to rule out hydrocephalus.

ALERT

Early subarachnoid hemorrhage may not be apparent on initial CT and

may require lumbar puncture (if safe to perform) or serial CT evaluation while the patient is under clinical observation.

DIFFERENTIAL DIAGNOSIS

- Ischemic stroke/transient ischemic attack
- Brain tumor
- Headache (migraine, primary thunderclap)
- Metabolic derangements (hyper/hyponatremia, hypoglycemia)
- Encephalitis
- Meningitis
- Seizure with post-ictal Todd paralysis

TREATMENT

MEDICATION

- Correction of coagulopathies (suggested by PT, PTT, platelet abnormalities) should be done promptly and may require hematology evaluation. Therapies include vitamin K, fresh frozen plasma, cryoprecipitate, or platelet infusion. Monitor for fluid overload, especially in patients with cardiac disease.
- Management of elevated blood pressure: Blood pressure should be maintained within normal parameters for age with a target of 50th–95th percentile according to age and height. Nicardipine drip (1 mcg/kg/min) or labetalol (0.2 mg/kg IV push over 2–3 minutes, repeat every 15 minutes PRN)
- Management of seizures: fosphenytoin or levetiracetam 20 mg/kg IV load + maintenance for clinical or electrographic seizures. No evidence for seizure prophylaxis in ICH.
- Acyclovir therapy if herpes simplex type 1 encephalitis is considered
- Recombinant factor VIIa is FDA-approved in children with hemophilia who have systemic bleeding and are resistant to factor VIII therapy.
- Corticosteroids NOT recommended; may result in harmful hyperglycemia

ADDITIONAL TREATMENT

General Measures

- Temperature management: maintain normothermia. Fever associated with worse neurologic outcome in adults
- Maintain normoglycemia and euvoemia
- Urgent neurosurgical consultation
- Management of elevated ICP: head of bed elevated to 30 degrees, maintain adequate analgesia and sedation, consider invasive ICP monitoring and aggressive therapies (mannitol, hypertonic saline, hyperventilation) in consultation with neurosurgery and PICU
- Consider continuous EEG monitoring for seizures.

ADDITIONAL THERAPIES

Physiotherapy, occupational therapy, speech therapy as required

SURGERY/OTHER PROCEDURES

- Elevated intracranial pressure may necessitate surgical hematoma evacuation or decompressive hemicraniectomy.
- Aneurysms or AVMs may require neurosurgical or neurointerventional treatment.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Admission to pediatric/neurointensive care unit
- Urgent management of coagulopathy, hypertension, seizures, elevated ICP as listed earlier

Admission Criteria

- Patients with altered mental status to monitor for elevated ICP
- Patients with focal neurologic deficits for workup and rehabilitation
- Patients with seizures for continuous EEG monitoring and anticonvulsant management
- Patients with hypertension for management
- Patients with coagulopathy for correction
- Patients requiring neurosurgical or neurointerventional management

IV Fluids

Avoid D5 and excessive fluid administration; maintain euvoemia.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Long-term observation for signs of injury: cognitive deficits, focal weakness, seizures

PROGNOSIS

- Children may develop long-term focal or cognitive deficits or seizures.
- Often, good neurologic recovery is possible.
- Predictors of poor neurologic outcome: infratentorial location, GCS ≤ 7 at admission, aneurysm, age < 3 years, underlying hematologic disorder

COMPLICATIONS

- Increased intracranial pressure and brain herniation syndromes
- Hydrocephalus
- Vasospasm secondary to blood and breakdown products of erythrocytes
- Seizures
- Motor, visual, and cognitive deficits
- Death (5–54%, pooled data 25%)

CODES

ICD10

- I62.9 Nontraumatic intracranial hemorrhage, unspecified
- S06.300A Unsp focal TBI w/o loss of consciousness, init
- Q28.2 Arteriovenous malformation of cerebral vessels

FAQ

- Q: What is the annual risk of hemorrhage in children with known AVM?
- A: The estimated annual hemorrhagic risk is 2–4%. In 25% of patients, the hemorrhage is fatal.
- Q: How often should an asymptomatic child at risk for AVM be screened, and with what imaging modality?
- A: Depending on the risk of aneurysm in a given condition, screening with MRA every 1–5 years is reasonable.

INTUSSUSCEPTION

Pradeep P. Nazarey

BASICS

DESCRIPTION

- The invagination or telescoping of a proximal portion of bowel (the intussusceptum) into a distal segment of bowel (the intussusciens)
 - Can be unremitting (80%) or transient (20%)
 - 85% are ileocolic; ileoileal and colocolic types also occur.
 - Telescoping of the bowel occurs over a “lead point”—a lesion or defect in the bowel wall.
- Telescoping of the bowel causes diminished venous blood flow and bowel wall edema, which can result in ischemia and obstruction.
 - Over time, arterial blood flow is inhibited and infarction of the bowel wall occurs, which results in hemorrhage.
 - If untreated, possible perforation and death
- Bowel necrosis can occur within 48–72 hours after onset.
- Clinical presentation can vary but usually includes the following:
 - “Paroxysms of pain”: episodes of calmness interspersed with fussiness
 - Bilious vomiting
 - “Currant jelly stools” which represent mucosal sloughing

EPIDEMIOLOGY

- 1–4/1,000 live births
- Male-to-female ratio: 2:1
- Generally occurs in patients 3 months to 3 years of age
- Peak age: from 5 to 10 months
- More common in winter months
- The most common abdominal emergency of early childhood and second most common cause of abdominal pain next to constipation
- Increased incidence in children who received the RotaShield rotavirus vaccine (no longer available). Currently available vaccines (RotaTeq or Rotarix) have not been shown to increase the risk.

ETIOLOGY

- Children <3 years: usually idiopathic (95%) or due to an enlarged Peyer patch (from viral infection)
- Children ≥3 years: higher incidence of a pathologic lead point (4%): Meckel diverticulum, polyps, and lymphomas are most common. Other common etiologies include Henoch-Schönlein purpura (HSP), Peutz-Jeghers syndrome, intestinal duplications, inflammatory bowel disease, and other tumors.
- Postoperative(1%): can occur in children who have had large retroperitoneal tumors removed

DIAGNOSIS

HISTORY

- Common to have recent history (prodrome) of a viral upper respiratory illness or gastroenteritis
- Classical presentation involves the sudden onset of severe intermittent (colicky) abdominal pain characterized by drawing the legs up to the abdomen and crying.
 - Subsequently, the child may appear asymptomatic between paroxysms of pain that recur in <24 hours.
 - Classical presentation only occurs in 25–30% of patients.
- Young infants may appear listless or lethargic during episodes.
- Nonbilious emesis initially, becomes bilious with progressive obstruction
- Currant jelly stools (sloughed mucosa, blood, and mucous) appear in 50% of cases and should be considered a late finding suggestive of a longer course of the disease prior to presentation.

PHYSICAL EXAM

- Lethargic with intermittent colicky abdominal pain
- Palpable abdominal mass, usually in right upper quadrant, tubular or “sausage” shaped
- Dance sign: absence of bowel contents in right lower quadrant
- Abdominal distention

- Rectal exam: blood-tinged mucous or currant jelly stool
- Symptoms and signs of peritonitis

DIFFERENTIAL DIAGNOSIS

- Infectious
 - Gastroenteritis
 - Enterocolitis
 - Parasites
- Immunologic
 - HSP
- Gastrointestinal
 - GER or GERD
 - Food allergy
 - Inflammatory bowel disease
 - Celiac disease
- Miscellaneous
 - Appendicitis
 - Peutz-Jeghers syndrome
- Obstruction
 - Adhesions
 - Hernias
 - Volvulus
 - Stricture
 - Foreign body
 - Polyp
 - Tumor

DIAGNOSTIC TESTS & INTERPRETATION

Lab

CBC, electrolytes

Imaging

- Abdominal x-ray
 - May show paucity of gas in right lower quadrant, air–fluid levels
 - “Meniscus sign” is indicative of a mass in the colon (25–45%).
- Abdominal ultrasound
 - Primary diagnostic modality

- Highly sensitive and specific with experienced radiologist
- “Target sign” with presence of several concentric rings of bowel
- Can sometimes indicate the pathologic lead point
- Contrast enema
 - Diagnostic and therapeutic with reduction often achieved (95%)
 - Air enema (good chance of success, low risk of perforation,) preferred over barium enema (more effective but higher risk of perforation)

ALERT

- Only 25–30% of patients present with the classical triad of abdominal pain, vomiting, and currant jelly stool, so high clinical suspicion is necessary.
- Patients should always have an IV placed and be undergoing fluid resuscitation prior to imaging or procedures.

TREATMENT

GENERAL MEASURES

- Prompt recognition and reduction is imperative.
- Spontaneous reduction occurs in 5–20%.
- IV insertion, fluid therapy, and surgical consultation should be obtained once diagnosis is entertained.
- Broad-spectrum antibiotics if perforation, peritonitis, or bacterial translocation due to a compromised gastrointestinal mucosa is suspected
- Radiologic, pneumatic reduction with air contrast enema is mainstay of therapy.
- Absolute contraindications to reduction by enema:
 - Peritonitis
 - Shock
 - Perforation
- Multiple attempts may be made at reduction if initially unsuccessful or patient transferred to tertiary care facility after failed attempt.
- Perforation during reduction occurs in <1% of cases, mostly in the

transverse colon, and requires immediate operative intervention.

SURGERY/OTHER PROCEDURES

- If patient presents with generalized peritonitis and/or signs of perforation, they should immediately go to the OR.
- Unsuccessful attempts at pneumatic reduction
- Open surgery involves milking the intussusceptum out of the intussusciens and rarely involves resection.
- Laparoscopic surgery has gained more traction with better outcomes, cosmesis, and shorter length of stay.

ONGOING CARE

FOLLOW-UP

- Some centers may discharge home immediately or observe after nonoperative reduction.
- Diets can be advanced quickly.

EDUCATION

- Parents should be counseled that a 10% recurrence risk exists after nonsurgical reduction in the first 24 hours.
- Recurrences may require repeat pneumatic reduction and/or ultimate operative intervention.

PROGNOSIS

- Timely diagnosis results in a highly favorable prognosis with no effects on the bowel.
- Recurrences or failed reduction in children >3 years old may require workup for pathologic lead point.

COMPLICATIONS

- Bowel necrosis secondary to local ischemia
- Gastrointestinal bleeding
- Bowel perforation
- Sepsis, shock, death

CODES

ICD10

K56.1 Intussusception

FAQ

- Q: Can my child have a recurrent intussusception?
- A: Yes, if your child has had a nonsurgical reduction via air (or barium) enema. However, the risk is considered low (<10%). If the lead point has been removed surgically, recurrence is very unlikely. The greatest risk for recurrence is in the first 24 hours after reduction.
- Q: What are common ages for presentation with intussusception?
- A: 3 months to 3 years is the age range associated with the greatest risk of intussusception, but it may occur at any age. The prevalence of intussusception being a sign of an underlying pathologic condition rises with age.
- Q: Could an infant have intussusception and not be crying in pain?
- A: Yes. Infants often present without the classical manifestations of intussusception. It is critical to have a high index of suspicion in any infant presenting with acute onset of emesis, especially bilious emesis,

and lethargy.

IRON DEFICIENCY ANEMIA

Irina Pateva • Peter de Blank

BASICS

DESCRIPTION

A reduction in hemoglobin production due to an insufficient supply of iron that results in a microcytic, hypochromic anemia

EPIDEMIOLOGY

- Iron deficiency is the most common nutritional deficiency of children.
- Leading cause of anemia among infants and children in the United States
- Most commonly seen in children ages 9 months–3 years and in teenage girls

Prevalence

- Prevalence is variable depending on socioeconomic status, availability of iron-fortified formulas, and prevalence and duration of breastfeeding.
- Prevalence of iron deficiency anemia in United States is generally between 1% and 5% of children.

RISK FACTORS

- Low socioeconomic status
- Certain ethnic groups (e.g., Southeast Asian) may be at increased risk due to dietary practices.
- History of prematurity

GENERAL PREVENTION

- Maintain breastfeeding for the first 5–6 months of life if possible.
 - Breast milk has lower iron concentration than formula, but iron in breast milk is more bioavailable (50% vs. 10%).
- Iron supplementation
 - 1 mg/kg/day for infants who are exclusively breastfed beyond 4 months

- 2 mg/kg/day by 1 month of life for low-birth-weight and premature infants who are breastfed because of poor iron stores and increased growth rate
- Iron-fortified formula for the first 12 months of life for infants who are not breastfed
- Encourage iron-enriched cereal when infants are started on solid food.
- Avoid whole cow's milk during the 1st year of life to prevent occult GI bleeding.
- Screen hemoglobin level at periodic intervals.
 - The American Academy of Pediatrics recommends screening at 12 months, 1–3 years old, and adolescents as well as annually in menstruating females.
 - CDC recommends screening high-risk groups annually between ages 2 and 5 years and all menstruating women every 5–10 years.

PATHOPHYSIOLOGY

- Iron is required for oxygen transport by hemoglobin.
- Iron absorption and distribution is regulated by hepcidin, a peptide hormone secreted by liver, macrophages, and adipocytes.
- Iron is absorbed primarily in the duodenum.
- Iron deficiency develops because of an inadequate supply or increased demand for iron or a combination of these.
- Sequential stages of iron deficiency
 - Depletion of iron stores: reflected by low serum ferritin and absent bone marrow stores
 - Iron-deficient erythropoiesis: Near-normal number of red blood cells (RBCs) produced, but they have abnormal hemoglobin synthesis with wide distribution in RBC size.
 - Iron deficiency anemia: microcytosis evident

ETIOLOGY

- Causes of inadequate supply include dietary deficiency and malabsorption.
 - Dietary deficiency in infants and young children results from introduction of cow's milk prior to age 12 months, exclusive

- breastfeeding beyond age 6 months without iron supplementation, and excessive cow's milk intake (>24 oz/day).
- Malabsorption results from surgical resection of intestine or celiac disease.
- Certain foods impair iron absorption (tannins in tea and coffee, phytates).
- Causes of increased demand include rapid growth and blood loss.
 - Periods of rapid growth include infancy (especially low-birth-weight and premature infants) and adolescence.
 - GI blood loss is most common and includes cow's milk enteropathy (seen in infants), inflammatory bowel disease (IBD), and bleeding from Meckel diverticulum.
- Other etiologies of blood loss include perinatal loss, menorrhagia, pulmonary hemosiderosis, and hematuria.

DIAGNOSIS

HISTORY

- Evaluate dietary intake of iron, including breast- or formula feeding and type of formula (iron fortified or low iron).
- Age at introduction of cow's milk
- Daily intake of cow's milk
- Birth history for prematurity or blood loss
- Lead exposure
- Blood loss from urine, stool, menorrhagia
- Iron deficiency anemia often develops slowly, and no symptoms may be present. When present, signs and symptoms include the following:
 - Irritability and behavioral disturbances
 - Fatigue, exercise intolerance
 - Pallor
 - Headache
 - Pica or pagophagia (chewing ice)

PHYSICAL EXAM

- Often normal

- Pallor, irritability
- Tachycardia, flow murmur if anemia is more severe
- Koilonychia (spoon nails)
- Glossitis or stomatitis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Hemoglobin level <2 standard deviations below the age-specific mean defines anemia.
- Low MCV (red cell volume) and MCH (hemoglobin concentration) for age
- High RDW (red cell distribution width)
 - Measures the variation in red cell size
 - Normal is $<14.5\%$.
 - Often increased before anemia is present
- Low serum ferritin (≤ 12 ng/mL) reflects reduced tissue iron stores.
 - Earliest laboratory abnormality
 - May be normal or increased with concurrent infection or inflammation
 - Higher cutoff improves sensitivity of the test.
 - Ferritin ≤ 30 ng/mL has sensitivity of 92% and PPV of 83% for iron deficiency anemia versus sensitivity of 25% for ferritin ≤ 12 ng/mL.
- Low serum iron
- Increased total iron-binding capacity
- Low transferrin saturation; measures the iron available for hemoglobin synthesis
- Increased soluble transferrin receptor (sTfR)
 - Indicator of increased tissue iron demand
 - Also increased in thalassemia syndromes but not in anemia of chronic inflammation
 - $\text{sTfR}/\log(\text{ferritin}) < 1$ suggests anemia of chronic inflammation.
 - $\text{sTfR}/\log(\text{ferritin}) > 2$ suggests iron deficiency anemia.
- Decreased reticulocyte hemoglobin content: This test is an early indicator of iron deficiency because reticulocytes have a short (1–2-day) lifespan before becoming mature red cells.
- Increased free erythrocyte protoporphyrin, a precursor molecule in

hemoglobin synthesis; also high in lead poisoning and chronic inflammation

- Thrombocytosis (can approach 1 million/dL)
- Peripheral blood smear with microcytosis, hypochromia, poikilocytosis (varying shapes), pencil forms, and anisocytosis (varying sizes)
- Test for occult blood in stool often positive with GI blood loss
 - However, the test can be positive with oral iron supplementation.
- Iron absorption test can assess adequacy of PO iron supplementation. 3 mg/kg elemental iron should increase serum iron more than 100 mcg/dL within 4 hours of ingestion.

Diagnostic Procedures/Other

Bone marrow examination: shows decreased iron stores by Prussian blue staining; it is the gold standard to determine iron stores but rarely needed to establish diagnosis.

DIFFERENTIAL DIAGNOSIS

- Recent infection
- Lead poisoning
- Thalassemia trait
- Anemia of chronic inflammation (e.g., juvenile rheumatoid arthritis, IBD)
- Sideroblastic anemias

TREATMENT

- Iron supplementation
- Family education regarding age-appropriate diet and iron-containing foods
- Specific treatment if underlying condition causing blood loss is found (e.g., hormonal therapy for menorrhagia, medications for IBD)
- May require initial inpatient observation in cases of severe anemia
- Red cell transfusion only if evidence of cardiovascular compromise (rarely indicated)

MEDICATION

First Line

Oral replacement with ferrous iron, 3–6 mg/kg/24 h of elemental iron divided into 2 or 3 doses

- Iron should be given on an empty stomach or with a vitamin C–containing juice to increase absorption. Ascorbic acid increases oral absorption of iron by ~30%.
- Side effects (in 10–20%) include nausea, constipation, GI upset, and vomiting. Iron suspensions can stain teeth temporarily.

Second Line

Parenteral iron formulations are indicated for severe noncompliance or malabsorption or if ongoing loss exceeds absorption capacity.

Administration may be associated with pain at injection site or anaphylaxis, less common with newer preparations such as ferric gluconate and iron sucrose.

ISSUES FOR REFERRAL

- Evaluation for source of GI blood loss
- Unexplained recurrence after treatment
- Failure to improve with iron supplementation

INPATIENT CONSIDERATIONS

Admission Criteria

- Active bleeding
- Severe anemia (hemoglobin level <6 g/dL) especially if symptoms or ongoing blood loss
- Tachycardia, S₃ gallop, or other signs of CHF

Nursing

Family education: teaching administration of iron and dietary counseling

Discharge Criteria

- No signs of CHF
- If blood loss, bleeding is controlled
- Stable hemoglobin level
- Parent demonstrates ability to administer oral iron therapy to young children and demonstrates adequate knowledge about dietary modifications.

- Adequate follow-up ensured

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Reticulocyte count increases in 3–4 days.
- Hemoglobin concentration should rise by at least 1 g/dL in 2–3 weeks.
- Continue iron for 2 months beyond correction of anemia to replenish body stores.
- Causes of poor response to oral iron supplementation include the following:
 - Nonadherence (most common)
 - Ongoing blood loss
 - Insufficient duration of therapy
 - High gastric pH
 - Concurrent lead intoxication
 - Other diagnosis: Thalassemia trait and anemia of chronic disease are not iron responsive.

DIET

- Milk should be restricted to <24 oz daily or eliminated in those with milk protein enteropathy.
- Bottle should be discontinued after 12 months.
- Diet should include foods rich in iron: meats, beans, iron-fortified cereal, strawberries, spinach.

PATIENT EDUCATION

- Activity: Usually, no activity restriction is needed. Those with severe anemia resulting in CHF should have limited activity until the anemia is corrected.
- Diet: A diet containing iron-rich foods should be encouraged. Limit milk intake to <24 oz daily.
- Prevention: Prevention of iron deficiency is preferable. Anticipatory guidance about diet, prolonged bottle use, etc., should be given.

PROGNOSIS

- Anemia is readily corrected with iron replacement.
- Developmental delay may be long lasting or irreversible.

COMPLICATIONS

- Impaired cognitive and motor development as well as behavioral changes in infants and toddlers
- Short-term memory impairment and poor exercise performance in adolescents

CODES

ICD10

- D50.9 Iron deficiency anemia, unspecified

- D50.8 Other iron deficiency anemias
- D50.0 Iron deficiency anemia secondary to blood loss (chronic)

FAQ

- Q: What dietary changes can help prevent the recurrence of iron deficiency?
- A: Limit milk to 24 oz/day to improve appetite for iron-containing foods. Heme iron, found in meats, fish, and poultry, is absorbed better than nonheme iron and enhances absorption of nonheme iron. Other foods that have iron are raisins, dried fruit, sweet potatoes, lima beans, chili beans, green peas, peanut butter, and enriched foods. Give iron on an empty stomach along with an ascorbic acid-containing juice to increase absorption. Foods that decrease absorption include bran, vegetable fiber, tannins found in tea, and phosphates. Antacids may also decrease iron absorption.
- Q: What are the side effects of iron therapy?
- A: Iron may cause temporary staining of the teeth, which can be decreased by diluting the iron with a small amount of juice. Iron will also change the color of bowel movements to greenish black. Constipation may occur.
- Q: What are the most important tests to do to establish the diagnosis of iron deficiency?
- A: For patients with a history of dietary deficiency or known blood loss, a CBC that shows a low hemoglobin and MCV and an elevated RDW is very suggestive of iron deficiency. A therapeutic trial of iron without further laboratory testing is an appropriate next step. A rise in the hemoglobin concentration of ≥ 1 g/dL after 1 month of therapy confirms the diagnosis. Otherwise, further laboratory testing is necessary and other diagnoses should be considered.
- Q: How does a concurrent infection affect the diagnosis of iron deficiency?
- A: Common childhood infections may be associated with a mild microcytic anemia that resembles iron deficiency. Laboratory tests to diagnose iron deficiency may be misleading while a child is acutely ill. Acute infection is associated with a shift of iron from serum to storage

sites, causing a decrease in serum iron and an increase in ferritin. It is more helpful to test a child for iron deficiency 3–4 weeks after an acute infection.

IRON POISONING

Carl Tapia • Angela Mazur

BASICS

DESCRIPTION

- Iron poisoning is a common and potentially fatal ingestion.
- Toxicity depends on the amount of elemental iron ingested, although tolerable and lethal concentrations are not firmly established.
- Doses of <20 mg/kg of elemental iron are generally not symptomatic, of 20–60 mg/kg are variably symptomatic, and of >60 mg/kg are severe toxic and potentially fatal.

EPIDEMIOLOGY

- Accounts for about 2–4% of all exposures in children and adolescents
- Many factors contribute to the incidence of iron ingestion:
 - High-iron preparations such as prenatal vitamins are readily available.
 - Many preparations are attractive and candy-like.
 - Caregivers often fail to appreciate the danger of overdose from vitamins and pure iron preparations.
- Although vitamin ingestions are increasing, the incidence of fatal iron ingestions has declined since the 1990s, perhaps due to changes in package labels and child-resistant packaging.

RISK FACTORS

- Birth of a sibling (increased availability of maternal vitamins)
- Among unintentional ingestion, almost all serious mortality and morbidity is in children younger than 5 years of age (ingestion of adult iron formulations).

PATHOPHYSIOLOGY

- Iron directly damages cells, interfering with aerobic respiration. The primary systems affected by iron are the gastrointestinal (GI) tract, including the liver, and the cardiovascular system.

- There are five classic stages of iron poisoning:
 - Stage I (GI phase)
 - Occurs up to 6 hours postingestion
 - Characterized by GI mucosal injury, leading to pain, vomiting, diarrhea, and GI bleeding
 - Metabolic acidosis may be present, and death may be caused by capillary leakage and hypovolemic shock.
 - Stage II (quiescent)
 - 6–24 hours after ingestion
 - Relative stability and temporary resolution of GI symptoms
 - Stage III (recurrence)
 - 24–48 hours after ingestion
 - Recurrence of GI injury leading to bleeding, shock, and acidosis
 - Vasodilation can lead to hypovolemia, and myocardial injury can lead to cardiogenic shock.
 - Coagulopathy is common.
 - Stage IV (hepatotoxicity)
 - Within 48 hours after ingestion
 - May result in liver failure
 - Stage V (late)
 - 2–8 weeks postingestion
 - Gastric injury may result in strictures, leading to vomiting and potentially gastric outlet obstruction.

DIAGNOSIS

HISTORY

- Witnessed or suspected iron product ingestion
- Determine the amount of elemental iron ingested and the time of ingestion.
- The percentage of elemental iron by iron salt is ferrous fumarate, 33%; ferrous chloride, 28%; ferrous sulfate, 20%; and ferrous gluconate, 12%.

PHYSICAL EXAM

ALERT

Strongly consider the diagnosis of acute iron poisoning in a lethargic, hypotensive toddler.

- Evaluate for poor perfusion: hypotension, decreased capillary refill, pallor, tachycardia, and CNS depression (lethargy or coma).
- Evaluate for GI injury: abdominal tenderness and occult or apparent GI bleeding.
- Evaluate for heart injury: distant heart sounds, poor pulses, mottled skin, distended jugular veins, pulmonary edema.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- Blood gas
- Complete blood count
- Glucose, liver function, and coagulation studies
- Renal function
- Electrolytes

Imaging

- Abdominal radiograph
 - May reveal iron pills. The absence of findings does not exclude iron toxicity (liquid preparations and multivitamins are not radiopaque).
 - GI decontamination may be recommended if undissolved tablets are confirmed.

Diagnostic Procedures/Other

- Serum iron level
 - Measure on presentation and every 1–2 hours.
 - The serum iron level peaks at 4–6 hours postingestion and can help determine the severity of overdose. Iron levels 300–500 mcg/dL: usually mild to moderate GI toxicity; 500–1,000 mcg/dL: serious toxicity; greater than 1,000 mcg/dL: severe and life-threatening toxicity
- Total iron-binding capacity (TIBC) not recommended (may be inaccurate in toxicity)

DIFFERENTIAL DIAGNOSIS

- Ingestions
 - Methanol
 - Propylene glycol
 - Ethanol
 - Ethylene glycol
 - Salicylate
 - Toluene
- GI bleeding
 - Trauma
 - Perforation
 - Intussusception
 - Gastritis
 - Esophageal inflammation or tear
 - Vascular malformation
- Other
 - Reye syndrome
 - Serious bacterial infection: sepsis, meningitis
 - Diabetic ketoacidosis

TREATMENT

GENERAL MEASURES

- Asymptomatic patients after 6 hours of ingestion or ingestions of less than 40 mg/kg elemental iron with mild symptoms can be observed at home.
- Symptomatic patients with persistent or severe GI symptoms, or ingestion with greater than 40 mg/kg elemental iron, should be evaluated in a health care facility.

SPECIAL THERAPY

- GI decontamination
 - Whole-bowel irrigation for patients with a significant number of pills on imaging studies
 - Gastric lavage with tap water or normal saline if early after

- ingestion and suspect a large iron load
- Activated charcoal is not recommended (iron binds poorly).
 - Syrup of ipecac is not recommended.
 - Rarely, endoscopy or gastrotomy may need to be performed to remove embedded pills.
 - Iron chelation with deferoxamine
 - Deferoxamine binds with free iron and is excreted by the kidneys. It is indicated if systemic signs of toxicity or peak iron concentration is greater than 500 mcg/dL.
 - Administered parenterally via continuous infusion at 15 mg/kg/h. (Consultation with a specialist or regional poison control center is recommended.)
 - Chelation can be discontinued with clinical improvement and resolution of metabolic acidosis.
 - Side effects of chelation include hypotension and acute respiratory distress.
 - Although iron cannot be dialyzed, the ferrioxamine complex after chelation can be, and dialysis may be indicated in the setting of acute renal failure.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Evaluate and stabilize shock.
- Intubation should be considered in a lethargic patient to facilitate GI decontamination.

Admission Criteria

- Patients with mild but persistent symptoms after 6 hours or ingestion with greater than 40 mg/kg (recommend consultation with a specialist or poison control center)
- Symptomatic patients with significant toxicity or shock should be treated in an intensive care setting by specialists skilled in management of pediatric ingestions.

Discharge Criteria

Stable hemodynamic status and resolution of metabolic acidosis
(recommend consultation with a specialist or poison control center)

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Monitor for possible late complications, such as strictures of the GI tract (can occur up to 2 months postingestion).

PATIENT EDUCATION

Encourage families to secure iron-containing vitamins and supplements out of reach of children.

PROGNOSIS

- Iron ingestions rarely result in serious injury.
- Shock and ingestion of elemental iron greater than 1,000 mcg/dL associated with mortality

COMPLICATIONS

- GI and hepatic infarction and necrosis
- Gastric or intestinal scarring and strictures
- Metabolic acidosis
- Shock (hypovolemic, hemorrhagic, cardiogenic)
- Coagulopathy
- Pulmonary edema
- *Yersinia enterocolitica* infection or sepsis (Chelation can encourage bacterial growth.)
- Death

CODES

ICD10

- T45.4X1A Poisoning by iron and its compounds, accidental, init
- T56.891A Toxic effect of other metals, accidental (unintentional), initial encounter

FAQ

- Q: Why isn't syrup of ipecac recommended to induce vomiting?
- A: Because the major early signs and symptoms involving the GI tract include vomiting, inducing vomiting may interfere with the clinical assessment. There is also the risk of aspiration in the patient with severe poisoning.
- Q: What is the recommendation regarding observation of a patient for development of symptoms with iron ingestion of an unknown quantity?
- A: Observe for 6 hours. Those who are asymptomatic 6 hours after ingestion are not likely to exhibit systemic illness.
- Q: What is the recommendation regarding nonintentional ingestion of children's vitamins with iron, carbonyl iron formulations, or polysaccharide iron complex formulations?
- A: These ingestions are generally deemed to contain low levels of iron, and the American Association of Poison Control Centers recommends against emergency room referral for nonacute patients with adequate home supervision. Even patients with mild diarrhea and emesis can be safely observed in the home following these ingestions, although consultation with a physician and poison control hotline is still advised.

IRRITABLE BOWEL SYNDROME

Laurie N. Fishman

BASICS

DESCRIPTION

- Irritable bowel syndrome (IBS) is a common functional GI tract disorder where defecation is disordered and associated with abdominal discomfort.
- Characterized by abdominal pain, bloating, diarrhea or constipation
- Symptoms of IBS do not result from inflammatory, infectious, metabolic, or anatomic causes. However, there can be overlap with other conditions.
- Symptoms typically exacerbated by stress or particular foods (i.e., spices, fatty foods, caffeine)

EPIDEMIOLOGY

- 10–15% of the general population is affected by IBS.
- More common in females
- Prevalence estimates vary based on whether the study is community-based or practice-based, as many people do not seek medical care.
- Prevalence is also based on whether Manning, Rome II, or Rome III criteria are used.
- IBS occurs in children and was found to affect 6% of middle school students and 14% of high school students in one community-based study.

RISK FACTORS

- Prior history of bacterial enteritis
- History of abuse or trauma

PATHOPHYSIOLOGY

- IBS considered a disorder of GI function relating to motility, sensation, and/or perception.
- Best model is a biopsychosocial construct with dysregulation of the

gut-brain homeostasis affected bidirectionally by both peripheral and central factors.

- The pathogenesis of IBS is believed to be multifactorial and include the following:
 - Abnormal gut motility
 - Genetics
 - Bacterial overgrowth
 - Visceral hypersensitivity
 - Behavioral response
 - Microscopic inflammation
 - Dysregulation of brain-gut axis
 - Malabsorption

DIAGNOSIS

HISTORY

- IBS is not a diagnosis of exclusion.
- Diagnosis is based on careful history with particular attention to characteristics of pain, precipitating factors, and defecation pattern.
- Symptoms that support constipation-predominant IBS (IBS-C) include the following:
 - <3 stools per week
 - Hard or lumpy stools
 - Straining with defecation
- Symptoms that support diarrhea-predominant IBS (IBS-D) include the following:
 - >3 stools per day
 - Loose or mushy stools
 - Urgency
- All IBS types may have the following:
 - Sense of incomplete evacuation
 - Mucus in stools
 - Abdominal bloating
- Symptoms may not only intensify with known stressors (such as school exams), but also with positive experiences (such as parties, amusement

park trips, dates, or prom).

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- There is no laboratory testing that confirms IBS. Tests are done solely to rule out other conditions.
- Selective testing:
 - CBC, ESR, or CRP,
 - Stool for occult blood
 - Stool for parasites (Giardia)
 - Total IgA, tissue transglutaminase (IgA)
 - Stool lactoferrin or calprotectin
 - Consider albumin.
 - Consider lactose testing.
- More testing needed if “red flags” present the following:
 - Weight loss (over 5–10 lb)
 - Bloody stool
 - Fever
 - Anemia
 - Family history of inflammatory bowel disease or GI cancer

Imaging

There is no imaging that can be used to diagnose IBS. Imaging studies should be performed if indicated to evaluate for other conditions.

Diagnostic Procedures/Other

- In severe IBS, with weight loss and diarrhea resulting in incontinence or nocturnal stooling, colonoscopy may be required to rule out colitis.
- If history and empiric restriction do not lead to clear answer, as to whether lactose intolerance is a contributing factor, can perform lactose breath testing to objectively quantify lactase activity

DIFFERENTIAL DIAGNOSIS

- Giardia infection
- Lactose intolerance
- Fructose intolerance
- Celiac disease

- Inflammatory bowel disease
- Constipation with overflow
- Endometriosis
- Medication effects
- Psychiatric disorder (especially anxiety, depression, posttraumatic stress disorder, or school avoidance)

TREATMENT

- The aims of IBS treatment are to:
 - Improve a global sense of well-being
 - Reduce specific symptoms
- It is important to remind patients that treatment will not cure their IBS.
- Comprehensive treatment consists of the following:
 - Education about IBS
 - Dietary changes
 - Fiber
 - Probiotics/antibiotics
 - Pharmacology
 - Herbal and natural products
 - Complementary techniques
 - Psychological techniques
 - Continued provider relationship

MEDICATIONS

- Antibiotics can be used intermittently for gassiness and bloating symptoms:
 - Neomycin, rifaximin (nonabsorbed)
 - Metronidazole, norfloxacin (systemic)
- Bile acid malabsorption has been postulated as a trigger in IBS-D (even in absence of liver or ileal disease). Potential medications include cholestyramine (Questran), colesevelam
- Symptomatic relief for diarrhea:
 - Consider loperamide (mu opioid receptor agonist).
 - Side effects include constipation.

- Symptomatic relief for constipation:
 - Consider magnesium, polyethylene glycol, senna, or bisacodyl; however, these therapies are not well-studied for this indication.
- Lubiprostone
 - Can be used at 8 mcg b.i.d. for general IBS discomfort or 24 mcg b.i.d. for constipation
 - Nausea is a frequent side effect.
- Linaclotide
 - Guanylate cyclase receptor agonist
 - Recently approved for patients older than 18 years of age with IBS-C
 - Minimal side effects as not absorbed systemically
- Antispasmodics (dicyclomine, hyoscyamine)
 - Can be used on a regular basis or as needed
 - It can be very reassuring to the patient to have a medication available when needed.
- Belladonna/phenobarbital is also described as useful, but is not available in United States.
- Low-dose antidepressants (amitriptyline, citalopram)
 - Can be very useful for the treatment of abdominal pain.
 - It is important to explain the rationale for using these medications to avoid the misperception by the patient that the diagnosis is a psychiatric disease.
- Placebo rates in IBS are often more than 40% in studies. Effectiveness of known placebos for patients with migraine may also be helpful in patients with IBS.

ADDITIONAL TREATMENTS

General Measures

- For patients with mild symptoms of IBS, reassurance, education, and lifestyle changes such as avoiding identified triggers may be adequate for management.
- In patients with more severe or complex symptoms, a multidisciplinary approach including pharmacotherapy and psychosocial intervention may be needed.

COMPLEMENTARY & ALTERNATIVE THERAPIES

- Probiotics
 - Current literature suggests mixed results from clinical trials
 - Different individual and combinations of probiotics strains of Bifidobacterium, Lactobacillus, and Saccharomyces have been used.
 - 3–4 weeks of treatment are considered adequate trial.
- Herbal products
 - Chamomile, in the form of warm tea, can be helpful for spasms.
 - Peppermint, either tea or capsules of peppermint oil, will relax the smooth muscle via the calcium channel. Can cause heartburn
 - Less commonly cited remedies have been reported such as artichoke leaf extract, turmeric, and natural clay powder.

ISSUES FOR REFERRAL

- Psychological therapies such a cognitive behavioral therapy (CBT) and psychodynamic therapy are helpful.
 - Acquiring CBT skills can help lower stress, address comorbid anxiety or depression, and often have lasting effect.
- Hypnotherapy requires trained provider, but has proven benefits lasting 6–12 months.

DIET

- Have patients systematically look at typical dietary triggers:
 - Spicy foods
 - Fatty or fried foods
 - high-sugar foods
 - Beans/legumes
 - Sugar-free gum, candy, or drinks
 - Lactose
- Try gluten withdrawal (after testing to rule out celiac), as some patients can have non-celiac gluten sensitivity.
- In conjunction with a nutritionist, consider trying elimination of FODMAP foods (fermentable oligosaccharides, disaccharides, monosaccharides and polyols)
- Fiber
 - Gradually increase to goal of 10 g (adults) or age +5 g (child)

- Fiber can help with global symptoms and constipation, less helpful for pain.
- Soluble fibers (psyllium, ispaghula, calcium polycarbophil) improve symptoms, whereas insoluble (bran, corn) worsen symptoms.
- Adequate trial of any particular fiber is at least 3–4 weeks, may need to try multiple types.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- The provider–patient relationship is an important component of therapy, and ongoing visits can help monitor symptoms.
- Planned medical follow-up also provides a sense of well-being, helps patients to anticipate flares, and prevent repeated evaluations.

PATIENT EDUCATION

- Establish a positive diagnosis:
 - It is important that patients perceive that their MD “knows they have IBS” rather than the MD has “ruled everything else out so the diagnosis must be IBS.”
- Reassurance about overall health
- Explain there are many interventions (diet, medication, techniques) that will improve, although not cure, symptoms.
- Reassure patients that you will not abandon them but continue to help.

COMPLICATIONS

- Patients with moderate to severe IBS can have significantly lower quality of life, absenteeism from school/work.
- IBS can also lead to frequent physician visits, unnecessary medical testing, and high health care costs.

CODES

ICD10

- K58.9 Irritable bowel syndrome without diarrhea
- K58.0 Irritable bowel syndrome with diarrhea

FAQ

- What is the FODMAP diet?
- The FODMAP diet involves the exclusion of foods that are “fermentable,” as well as those with “oligosaccharides, disaccharides, monosaccharides, and polyols.” Following the FODMAP diet has been shown to provide relief for patients with IBS.

JAUNDICE

Kathleen M. Loomes

BASICS

DESCRIPTION

- Jaundice: a yellow or green/yellow hue to the skin, sclerae, and mucous membranes which can be appreciated at serum bilirubin levels >2 mg/dL. Intensity of color is directly related to the serum bilirubin level.
- Unconjugated bilirubin: 80% is due to hemoglobin turnover and 20% is from degradation of hepatic and renal heme proteins. It is a hydrophobic compound that must be carried to the liver by albumin for processing.
- Conjugated bilirubin: conjugated to glucuronic acid in the liver, a water-soluble derivative that helps lipid emulsification and absorption
- Conjugated hyperbilirubinemia (direct hyperbilirubinemia): a conjugated bilirubin of >2 mg/dL or $>20\%$ of the total bilirubin

EPIDEMIOLOGY

The most common causes of pathologic jaundice are as follows:

- Newborn period: biliary atresia, idiopathic neonatal hepatitis, α -1-antitrypsin deficiency, infection
- Older child: autoimmune hepatitis, viral hepatitis, Wilson disease, biliary obstruction

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- **Unconjugated hyperbilirubinemia**
 - Congenital/anatomic
 - Placental dysfunction/insufficiency resulting in polycythemia (e.g., infants of diabetic mothers)
 - Upper GI tract obstruction (e.g., pyloric stenosis, duodenal web, atresia)

- Congenital hypothyroidism
- Infectious
 - Sepsis
- Trauma/delivery complications
 - Cephalohematoma/bruising
 - Delayed cord clamping, twin–twin transfusion, maternal–fetal transfusion leading to polycythemia
 - Intrauterine hypoxia (secondary to cocaine abuse, high altitude) resulting in polycythemia
 - Induction of labor with oxytocin
 - Prematurity
- Genetic/metabolic
 - Inherited red cell enzyme, membrane defects (e.g., spherocytosis, glucose-6-phosphate dehydrogenase [G6PD] deficiency, phosphokinase deficiency, elliptocytosis)
 - Hemoglobinopathies (sickle cell anemia, thalassemia)
 - Defect in hepatic bilirubin conjugation (e.g., Crigler-Najjar types I and II, Gilbert)
 - Inborn errors of metabolism
- Allergic/inflammatory/immunologic
 - Isoimmunization (ABO, Rh, Kell, other incompatibility)
- Functional
 - Physiologic jaundice
 - Breastfeeding-associated jaundice
 - Swallowed maternal blood
 - Increased bilirubin load due to infant bleeding from a clotting disorder
 - Familial benign unconjugated hyperbilirubinemia in mother and neonate (Lucey-Driscoll syndrome)
- **Conjugated hyperbilirubinemia**
 - Extrahepatic
 - Extrahepatic biliary atresia
 - Choledochal cysts and other abnormalities of the choledochopancreatic ductal junction
 - Spontaneous perforation of the bile duct

- Bile or mucous plug or biliary sludge
 - Gallstones
- Infectious etiologies
 - Bacterial: gram-negative sepsis, urinary tract infection
 - Viral: cytomegalovirus; echovirus; herpes simplex virus; rubella; Epstein-Barr virus; HIV; hepatitis A, B, C, D, and E
 - Toxoplasmosis
 - Pneumocystis carinii
 - Entamoeba histolytica
 - Mycobacterium tuberculosis
 - Mycobacterium avium-intracellulare
 - Syphilis
- Toxic, environmental, drugs
 - Post shock or post-asphyxia (ischemic injury to liver)
 - Drugs: acetaminophen, valproate, chlorpromazine, Amanita toxin, and others
 - Hyperalimentation (total parenteral nutrition)
- Neoplastic
 - Neuroblastoma, hepatic, biliary, pancreatic, duodenal, peritoneal
 - Infiltrative processes such as HLH
 - Langerhans cell histiocytosis
- Genetic/metabolic
 - Arteriohepatic dysplasia (Alagille syndrome)
 - Progressive familial intrahepatic cholestasis (including FIC1, BSEP, and MDR3 deficiency)
 - Benign recurrent intrahepatic cholestasis
 - Defects in bile acid metabolism
 - Defects in amino acid metabolism
 - Defects in lipid metabolism: Wolman disease, Niemann-Pick disease, Gaucher disease
 - Defects in carbohydrate metabolism: galactosemia, hereditary fructose intolerance, glycogenosis type IV
 - Defects in fatty acid oxidation
 - Defects in mitochondrial DNA and respiratory chain defects
 - α -1-antitrypsin deficiency

- Cystic fibrosis
- Wilson disease (older children)
- Inherited noncholestatic conjugated jaundice syndromes (e.g., Dubin-Johnson and Rotor syndrome)
- Hereditary cholestasis with lymphedema (Aagenaes syndrome)
- Inflammatory/immunologic/endocrine:
 - Idiopathic neonatal hepatitis
 - Congenital alloimmune hepatitis
 - Idiopathic panhypopituitarism
 - Autoimmune hepatitis (children and adolescents)
 - Sclerosing cholangitis (children and adolescents, unless neonatal form)

APPROACH TO THE PATIENT

- **Phase 1:** Determine if hyperbilirubinemia is unconjugated or conjugated.
- **Phase 2:** if unconjugated hyperbilirubinemia
 - Obtain CBC and indices.
 - Reticulocyte count
 - Coombs test: If test is positive, the diagnosis is isoimmune; if test is negative, then consider polycythemia, extravascular bleed, or RBC structural or enzyme defects.
- **Phase 3:** if conjugated hyperbilirubinemia
 - Alanine aminotransferase (ALT), aspartate aminotransferase (AST), γ -glutamyltranspeptidase (GGT)
 - PT/PTT/international normalized ratio (INR)
 - Ultrasound of the liver/pancreas/gallbladder and biliary tree
 - Rule out those etiologies of conjugated hyperbilirubinemia that may adversely affect the outcome if diagnosis is delayed (biliary atresia, tyrosinemia, galactosemia, inborn error of bile acid synthesis, hereditary fructose intolerance, panhypopituitarism, and others).

HISTORY

- **Question:** Unexplained itching?
- **Significance:** Cholestatic liver disease (conjugated hyperbilirubinemia)
- **Question:** History of poor school performance, change in mental

status, handwriting?

- Significance: Wilson disease
- **Question:** History of other family members having prolonged jaundice, hepatic failure, or sudden death in infancy?
- Significance: Suggests an underlying inborn error of metabolism such as tyrosinemia, galactosemia, or a fatty acid oxidation defect
- **Question:** History of IV drug abuse or exposure to blood or blood products, especially prior to 1992?
- Significance: The patient may have transfusion-associated hepatitis (e.g., hepatitis C).

PHYSICAL EXAM

- **Finding:** Scratch marks?
- Significance: Pruritus secondary to cholestasis
- **Finding:** Spider angioma, palmar erythema?
- Significance: Chronic liver disease
- **Finding:** Petechiae, purpura, microcephaly, thrombocytopenia?
- Significance: Congenital TORCH infection
- **Finding:** Heart murmur?
- Significance: Alagille syndrome (peripheral pulmonic stenosis)
- **Finding:** Splenomegaly?
- Significance: Suggests acute hemolysis (in unconjugated hyperbilirubinemia) or chronic liver disease and portal hypertension (conjugated hyperbilirubinemia)
- **Finding:** Ascites?
- Significance: Suggests portal hypertension
- **Finding:** Acholic stool?
- Significance: Severe cholestasis or biliary obstruction

DIAGNOSTIC TESTS & INTERPRETATION

- Percutaneous liver biopsies: Liver pathology—in infants with cholestasis, the most common patterns are giant cell hepatitis, bile duct proliferation, and bile duct paucity. A pattern of duct proliferation, bile plugs, portal expansion, and fibrosis suggests biliary obstruction, most likely biliary atresia.
- Intraoperative cholangiogram is indicated for infants with a liver

biopsy suggestive of biliary obstruction and possible biliary atresia. If the cholangiogram is consistent with biliary atresia, the surgeon will perform the Kasai portoenterostomy.

- Total bilirubin with fractionation into unconjugated, conjugated, and delta fractions
- Significance: Direct versus indirect hyperbilirubinemia

If unconjugated hyperbilirubinemia, investigation is initiated with the following:

- **Test:** CBC with indices, reticulocyte count, and peripheral blood smear for RBC morphology
- Significance: Polycythemia in neonate, hemolysis, or other conditions associated with increased destruction of red cells
- **Test:** Coombs test
- Significance: Isoimmune and autoimmune hemolytic anemia
- **Test:** PT/PTT/INR, platelet count
- Significance: Coagulopathy associated with hemorrhage that causes an increased bilirubin load

If neonatal conjugated hyperbilirubinemia, investigation is initiated with the following:

- **Test:** Serum aminotransferases (ALT, AST)
- Significance: Ongoing liver inflammation
- **Test:** Alkaline phosphatase and GGT
- Significance: Biliary tree obstruction, bile duct injury, or cholestasis
- **Test:** PT/INR, PTT, serum albumin, fibrinogen
- Significance: Liver synthetic function
- **Test:** Sepsis evaluation (blood and urine and spinal fluid)
- Significance: Sepsis can impair conjugation and excretion of bilirubin
- **Test:** Free T₃, T₄, and thyroid-stimulating hormone
- Significance: Congenital hypothyroidism
- **Test:** α -1-Antitrypsin serum levels and PI phenotype
- Significance: Serum α -1-antitrypsin levels will be low in inherited protease inhibitor deficiency.
- **Test:** Urine dipstick for glucose and reducing substances
- Significance: Positive reducing substances are seen in galactosemia and hereditary fructose intolerance.

- **Test:** Urine for bile acid analysis
- **Significance:** Inborn error of bile acid metabolism
- Metabolic workup may be performed depending on clinical setting, including plasma amino acids, urine organic acids, succinylacetone, lactate, pyruvate, and other tests as indicated.
- In an older child presenting with conjugated hyperbilirubinemia, the most common causes are biliary obstruction due to gallstones, viral hepatitis, and autoimmune hepatitis.

Imaging

- **Ultrasound**
 - A noninvasive method to examine the overall liver appearance, size, and density
 - Allows for examination of the biliary tree and gallbladder to rule out choledochal cysts, sludge/stones, and ductal dilatation indicating possible obstruction
 - Infants with biliary atresia/splenic malformation syndrome may have other findings including polysplenia, asplenia, and preduodenal portal vein with azygous continuation.
- Hepatobiliary scintigraphy (HIDA scan): Tracer secretion into the duodenum excludes biliary atresia or extrahepatic biliary obstruction.

TREATMENT

GENERAL MEASURES

- Treat Crigler-Najjar syndrome promptly with phototherapy and phenobarbital to prevent kernicterus.
- Older children with Wilson disease may present with profound hemolysis and may have predominantly unconjugated hyperbilirubinemia with severe parenchymal liver disease and fulminant liver failure.

ISSUES FOR REFERRAL

- Any infant with jaundice beyond 10–14 days of age should have a fractionated bilirubin sent.
- Any infant with conjugated hyperbilirubinemia should be referred

immediately to a pediatric gastroenterologist for further workup.

CODES

ICD10

- R17 Unspecified jaundice
- P59.9 Neonatal jaundice, unspecified
- P59.0 Neonatal jaundice associated with preterm delivery

FAQ

- Q: Are there any findings in neonatal jaundice that are specifically concerning?
- A: These findings are concerning until proven otherwise:
 - Jaundice before 36 hours of life
 - Persistent jaundice beyond 10 days of life

- Serum bilirubin concentration >12 mg/dL
- Elevation of direct bilirubin >2 mg/dL or 20% of total bilirubin at any time
- Q: Are there any specific factors associated with higher bilirubin levels in neonates?
- A: Factors that have been associated with high serum bilirubin levels are low birth weight, certain ethnic groups (Asian, Native American, Greek), delayed meconium passage after birth, and breastfeeding. G6PD deficiency has also been associated with a higher risk of neonatal jaundice. Factors that have been associated with lower serum levels in neonates include maternal smoking and certain drugs such as phenobarbital. Of note, African American neonates have a lower risk of jaundice overall but are overrepresented in the U.S. Kernicterus Registry. This finding is due partially to a higher incidence of G6PD deficiency in males.
- Q: Where does the term “jaundice” come from?
- A: Jaundice is derived from the French word jaune, which means “yellow.”

KAWASAKI DISEASE

Rebecca Reindel • Stanford Shulman

BASICS

DESCRIPTION

- Kawasaki disease (KD) is a medium vessel vasculitis of early childhood with a predilection for the coronary arteries, which can result in dilatation, aneurysms, thrombosis, and stenosis.
- No diagnostic test exists, and incomplete presentations are common. Prompt recognition and treatment can reduce risk of coronary artery involvement from 25% to 5%.

EPIDEMIOLOGY

- Worldwide with highest incidence in Japan
- Peak of hospitalizations December–March
- 76% of children with KD are <5 years old.

Incidence

- U.S. hospitalization data (1997–2007) demonstrate an annual incidence of 17.1–20.8/100,000 children aged <5 years.
- KD is more common in boys than girls. In 2006, the hospitalization rate for boys was 24.2/100,000 versus 16.8/100,000 in girls.
- More common in Asian/Pacific Islanders, with highest rates in Japan
 - Ethnic predisposition persists in different geographic locations, with highest incidence in the United States in Asian/Pacific Islander children <5 years of age (30.3/100,000).
 - Rates are higher in black and Hispanic children compared to white children.

Prevalence

5,523 reported cases of KD in the United States in 2006

RISK FACTORS

- Asian/Pacific Islander descent
- Young age

Genetics

- Siblings have 10–30-fold higher risk of KD.
- Genome-wide linkage studies suggest single nucleotide polymorphisms in the ITPKC gene confer susceptibility to KD.

PATHOPHYSIOLOGY

- Generalized vasculitis with early neutrophilic infiltrate, with later transition to lymphocyte infiltration, and lastly to luminal myofibroblastic proliferation
- Can very rarely result in destruction of the endothelium through to the adventitia resulting in aneurysms and rupture

ETIOLOGY

- Etiology is unknown.
- Infectious cause suggested by the following:
 - Abrupt onset and resolution of symptoms without recurrence
 - Clusters and epidemics
 - Age of affected patients
 - Seasonal predominance
 - Oligoclonal IgA plasma cells noted in KD tissues, which bind to cytoplasmic inclusion bodies found in affected tissues
- Data suggest that KD is caused by a previously unrecognized ubiquitous RNA virus that causes disease in an immunologically susceptible population.
 - No supporting evidence for multiple proposed etiologic agents: toxic shock toxin, rug shampoo, retrovirus, bocavirus, coronavirus, mercury, EBV/CMV.

DIAGNOSIS

- KD is a clinical diagnosis.
- Current diagnostic criteria: fever for ≥ 5 days and ≥ 4 of 5 clinical findings, which need not be present at the same time
 - Extremity changes (erythema of palms, soles, and/or edema of hands, feet)
 - Polymorphous exanthema (frequently in perineal region with early

- desquamation)
- Nonexudative bilateral bulbar conjunctivitis (with limbic sparing)
- Mucosal changes (erythema of lips and oropharyngeal mucosa, strawberry tongue, cracked/swollen lips)
- Unilateral cervical lymphadenopathy (>1.5 cm in diameter)
- Incomplete KD
 - If patient has characteristics consistent with KD along with fever for ≥ 5 days with 2 or 3 clinical criteria and $\text{CRP} \geq 3$ and/or $\text{ESR} \geq 40$, obtain echocardiogram (ECHO). If patient with ≥ 3 supplemental lab criteria, treat for KD.
 - Supplemental lab criteria for incomplete KD: albumin ≥ 3 , platelets (after 7 days) $\geq 450,000/\mu\text{L}$, $\text{WBC} \geq 15,000/\mu\text{L}$, urine ≥ 10 WBC/HPF, anemia for age, ALT elevation

ALERT

Young infants with KD often present with few, if any, clinical characteristics of KD. Maintain a high index of suspicion for KD in young infants with prolonged fever.

HISTORY

- High-spiking fevers usually greater than 39°C can persist up to 3–4 weeks (mean 11 days).
- In addition to the clinical criteria above, the following complaints are sometimes seen:
 - Irritability
 - Abdominal pain/emesis/diarrhea
 - Refusal to ambulate or pain with ambulation
 - Poor appetite

PHYSICAL EXAM

- Extremity changes with palmar/plantar erythema and/or hand/foot swelling
 - Periungual desquamation of hands and feet within 2–3 weeks of fever onset
 - Beau lines (transverse grooves across nails) within 1–2 months of fever onset
- Polymorphous rash

- Usually, diffuse maculopapular rash
- Often, perineal rash with desquamation
- Also seen: erythema multiforme, erythroderma, urticaria, scarlatiniform
- Not vesicular or bullous
- Bilateral nonexudative conjunctivitis
 - Bulbar, with limbic sparing
 - Painless
 - Anterior uveitis/iridocyclitis can be seen.
- Mucosal changes
 - Cracked, red, swollen lips
 - Strawberry tongue with erythema and prominent papillae
 - Buccal and pharyngeal mucosa erythema

ALERT

In a patient with ongoing fever and nonsuppurative lymphadenitis despite adequate antibacterial therapy, consider KD.

- Unilateral cervical lymphadenopathy of one or more nodes that are >1.5 cm in diameter
 - Can be misdiagnosed as bacterial lymphadenitis
 - Usually without overlying erythema
 - Least common clinical finding in KD
- Other clinical findings
 - Myocarditis with tachycardia, gallop, innocent flow murmur
 - Shock and hypotension
 - Arthritis and arthralgias (early can be multiple joints, later is usually weight-bearing joints)
 - Urethritis, meatitis
 - Rare findings: transient hearing loss

DIAGNOSTIC TESTS & INTERPRETATION

- No definitive diagnostic test
- The presence of ancillary lab findings can support diagnosis of KD and be helpful in identifying those patients with incomplete KD.

Lab

- Elevated ESR and/or CRP

ALERT

ESR is artifactually elevated after administration of IVIG and therefore not useful in this scenario.

- CBC
 - WBC normal to elevated with left shift
 - Anemia (normocytic/normochromic)
 - Platelets usually normal in the 1st week of illness and increase over the next 2–3 weeks, sometimes to $>1,000,000/\text{mm}^3$
- Chemistries
 - Hypoalbuminemia
 - Hyponatremia
 - Transaminitis and elevated GGT
 - Hyperbilirubinemia
- Aseptic meningitis with CSF pleocytosis
- Sterile pyuria
- Synovial fluid leukocytosis
- Elevated triglycerides and LDL, low HDL

Imaging

- Chest x-ray
 - Interstitial pneumonitis
- ECHO
 - Aneurysms or ectasias of the epicardial coronary arteries that evolve over time
 - Z-score corrects for variations in body surface area among children.
 - Larger aneurysms with higher risk of thrombosis and death
 - Decreased myocardial contractility
 - Mitral or aortic (rare) regurgitation
 - Pericardial effusion
 - Rarely, aneurysms of other medium sized vessels, including iliac and axillary
- Abdominal ultrasound
 - Hydrops of the gallbladder

DIFFERENTIAL DIAGNOSIS

- Viral infections
 - Measles, adenovirus, Epstein-Barr virus
- Bacterial infections
 - Scarlet fever
 - Streptococcal or staphylococcal toxic shock
 - Staphylococcal scalded-skin syndrome
 - Leptospirosis
 - Rocky Mountain spotted fever
 - Cervical lymphadenitis
- Rheumatologic conditions
 - Juvenile idiopathic arthritis, especially systemic onset
- Drug reactions
 - Stevens-Johnson syndrome
- Mercury hypersensitivity

TREATMENT

MEDICATION

- Combination therapy with IV immunoglobulin (IVIG) and aspirin
 - Proven efficacy in reducing coronary artery aneurysms when given by 10th day of illness
 - Clinical benefit to therapy after 10th day, although prevention of coronary aneurysms unclear
 - IVIG dose: 2 g/kg given over 10–12 hours
 - Aspirin dose: 80–100 mg/kg/24 h PO divided q6h until acute-phase reactants normalize and patient defervesces, or until 14th day of illness, at which time the dose is reduced to 3–5 mg/kg once daily
- Treatment of refractory KD
 - 5–15% of patients do not respond to the first dose of IVIG.
 - 70–80% of nonresponders will respond to a second dose of IVIG.
 - Limited evidence to support a treatment recommendation for those not responding to 2nd IVIG dose, but salvage therapy with a 3rd dose of IVIG, IV corticosteroids, infliximab, cyclophosphamide, and methotrexate has been reported.

- Corticosteroids as adjunctive therapy
 - Primary adjunctive corticosteroid therapy appears to reduce the incidence of coronary artery disease in a subset of high-risk Japanese patients.
 - Some data support adjunctive corticosteroids for IVIG-refractory patients to reduce coronary artery disease risk.
 - Optimal dose, duration, and formulation of steroid has not been established.
- Antithrombotic therapy for aneurysms
 - Consider addition of antiplatelet therapy or anticoagulation in consultation with cardiology depending on size and extent of aneurysms.

ADDITIONAL TREATMENT

- Surgical therapy for life-threatening aneurysms
 - Coronary artery bypass
 - Heart transplantation (rarely)

General Measures

- Rapid diagnosis and treatment can decrease the risk of coronary artery aneurysms.
- Close follow-up and monitoring for the development of aneurysms after discharge

INPATIENT CONSIDERATIONS

Admission Criteria

Prolonged fever and clinical and laboratory findings suggestive of KD

Nursing

- Frequent vital signs and monitoring during IVIG administration
- Patient education

Discharge Criteria

- Resolution of fever for 24 hours after completion of IVIG administration
- Improvement in clinical symptoms
- Patients should have ECHO completed and interpreted prior to discharge, with additional therapy, monitoring, and prolonged hospital

stay as indicated.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Low-dose aspirin should be continued until follow-up ECHO at 2 weeks and 6–8 weeks after discharge are normal.
- Some centers perform ECHO at 6–12 months after discharge.
- Inflammatory markers and CBC should be followed until normalized.
- More frequent follow-up and monitoring for those with coronary abnormalities; advise to monitor for emesis, irritability, and nonspecific symptoms of myocardial ischemia.

Patient Monitoring

- No coronary abnormalities: routine pediatric care after follow-up ECHOs complete
- Transient coronary arteritis that resolves by 6–8 weeks: low-dose aspirin until ECHO normalizes, follow-up every 3–5 years
- Isolated small- to medium-sized (3–6 mm) aneurysm: low-dose aspirin until regression is documented on annual follow-up ECHOs. Biennial stress test or myocardial perfusion assay for patients 11 years or older. Perform angiography if stenosis or ischemia suggested.
- One or more large (>6 mm) or giant (>8 mm) aneurysm/multiple smaller or complex aneurysms: long-term antiplatelet therapy or clopidogrel indefinitely, with anticoagulation with warfarin or subcutaneous low-molecular-weight heparin. ECHO and ECG q6 months, stress testing yearly. Angiography 6–12 months after diagnosis and repeated if concerns for myocardial ischemia; no strenuous activity, additional limits on activity based on stress testing
- Evidence of stenosis or obstruction: emergent referral for cardiovascular surgical evaluation and thrombolytic therapy

PROGNOSIS

- The process of resolution of aneurysms is incompletely understood. Some histopathologic changes in the arterial lumen likely persist despite angiographic regression.

- Smaller aneurysms are more likely to resolve than larger aneurysms.
- Resolution of aneurysms (by angiography) is reported in ~50–67% of vessels.
- Improved prognosis with age <1 year, fusiform rather than saccular aneurysm, distal location
- Giant aneurysms with worst prognosis: higher likelihood of thrombosis and stenosis
- Cause of death usually myocardial infarction due to thrombosis
- Long-term implications for cardiovascular health unclear, even when no aneurysms

COMPLICATIONS

- Aneurysmal rupture (very rare)
- Myocardial infarction
- Coronary artery stenosis years after onset
- Rare association with hemophagocytic syndrome
- Recurrence rate <1%, higher in Asian populations

M30.3 Mucocutaneous lymph node syndrome [Kawasaki]

KNEE PAIN, ANTERIOR/PATELLOFEMORAL MALALIGNMENT SYNDROME

Theodore J. Ganley • Matthew Grady

BASICS

DESCRIPTION

- Condition characterized by discomfort at the anterior aspect of the knee that is generally associated with activities, especially those that involve running, jumping, and climbing stairs
- Has also been called “miserable malalignment syndrome”

PATHOPHYSIOLOGY

- Predisposing factors for patellofemoral malalignment syndrome include the following:
 - Femoral anteversion
 - Genu valgus
 - Pes planus
- These three anatomic features have been commonly referred to as a terrible triad contributing to anterior knee pain. Because the entire kinetic chain is linked in function, malalignment at one area can lead to secondary stresses at a distant location.
- Excess femoral anteversion, as well as marked pes planus, can contribute to increased lateral pull on the patella and subsequent patellofemoral pain.
- Further contributing factors include a wider pelvis and a more laterally positioned tibial tubercle, both of which also contribute to altered biomechanics at the knee.
- Weak hip abductors and quadriceps muscles and tight hamstrings, iliotibial band, Achilles tendon, and quadriceps can lead to increased forces across the patellofemoral joint.

DIAGNOSIS

HISTORY

- Pain under and around the kneecap with activities including squatting, sitting for prolonged periods with the knees bent, and going up or down stairs or hills: These activities increase patellofemoral contact stress.
- Recent history of direct trauma to the kneecap: A blunt trauma to the kneecap can cause soft tissue or subchondral contusion that may exacerbate this condition.

PHYSICAL EXAM

- Assess one-legged squat for weak hip abductors—knee will go into valgus.
- Palpate medial and lateral patellar facets for areas of pain due to increased contact forces.
- Cracking noises from the front of the knee with flexion and extension
 - Cracking can be a sign of softening of the undersurface of the patella.
 - Chondromalacia is patellar articular cartilage pathologic change, which ranges from mild cracking attributed to softening to locking and catching attributed to cartilage disruption.
- There is no single angulation or rotation profile that is universal for all anterior knee pain patients. However, many have femoral anteversion, genu valgus, and pes planus. Weak hip abductors and tight hamstrings or quadriceps may also be found.

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- Anterior and posterior, lateral, Merchant plain radiographs of the knee
 - The Merchant kneecap view shows the shape of the patella within the trochlea.
 - Patients will frequently be found to have lateral patellar tilt, as well as an abnormally shaped patella with excessive elongation of the lateral portion of the patella/lateral patellar facet.
- MRI: not a 1st-line study for patellofemoral syndrome; however, it

may be performed to rule out associated pathology in patients with recalcitrant pain and unusual clinical presentations.

DIFFERENTIAL DIAGNOSIS

- Osgood-Schlatter disease
 - Tenderness not at the patella but at the anterior tibial tubercle
 - A self-limiting inflammation of the apophysis that tends to occur in growing teenagers and preteens
 - Irregularity and fragmentation of the apophysis are seen on lateral radiographs.
- Meniscus tear
 - Disruption of the crescent-shaped fibrocartilaginous tissue adjacent to the tibial and femoral articular surfaces
 - Most commonly presents as posteromedial or posterolateral hemijoint tenderness with knee hyperflexion and rotation
- Distal iliotibial band tendonitis
 - Irritation of distal iliotibial band as it rubs over the lateral condyle before attaching on lateral tibia (Gerdy tubercle)
 - Common in runners or those with weak hip abductors
- Prepatellar bursitis
 - An inflammation of the fluid-filled bursa sac beneath the SC tissue and immediately anterior to the patella
 - More common in patients who kneel for extended periods of time and has been called “carpet layer’s knee”
 - Swelling and tenderness immediately anterior to the patella; does not primarily present with deeper tenderness in the medial and lateral parapatellar regions found in patellofemoral syndrome

ALERT

Patients with a traumatic effusion, locking, catching, instability to ligamentous stress testing, multiple joint effusions, or night waking should be evaluated for other traumatic or medical conditions.

TREATMENT

GENERAL MEASURES

- A progressive exercise program is the main focus of treatment.
- Strength and flexibility exercises are needed to improve the mechanics of the patellofemoral joint.
- Strengthening should include hip abductors, hip extensors, hamstrings, and the quadriceps muscles.
 - This strengthening can be performed several times each day as a home exercise program or formally with physical therapy in more recalcitrant cases.
- Stretching should include quadriceps, hamstrings, iliotibial band, and tendoachilles stretches as indicated by the physical examination (PE).
- Patients can be advanced from low-resistance exercises such as swimming, stationary bike, and elliptical trainers to higher level running activities.
- Activity restriction in the initial acutely symptomatic stage is instituted to eliminate high-impact sports, including especially those that involve running and jumping.

CODES

ICD10

- M25.569 Pain in unspecified knee
- M22.2X9 Patellofemoral disorders, unspecified knee

- M22.40 Chondromalacia patellae, unspecified knee

FAQ

- Q: Is it acceptable to play sports, or is this condition too dangerous?
- A: Patients with a history of patellofemoral syndrome who have regained their strength and flexibility are permitted to return to their activities, provided that they do not have pain and limping during their activities. A history of catching, locking, or knee effusions may be a sign of further biomechanical intra-articular pathology that should be addressed.
- Q: Is bracing indicated?
- A: Some patients with anterior knee pain respond to neoprene sleeves, and those with a component of increased lateral translation may benefit from neoprene sleeves with lateral patellar supports. Bracing, however, is not a substitute for strength and conditioning program.
- Q: Is chondromalacia patella the same as patellofemoral syndrome?
- A: No. Chondromalacia is a classification of the anatomic pathologic changes of the undersurface of the patella. Patellofemoral syndrome is the clinical condition encompassing the patient's history, physical, and radiographic elements of anterior knee pain.

LACRIMAL DUCT OBSTRUCTION

Bethlehem Abebe-Wolpaw

BASICS

DESCRIPTION

A congenital blockage identified in infants from failure of canalization, most commonly at the distal portion, of the nasolacrimal duct. Epiphora (constant tearing) is the most common presentation followed by discharge unresponsive to treatment. Less commonly, the blockage is an acquired condition.

EPIDEMIOLOGY

- Most common cause of persistent tearing in infants
- True congenital nasolacrimal duct obstruction affects about 6% of newborns.
- Spontaneous resolution occurs in 90% of cases within 1 year.

RISK FACTORS

Incidence is higher in infants with craniofacial malformations and Down syndrome.

PATHOPHYSIOLOGY

- Congenital obstruction most commonly occurs at the level of the valve of Hasner in the distal portion of the nasolacrimal duct as it enters the nose.
- Types of distal obstruction include an imperforate membrane or cellular debris at the level of the valve, bony obstruction, or narrowing of the inferior meatus.
- Acquired obstructions are rare in children but do occur as a result of chronic inflammation and scar tissue occluding the duct. Causes include infection (i.e., ethmoidal sinusitis), inflammation, malignancy, and trauma.

ETIOLOGY

Canalization of the duct is usually complete by the 7th month of gestation,

but a persistent membrane can remain and may represent the embryologic basis of lacrimal duct obstruction.

COMMONLY ASSOCIATED CONDITIONS

- Dacryocystocele (distention of the lacrimal sac) is a rare variant of lacrimal duct obstruction seen in 0.1% of infants with the disorder. There is the typical distal obstruction as well as a proximal obstruction at the junction of the common canaliculus and the lacrimal sac.
- Acute dacryocystitis is strongly suggestive of the presence of obstruction. Unclear whether obstruction is the primary cause leading to secondary infection from accumulation of tears and cellular debris or that dacryocystitis is the primary event with an acquired obstruction from fibrosis and inflammation

DIAGNOSIS

HISTORY

- Congenital obstruction presents in first few weeks of life.
- Symptoms can be either unilateral or bilateral.
- Chronic tearing
- Mucoid discharge
- Crusting on eyelids and eyelashes
- Acquired obstruction is associated with chronic eye infections or a history of trauma (i.e., naso-orbito-ethmoidal fractures, lid laceration).

PHYSICAL EXAM

- Discharge and/or crusting on the eyelashes
- Eyelid excoriation
- Compression of lacrimal sac reveals mucoid discharge and/or tears expressed through the punctum.
- Usually absence of conjunctival injection
- Bluish firm mass below the medial canthus suggests presence of dacryocystocele.

DIAGNOSTIC TESTS & INTERPRETATION

Usually, patients are treated without imaging and testing. If symptoms are

intermittent and diagnosis is unclear, imaging and tests may be done.

Lab

Bacterial cultures are not a reliable indicator of the presence of obstruction or infection thus is not indicated for diagnostic purposes.

Imaging

- Radionuclide dacryocystography (also known as dacryoscintigraphy) helps evaluate the functioning of the lacrimal system by taking pictures as a radioisotope passes through the lacrimal system.
 - Technically difficult to perform in children so is rarely done
 - Does not allow for visualization of surrounding bony structures
- CT scan is useful for trauma or to assess bony obstruction resulting from craniofacial malformations or presence of dacryocystocele or other masses.

Diagnostic Procedures/Other

- Fluorescein dye disappearance test
 - Preferred tool for diagnosis of congenital obstruction if symptoms are intermittent
 - 90% sensitive and 100% specific for nasolacrimal duct obstruction
 - Fluorescein is placed in the lower conjunctival fornix and the patient is observed for 5 minutes.
 - If there is no obstruction, most of the fluorescein drains into the nose and minimal amounts of fluorescein is noted in the eye.
 - If there is an obstruction, fluorescein will be seen in the eye with an increased tear meniscus with likely overflow of tears onto the cheeks.
- If dacryocystocele is suspected, nasal endoscopy is recommended. Application of a topical decongestant such as oxymetazoline hydrochloride to the nasal mucous membranes enhances visualization.

DIFFERENTIAL DIAGNOSIS

- Neonatal conjunctivitis
- Acute dacryocystitis
- Agensis or imperforation of the lacrimal puncta or canaliculi
- Excess tear production
 - Congenital glaucoma

- Corneal abrasion
- Abnormal eyelid position (entropion, epiblepharon)
- Trichiasis
- Foreign body
- Blepharitis
- Keratitis
- Uveitis

TREATMENT

MEDICATION

Topical ophthalmic antibiotics are used in congenital obstruction when there is an increase in discharge, purulent discharge, or findings consistent with conjunctivitis. Topical antibiotics of choice include erythromycin, tobramycin, sulfacetamide, gentamicin, or fluoroquinolones.

ADDITIONAL TREATMENT

General Measures

- Primary treatment for congenital obstruction is lacrimal sac massage in a downward fashion. Topical antibiotics are added as needed.
- Crigler maneuver can be effective in rupturing the membranous obstruction.
- Probing and irrigation are generally recommended if symptoms persist after 6–12 months of age.
 - Some ophthalmologists prefer to perform the procedure prior to 12 months of age, and some continue with conservative measures until 15–18 months of age.
- Failed probing is usually noted within 6 weeks of procedure with return of symptoms.
- Probing may be repeated, although with increasing age, repeated probing may be less successful.
- Additional procedures may be done at the time of repeat probing that may increase the success rate, including the following:
 - Balloon catheter dilatation. Some experts advocate that this can be considered as a primary treatment in place of probing.

- Nasal endoscopy allows visualization of the probe entering the nose, helping to avoid false passage.
- Silicone tube intubation helps prevent formation of granulation tissue and can aid in dilating stenotic segments of the lacrimal outflow system. Tube is left in place for 2–6 months but success has been seen with removal as early as 6 weeks in patients younger than age 2 years.

ISSUES FOR REFERRAL

- Referral to a pediatric ophthalmologist is indicated if symptoms persist beyond 6–12 months of age with the application of conservative measures. Depending on severity and preference of the ophthalmologist, probing is done or conservative measures are continued.
- Early referral is warranted in cases of acute dacryocystitis and dacryocystocele.
- Cases of acquired obstruction should be referred for surgical treatment.

SURGERY/OTHER PROCEDURES

- Dacryocystorhinostomy
 - Indicated when aforementioned procedures have failed and in cases of chronic dacryocystitis, bony obstruction, or dacryocystocele
 - Creates a bypass fistula between the lacrimal sac and the nose to provide an alternate pathway for lacrimal flow
- Primary conjunctivodacryocystorhinostomy
 - Creates a direct bypass tract between the medial canthus and the nose
 - Limited reports on this technique being used in children
- Surgery is typically performed on patients with acquired obstructions and congenital anomalies of the upper lacrimal system.

INPATIENT CONSIDERATIONS

Admission Criteria

- Neonates with dacryocystocele with an associated intranasal cyst obstructing their airway causing significant respiratory distress need to be admitted for airway management.
- Acute dacryocystitis should be admitted for parenteral antibiotic

therapy with ophthalmology involved in the plan of care; may need surgery to drain the collection.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Conservative measures are appropriate for infants with congenital obstruction, although at 6–12 months of age, referral should be considered for possible probing and irrigation.
- Children with a history of lacrimal duct obstruction need close follow-up for anisometropic amblyopia.

PROGNOSIS

- About 90% of cases of congenital obstruction resolve by 12 months of age.
- Success rate of initial probing when performed at 12 months of age is about 80–90%.
- Probing is less successful after age 3 years.

COMPLICATIONS

- Infections such as bacterial conjunctivitis, acute and chronic dacryocystitis, and orbital cellulitis
- Respiratory distress in neonates with dacryocystocele that have an associated intranasal cyst at the valve of Hasner that obstructs their airway
- Anisometropic amblyopia

CODES

ICD10

- H04.559 Acquired stenosis of unspecified nasolacrimal duct
- H04.539 Neonatal obstruction of unspecified nasolacrimal duct
- Q10.6 Other congenital malformations of lacrimal apparatus

FAQ

- Q: Why not fix the obstruction upon diagnosis?
- A: Studies have shown that about 90% of cases of congenital obstruction resolve by 12 months of age using conservative measures consisting of massage with occasional addition of topical antibiotics for infection that can occur concurrently with obstruction.
- Q: When is the optimal age for probing and irrigation?
- A: This is controversial, although most studies suggest conservative measures are preferred younger than 12 months of age. After 12 months of age, continued conservative measures or probing are selected based on severity of symptoms. Recent studies indicate that probing becomes less successful as a primary treatment in patients

around age 3 years. This may be due to factors other than increasing age, including severe symptoms, canalicular stenosis, and nonmembranous obstruction.

- Q: Does probing and irrigation require general anesthesia?
- A: Sometimes probing is performed as an in-office procedure without general anesthesia if done when patient is young, younger than 12 months of age. When child is older than 12 months of age, probing is ideally performed under general anesthesia to ensure procedure is controlled and safe as well as allowing for direct visualization with endoscopy.

LACTOSE INTOLERANCE

Elizabeth J. Hait

BASICS

DESCRIPTION

- Lactose intolerance is defined as the inability to digest the ingested disaccharide lactose secondary to a deficiency of the intrinsic enzyme lactase, resulting in clinical symptoms.
- Lactose is a disaccharide composed of glucose and galactose.
- Lactose is important as a source of energy; it is the major carbohydrate in human and other mammalian milks; promotes the absorption of calcium, phosphorus, and iron; and has a probiotic effect on the gut flora.
- Four types of lactase deficiency
 - Congenital lactase deficiency
 - Extremely rare
 - Presents during the newborn period
 - Will cause severe diarrhea and failure to thrive and risk the newborn's life
 - Primary lactase deficiency (adult-type hypolactasia)
 - Due to relative or absolute absence of lactase
 - Develops during childhood at different ages in different racial groups
 - Most common cause of lactose intolerance
 - Secondary lactase deficiency
 - Results from small bowel injury (acute gastroenteritis, persistent diarrhea, small bowel bacterial overgrowth, chemotherapy)
 - Can present at any age, more common in infancy
 - Developmental lactase deficiency
 - A relative lactase deficiency observed in premature infants <34 weeks' gestation

EPIDEMIOLOGY

Prevalence

- ~70% of the world's population is prone to primary lactase deficiency.
 - The prevalence of primary lactase deficiency in northern Europeans, who have a diet rich in dairy, is 2%.
 - In Hispanic populations, the prevalence of primary lactase deficiency is 50–80%.
 - In Ashkenazi Jewish and African American populations, the prevalence is 60–80%.
 - In Asian populations, the prevalence of primary lactase deficiency is nearly 100%.
- Nearly 20% of children <5 years from Hispanic, Asian, or African American descent have lactase deficiency and lactose malabsorption.
- Caucasian children usually do not develop symptoms until after 5 years of age.

RISK FACTOR

Genetics

- Posttranslational regulatory mechanisms in primary lactase deficiency or adult-type hypolactasia
- Correlation between the genetic polymorphism of mRNA and persistence of lactase activity with early loss at 1–2 years in Thai children and late loss at 10–20 years in Finnish children

PATHOPHYSIOLOGY

- Symptoms depend on the amount of lactose ingested.
- Malabsorbed lactose creates an osmotic load that draws fluid and electrolytes into the bowel lumen, leading to an osmotic diarrhea.
- Nonabsorbed lactose acts as a substrate for intestinal bacteria.
- In the colon, bacteria metabolize lactose, producing volatile fatty acids and gases leading to flatulence, bowel distension, pain, and low pH.

DIAGNOSIS

HISTORY

- Classic symptoms include bloating, gaseousness, colicky abdominal pain, and diarrhea after digestion of lactose-containing meal.
- Dietary intake history provides important information.

- Association with milk ingestion may not be evident.
- Symptoms vary in severity with dose of lactose ingested.
- Detailed history of symptoms:
 - Blood or mucus in the stools, weight loss, poor growth, fat malabsorption, or any extraintestinal symptoms strongly suggest different causes.

PHYSICAL EXAM

- Height and weight should be measured and plotted against age-appropriate norms; any deviation should not be attributed to lactose intolerance alone.
- Abdomen percussion: Abdomen may be distended and tympanitic.
- Blood in the stool must be further evaluated as lactose intolerance does not cause bleeding.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Stool-reducing substances and fecal acidity
 - A pH <6.0 or reducing substances >0.5% should be interpreted as positive results.
 - Positive results indicate malabsorption of carbohydrates.
- Lactose hydrogen breath test
 - Noninvasive and highly sensitive
 - A rise of breath H₂ concentration of ≥20 ppm over baseline has been shown to correlate with enzyme deficiency.
 - However, there is poor association between symptoms of lactose intolerance and breath H₂ excretion, which underscores the need for caution in the interpretation of the clinical significance of the breath hydrogen test.
 - False-positive test results can occur if inadequate fasting before the test, rapid intestinal transit, toothpaste, smoking, and bacterial overgrowth.
 - False-negative results occur with diarrhea, hyperventilation, recent antibiotic exposure, and delayed gastric emptying. In addition, up to 10% of the population is colonized with bacteria unable to produce hydrogen, which can lead to a falsely negative result.

- Lactase activity measurement from endoscopically obtained duodenal tissue biopsies (invasive and expensive)

Pathologic Findings

The small bowel intestinal histology will often be normal in primary lactase deficiency (unless the reason is insult/damage to the small bowel mucosa).

DIFFERENTIAL DIAGNOSIS

- Infection
 - Viral and bacterial infections can cause secondary lactose intolerance due to villous injury.
 - Most common pathogen is rotavirus.
 - Parasitic infections can mimic lactose intolerance (giardiasis).
- Inflammatory conditions
 - Small intestinal Crohn disease
 - Celiac disease
- Congenital
 - Other carbohydrate enzyme deficiencies can mimic lactose intolerance. These include sucrase–isomaltase or glucose–galactose malabsorption.
 - Cystic fibrosis
 - Shwachman-Diamond syndrome (SDS): Primary features include the following:
 - Bone marrow insufficiency
 - Pancreatic insufficiency
 - Skeletal abnormalities
 - Short stature
- Allergic/immune
 - Food protein allergies
 - Oral medications containing lactose: common in tablets

TREATMENT

MEDICATION

- Oral lactase replacement capsules

- Calcium supplements to ensure daily recommended intake levels despite dairy restriction

ADDITIONAL TREATMENT

General Measures

- Removal of lactose from the diet is effective in eliminating symptoms.
- However, it is important to recognize that a milk-free diet is associated with calcium deficiency.
- Predigestion of lactose can be done by the addition of commercially available enzyme supplementation (extrinsic lactase). Multiple products are available over the counter. Liquid preparations, capsules, and chewable tablets can be obtained.
- Acquired deficiencies, particularly those associated with infection, may resolve over time or with specific treatment. Many patients with lactose intolerance do not recover the ability to digest lactose.
- Supplemental probiotics may improve symptoms of lactose intolerance.

ONGOING CARE

DIET

- Lactose-free formula, lactase-containing milk
- Cow milk substitutes (e.g., rice or soy milk)
- Yogurt and aged cheeses, which generally have smaller content of lactose.

PROGNOSIS

- Prognosis of lactase deficiency and clinical intolerance is excellent with lactose reduction or elimination as well as enzyme replacements are possible.
- Lactose intolerance secondary to disease processes should be recognized and treated appropriately.

CODES

ICD10

- E73.9 Lactose intolerance, unspecified
- E73.0 Congenital lactase deficiency
- E73.8 Other lactose intolerance

FAQ

- Q: When is the usual time for presentation of lactose intolerance?
- A: In whites, the age of presentation is after 5 years of age. In African Americans, 2–3-year-old children may present with clinical signs and symptoms. The differential diagnosis must distinguish primary from secondary causes.
- Q: Does lactose intolerance prevent a child from ever eating lactose?
- A: No. The patient can take smaller amounts of lactose in the diet or have the enzyme supplemented.
- Q: Does this problem ever get better?
- A: No. It is a lifelong problem, but seems to become less symptomatic

for adults, in light of their individual desire to tolerate symptoms. Secondary lactose intolerance may improve with time or treatment of the primary disorder.

LEAD POISONING

Julie O'Brien • Kent Olson

BASICS

DESCRIPTION

- Lead poisoning is one of the most common pediatric environmental health problems, most often involving systemic intoxication with inorganic lead. Lead poisoning is an older term that is less specific than an actual blood lead level (BLL).
- The Centers for Disease Control and Prevention (CDC) considers an elevated BLL to be ≥ 5 mcg/dL.
 - This “reference value” is based on the 97.5th percentile for lead levels of children aged 1–5 years collected for the National Health and Nutrition Examination Surveys (NHANES).
 - This replaces the previous “level of concern” terminology for levels ≥ 10 mcg/dL based on the Advisory Committee on Childhood Lead Poisoning Prevention (ACCLPP) recommendations in light of many studies demonstrating cognitive and behavioral effects at BLL less than 10 mcg/dL.

EPIDEMIOLOGY

A recent national survey estimates that 38 million housing units have lead-based paint (1/3 of all U.S. housing).

- 24 million housing units have hazards from lead-based paint.
- ~83% of American pre-1978 privately owned units contain some lead-based paint.

Prevalence

The prevalence of elevated BLLs and the geometric mean BLLs have decreased significantly in the past 20 years.

- ~450,000 American children aged 1–5 years are estimated to have BLLs of ≥ 5 mcg/dL.
- Racial income disparities persist due to disparities in housing quality, nutrition, and access to health care.

RISK FACTORS

- Young children with more oral behaviors
- Children with developmental delays/mental retardation
- Children with pica
- Residence in older homes with flaking or deteriorating lead-based paint
- Renovation or remodeling of older homes without lead hazard controls in place
- Recent immigration from countries where ambient lead contamination is high (i.e., where leaded gasoline is still used)
- Use of lead-glazed ceramic pottery
- Use of traditional therapies containing lead (e.g., Azarcon, some Ayurvedic and Chinese medicines)
- Ingestion of lead-containing candies from Mexico

GENERAL PREVENTION

- Primary prevention: removal of potential environmental lead hazards prior to exposure
 - The ACCLPP focuses on primary prevention as it emphasizes that there is no “safe” level of lead and the effects of lead are likely irreversible.
 - Clinicians should provide anticipatory guidance to all parents about lead exposure pathways and the prevention of exposures.
- Secondary prevention: screening for elevated BLLs
 - Minimum screening recommendations: blood lead test for children at 1 and 2 years and for those 36–72 months old who have not had previous screening
 - Screening children immigrating from other countries and screening pregnant and lactating women and their neonates and infants for lead exposure prior to or during pregnancy and lactation
- Tertiary prevention: case management and environmental remediation for children with lead poisoning
- Control measures
 - Abatement of building-based (residential) lead hazards by removal, encapsulation, or enclosure of lead-containing structures
 - Control of environmental lead dust exposure and ingestion by good housekeeping (wet dusting and mopping of household dust);

personal hygiene (cleaning of child's hands, toys, personal items, wiping feet on mats prior to entering the home), and hiring certified renovators who are EPA-approved to perform renovations that may disrupt lead-based paint

- Removal of any other known lead source from the child's environment

PATHOPHYSIOLOGY

- Lead adversely affects many organ systems including neurologic, hematologic, GI, renal, and reproductive.
 - Many toxic effects result from inhibition of enzymes involved in heme biosynthesis, as the electropositive metal binds to negatively charged sulfhydryl groups on active sites of δ -aminolevulinic acid dehydratase (ALAD), ferrochelatase, uroporphobilinogen synthase, coproporphyrinogen oxidase, and other enzymes.
 - Divalent lead also acts competitively with calcium in various biologic systems.
- Children absorb lead more efficiently from the GI tract and are more likely than adults to ingest lead through hand-to-mouth activities.
- Because the developing, immature CNS is susceptible to toxic effects of lead, the neuropsychologic effects of lead poisoning on fetuses/young children are of particular concern. Even relatively low BLLs are associated with IQ deficits, attention-related behaviors, and poor academic achievement.

DIAGNOSIS

HISTORY

- It is important to assess for risk factors for exposure, as most children are asymptomatic.
- Etiology/common sources of lead:
 - Ingestion of lead-based paint or contaminated dust or soil through residence in or visitation of older (pre-1980), deteriorated housing
 - A parental occupation or hobby involving lead exposure (e.g., construction or battery plant work, stained glass window or pottery

- making)
 - Use of remedies, cosmetics, pottery, toys, or consumer products containing lead
 - Ingestion of contaminated water, food, or beverages
- Typical symptoms:
 - Most children are asymptomatic; many clinical manifestations are nonspecific. A cluster of complaints including anorexia, intermittent abdominal pain, constipation, sporadic vomiting, change in mental status (e.g., irritability or lethargy), decreased play activity, and change in developmental status (e.g., regression of developmental milestones) may herald this condition.
- Lead encephalopathy
 - Can present with change in consciousness, ataxia, persistent vomiting, seizures, and coma
 - Often presents after a prodrome of symptoms mentioned above

PHYSICAL EXAM

As patients are generally asymptomatic, physical exam is not generally helpful at lower lead levels.

- Symptomatic and/or encephalopathic patients may have acute GI, neurologic, hematologic, and systemic manifestations.
- Assess for developmental delay.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Blood lead test, either venous or capillary (but must be drawn in lead-free tube):
 - Results may be reportable to local health authorities.
 - The test result is a measure only of recent lead exposure and does not indicate total body burden of lead.
 - Capillary testing is associated with more false-positive results. If abnormal, a venous lead should be sent.
 - A confirmed elevated BLL is defined as a child with a venous blood sample ≥ 5 mcg/dL.
- CBC: to assess for anemia
 - Iron deficiency anemia is often seen concomitantly.

- Anemia related to lead toxicity is typically normocytic and normochromic; a microcytic, hypochromic anemia may be seen with a mixed etiology.
- Basophilic stippling is sometimes seen on peripheral blood smear.
- Free erythrocyte protoporphyrin
 - Marker of lead-induced inhibition of heme synthesis
 - Can be useful clinically to follow the recovery from heme synthesis inhibition during management

Imaging

- Abdominal radiograph: Look for radiopaque foreign material suggestive of ingestion of lead paint chips or other lead-containing foreign body, when ingestion of such is suspected in the history or with very high BLLs.
- Long bone radiographs are not recommended for routine screening.

DIFFERENTIAL DIAGNOSIS

Consider lead poisoning as the etiology for the following diagnoses:

- Seizures, altered mental status, and/or coma
- Anemia

ALERT

Failure to diagnose results from the following:

- Delay in checking a blood lead test in the presence of clinical signs, symptoms of lead poisoning, or neuropsychologic disorders
- Failure to inquire about lead exposure possibilities

TREATMENT

Treatment for most individuals is focused on environmental management to prevent further lead exposure. Medications are only required at higher BLLs.

GENERAL MEASURES

- Environmental management
 - Remove children from the lead source(s).
 - Should occur when venous lead levels are recurrently 10 mcg/dL

(CDC class IIA) and higher; could be done for lower BLLs as resources allow

- Reduction of lead levels in the household
- Consultation with a qualified lead abatement contractor is advised.

MEDICATION

- Chelation therapy
 - Should complement environmental management in all children with venous levels of ≥ 45 mcg/dL using parenteral calcium disodium ethylenediaminetetraacetate (Ca-EDTA; calcium disodium versenate) or oral agents such as meso-2,3-dimercaptosuccinic acid (DMSA, succimer, Chemet)
 - Chelation of children with levels < 45 mcg/dL is not recommended, as evidence suggests it does not reverse or diminish neuropsychological effects of lead.
 - Outpatient therapy can take place if a lead-safe environment has been identified and compliance is expected.
 - Succimer is given at 10 mg/kg (or 350 mg/m²) q8h for 5 days, then q12h for 14 more days. Weekly monitoring for neutropenia, platelet abnormality, and increased liver enzymes is recommended.
- Children with symptomatic lead poisoning or with levels of ≥ 70 mcg/dL should be admitted immediately to a hospital for parenteral chelation with both IM dimercaprol (British anti-Lewisite, BAL) and IV or IM calcium disodium EDTA. Because there are many issues involved with administration of both chelating agents, consultation with a clinician experienced in lead toxicity treatment is advised.
- Children with encephalopathy constitute a medical emergency and should receive the preceding treatment in an intensive care setting with attentive neurosurgical support.
- Ingested lead-containing foreign bodies should be evacuated with whole-bowel irrigation using a polyethylene glycol electrolyte solution.

ISSUES FOR REFERRAL

- Close communication with the local health department is essential before, during, and after admission.

- Referral may be made to early intervention or development assessment programs, social workers, therapists, neurologists, or other specialists, as needed.

INPATIENT CONSIDERATIONS

Admission Criteria

Admit all symptomatic children, those with BLLs ≥ 70 , and those with BLLs ≥ 45 for which one cannot ensure a lead-safe environment and/or compliance with oral medication.

Discharge Criteria

Consider discharge when symptoms have resolved, BLL has significantly declined, and a lead-safe discharge environment has been identified.

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Prompt environmental follow-up of current lead exposure situations and investigation for additional exposure (e.g., with family moves, visitation of new residences) should occur.
- Follow-up venous lead levels should be performed for those with BLLs ≥ 5 mcg/dL about every 1–3 months, with less frequent follow-up after levels decline.
- Follow-up venous levels should be performed 1–3 weeks following chelation therapy, with frequent monitoring thereafter until levels have decreased significantly and no new lead exposure is apparent. BLLs will increase from the nadir level immediately after treatment to rebound to a level between this and the pretreatment level.

DIET

- Nutritional support with calcium and iron supplementation should be given if intake is inadequate; deficiencies of these increase lead absorption from the GI tract.
- The recommendation for adequate intake of calcium is 500 mg/day, which can typically be achieved through a regular healthy diet.
 - There is currently no evidence that supplementation of calcium beyond the recommended “adequate intake” is beneficial for children with elevated BLLs.

- Iron repletion should be initiated with 3 mg/kg of elemental iron for those children who are found to be iron deficient.
 - Iron supplementation should be withheld during chelation therapy.
- Additionally, it is recommended to consume at least two servings daily of foods high in vitamin C, such as fruits, vegetables, and juices.

PROGNOSIS

There is an increased risk for long-term neuropsychological sequelae, which increases with lead exposure and absorption that is more intense, of longer duration, and begins at an early age when the CNS is still developing.

- Recurrent episodes of symptomatic lead poisoning increase the risk for permanent sequelae.
- Subtle effects may be missed until school entry.

COMPLICATIONS

- Acute encephalopathy
- Seizures
- Coma
- Death (predominantly owing to cerebral edema)
- Mental retardation
- Cognitive, behavioral, attentional, and neurodevelopmental impairment
- Anemia
- Fanconi syndrome
- Abdominal colic
- Adverse reproductive outcomes

CODES

ICD10

- T56.0X4A Toxic effect of lead and its compounds, undetermined, init
- T56.0X1A Toxic effect of lead and its compounds, accidental, init

FAQ

- Q: What is lead abatement?
- A: Lead abatement is removal of a lead hazard from the environment either by replacing it (e.g., installing a new window), enclosing the area with the lead source (e.g., installing paneling), removing the lead-based paint from a surface (burning or dry sanding methods should never be used), or encapsulating the area (placement of a specific coating over the lead-containing surface, which prevents access to the lead hazard).
- Q: Is lead abatement permanent?
- A: Often, lead paint that is chipping or peeling is removed from a home. Any areas with intact lead-based paint may become deteriorated with aging, leading to new lead hazards, although ongoing maintenance and repair may prevent this.
- Q: Why didn't my child's brother and sister get lead poisoning at the same age since they lived in the same house?
- A: Children are different; some do much more hand-to-mouth activity than others, which is the main way that children get lead into their bodies. Also, your home may not have had the same lead dangers (hazards) when the siblings were younger.

LEARNING DISABILITIES

Monica D. Dowling • Jeffrey P. Brosco

BASICS

DESCRIPTION

Learning disabilities (LD) are a group of disorders characterized by unexpected and sustained difficulties acquiring and applying academic skills, including reading accuracy, reading fluency, reading comprehension, written expression, mathematic calculations, and mathematic problem-solving.

- LD comprise one category within the classification of Neurodevelopmental Disorders (NDDs) in the Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-V, 2013) and the International Classification of Diseases, Code Book 10 (ICD-10, 2013).
- Academic achievement must be substantially below the level expected for age and not attributable to intellectual disability (ID), neurologic or motor disorders, lack of schooling, psychosocial factors, economic disadvantage, or major sensory problems.
- LD have neurobiologic and genetic roots.
- Reading disability is the most frequently diagnosed type of LD and is typically characterized by impairments in phonologic processing and/or orthographic coding skills. Children with math disability show procedural, retrieval, and number sense deficits.
- The role of the pediatrician is to advocate for a child with LD, interpret predisposing factors in child's developmental and medical history, and offer scientific interpretation of the range of theories and interventions.
- Early intervention improves outcomes.

EPIDEMIOLOGY

- In 2009–2010, 2.4 million or 5% of total public school enrollees (ages 3–21 years) identified with LD as eligible for special education based on U.S. Department of Education National Center for Education Statistics, 2012.

- The National Institutes of Health (NIH) estimates that as many as 15–20% of Americans are affected by LD.

RISK FACTORS

- LD are familial and moderately heritable.
- Risk loci and genes have been identified for reading and language disorders.
- Aberrant neuronal migration hypothesized as principal pathophysiology
- Genetic contribution increases with a high level of parent education (a bioecologic gene by environment interaction).
- Environmental factors include prematurity, low birth weight, prenatal nicotine or alcohol exposure, infections, and traumatic brain injury.

COMMONLY ASSOCIATED CONDITIONS

- Language disorders
- Speech sound disorders
- Auditory processing disorders
- Developmental coordination disorder
- ADHD/executive function deficits

GENERAL PREVENTION

- High-quality developmentally appropriate preschool experiences
- Early literacy initiatives (e.g., Reach Out and Read)
- Early intervention for speech, language, motor difficulties
- Evidence-based reading curricula and ongoing academic progress monitoring beginning in kindergarten
- Supplemental instruction for children who show early signs of learning problems

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- ID
 - Borderline intellectual functioning or mild ID may not be evident in early childhood.

- ADHD
 - Especially when inattentive and distractible symptoms are greater than hyperactive symptoms
 - Comorbidity is approximately half of diagnosed cases of LD.
- Sensory impairments
 - Hearing or vision impairments
 - School screening results should be confirmed by the pediatrician in children with academic problems.
- Neurologic etiologies
 - Absence seizures and other nonconvulsive epileptic disorders
 - Neurodegenerative disorders such as Niemann–Pick disease, adrenoleukodystrophy, ceroid lipofuscinosis, and subacute sclerosing panencephalitis may rarely present as school-age learning problems.
 - CNS trauma
- Genetic syndromes
 - Some genetic syndromes may show subtle dysmorphism that is not noted until learning problems arise. Examples include the following:
 - Sex chromosome aneuploidies
 - Fragile X syndrome
 - Neurofibromatosis
 - Tuberous sclerosis
 - Velocardiofacial/DiGeorge syndrome
- Hypothyroidism
- HIV infection
- Lead intoxication
- Chronic malnutrition
- Iron deficiency
- Iatrogenic interventions
 - Some medications (e.g., antiepileptic drugs) affect cognition.
 - Cancer treatment
- Psychosocial issues
 - Issues related to family stress, peer relationships, illness, school absence, or adolescence may present as academic difficulty.

- Conversely, behavior problems at home or at school always should prompt evaluation of school functioning.
- Psychiatric comorbidity
 - Adjustment disorders, anxiety, mood disorders, oppositional defiant disorder, conduct disorder, tic disorders, substance abuse, and other behavior problems may precede or follow the presentation of LD.

APPROACH TO THE PATIENT

- Many learning problems respond to appropriate educational interventions, regardless of specific etiology, and failure to respond to intervention is part of the diagnostic process for specific LD.
- It is the role of the educator to (a) monitor academic progress of all students, (b) provide educational intervention and frequent progress monitoring to struggling students, and (c) conduct a psychoeducational assessment of students who do not respond to initial intervention.
- Once a child presents with learning problems, it is the role of the pediatrician to
 - Help the family obtain timely and evidence-based educational interventions. LD Navigator (<http://www.ncld.org>) provides health care professionals with resources.
 - Identify and treat underlying medical problems.
 - Identify and help treat underlying psychosocial issues:
 - Psychosocial stresses may exacerbate learning difficulties or be a primary etiologic factor.
 - School attendance is a particularly important factor in learning.
 - Identify and treat comorbid psychiatric disorders.

HISTORY

- **Question:** When and how does the child fail in his or her daily academic pursuits?
- Significance:
 - LD typically impact only school activities and are often limited to one skill area such as reading or math.
 - Children with ADHD typically show problems in multiple settings (school, home, extracurricular, peers).
 - Children with ID usually have a history of developmental concerns.

- **Question:** Is decline in school performance recent and/or abrupt?
- **Significance:** If abrupt, consider pathophysiologic processes such as vision or hearing impairment, side effect from medication, neurodegenerative disorders (rare), or recent psychosocial issue.
- **Question:** Past medical history, medications, review of systems, psychosocial stresses?
- **Significance**
 - School attendance (illness vs. avoidance)
 - Early development and behavior
 - Family history of learning problems
 - Sleep patterns (apnea, insomnia)

PHYSICAL EXAM

- **Finding:** Subtle dysmorphology?
- **Significance:** May suggest the presence of a genetic syndrome or a pattern of malformation resulting from teratogenic fetal exposures (e.g., alcohol, phenytoin)
- **Finding:** Skin lesions?
- **Significance:** May suggest underlying genetic syndromes such as tuberous sclerosis
- **Finding:** Enlarged tonsils?
- **Significance:** May cause sleep disturbance that affects learning and/or behavior
- **Finding:** Abnormal neurologic examination?
- **Significance**
 - Any focal signs demand additional evaluation
 - Slow rapid alternating finger movements (neuromaturational signs) are often present in children with LD but are generally not helpful clinically.

DIAGNOSTIC TESTS & INTERPRETATION

- **Physician**
 - Audiology and vision screening
 - Standardized behavior questionnaires (e.g., Teachers and Parent Vanderbilt)
 - Consider other screening tools for depression, anxiety, family

- dysfunction, parental depression, and substance abuse.
- Genetic, neurologic evaluation if indicated by history or physical exam
 - Educator
 - Teacher-administered measures or computer-administered tests to monitor progress. Standardized achievement tests can be administered yearly to measure current functioning and review progress.
 - Psychologist
 - Testing must be performed individually and include intellectual and academic functioning at a minimum.
 - Federal law requires schools to provide comprehensive evaluations on written request by the parents. Specific information for each state is available from the National Dissemination Center for Children with Disabilities (800-695-0285; <http://www.nichcy.org>).
 - University- and hospital-based centers outside the school system also conduct evaluations of children with LD.
 - For children who do not respond to educational interventions, or if the psychoeducational evaluation is inconclusive, neuropsychologic testing may identify specific cognitive factors that are helpful in developing an effective educational plan.

TREATMENT

- Discourage a “wait and see” approach to decision making.
- Begin evidence-based interventions as soon as problems are evident; children who do not respond require more thorough etiologic workup.
- Academic or attention difficulties may lead to spiraling psychological problems from depression or damaged self-esteem to conduct disorder and school dropout.

GENERAL MEASURES

- Physician
 - Responsible for treatment of underlying medical diagnoses
 - Ensure appropriate treatment of psychological problems with

pharmacologic therapy and behavioral therapy (family therapy, social skills training, cognitive-behavioral therapy) as needed.

- **School**

- Educational treatment varies with the age and educational level of the child and should follow an approach of increasing intensity as needed.
 - Tier 1: For patients displaying poor academic achievement, begin with extra support (e.g., homework clinic, tutoring) in the regular educational program (assuming culturally and linguistically appropriate instruction).
 - Tier 2: If academic problems disrupt classroom participation and impede progress, refer to school-based child study team and provide intensive assistance as part of general curriculum, such as summer school or specialized materials.
 - Tier 3: If child is >1 year behind or has shown minimal response to Tier 2 interventions, refer for a comprehensive psychoeducational evaluation to identify specialized interventions, typically provided under the umbrella of special education.
- Specialized instruction is at the center of treatment, often within the regular classroom (inclusion) with supplemental instruction through either a consultant special teacher or a resource room.
- Children may also benefit from classroom accommodations such as preferential seating, extra time for test taking, word processors and computer applications, text-to-speech programs, calculators, note-takers, and modified instructions.
- Treatment is most effective when it uses a team approach, including parents, teachers, and other therapists.
- Grade retention has not been shown to be effective.

ONGOING CARE

Children with LD require continued monitoring of academic progress. Even when the initial learning problems are resolved, later difficulties may arise in writing, note-taking, composition, organization, or with more

abstract academic subjects.

PROGNOSIS

- In most cases, prognosis is quite good with treatment, although LD never go away.
- Prognosis varies with intensity, timing, and appropriateness of intervention.
- Early diagnosis and treatment is essential for minimizing impact and to take advantage of typical developmental progression.
- Current brain imaging research shows remedial reading instruction alters brain functioning if provided during critical window of development (younger than age 8–10 years).

CODES

ICD10

- F81.9 Developmental disorder of scholastic skills, unspecified

- F81.0 Specific reading disorder
- F81.2 Mathematics disorder

FAQ

- Q: What is the evidence that visual training will improve reading?
- A: Despite anecdotal reports of value, there is strong evidence that visual dysfunction is not causal to reading disability; there is insufficient evidence to recommend vision therapy.

LEUKOCYTOSIS

Monica Khurana • Caroline Hastings

BASICS

DESCRIPTION

Leukocytosis refers to a total white blood cell (WBC) count above the normal range for age.

RISK FACTORS

- Very low-birth-weight neonates
- Immunodeficiencies or immunocompromised states
- Inflammatory disorders
- Autoimmune disorders

ALERT

Children with trisomy 21 (Down syndrome) have an increased risk of developing transient myeloproliferative disorder (TMD) or leukemoid reactions.

PATHOPHYSIOLOGY

Leukocytosis results from increased marrow production, demargination, prolonged cell survival, and/or defective extravasulation in response to external stimuli or, less commonly, from an underlying marrow disorder.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Atopy
 - Allergies
 - Asthma
 - Eczema
 - Psoriasis
- Congenital/genetic
 - Down syndrome

- Hereditary neutrophilia
- Leukocyte adhesion deficiency (LAD)
- Sickle cell anemia
- Hemolysis
 - Hemolytic anemia
 - Transfusion reaction
- Infectious
 - Bacterial
 - ▢ Brucella
 - ▢ Bartonella
 - ▢ Bordetella pertussis
 - ▢ Clostridium difficile
 - ▢ Francisella tularensis

- Smoking
- Thyrotoxicosis
- Vasculitis including Kawasaki disease
- Malignancy
 - Acute leukemias
 - Chronic leukemias
 - Lymphomas
 - Solid tumors
- Medications
 - Antiepileptics
 - Beta agonists
 - Corticosteroids
 - Epinephrine
 - Granulocyte or granulocyte–macrophage colony-stimulating factor
 - Heparin
 - Lithium
 - Minocycline
 - Prostaglandin
- Myeloproliferative disorders
 - Polycythemia vera
 - Essential thrombocytopenia
 - Myelofibrosis (but more often associated with cytopenias)
- Poisons
 - Lead
- Stress
 - Anesthesia

- Anxiety
- Emotional stress
- Overexertion
- Seizures
- Trauma
 - Acute hemorrhage
 - Severe burns
- Nonaccidental trauma

DIAGNOSTIC TESTS & INTERPRETATION

- Step 1: Confirm that the leukocytosis is real.
 - Etiologies of spurious leukocytosis by automated analyzers of whole blood include nucleated or partially lysed RBCs, cryoglobulin or cryofibrinogen, or platelet clumps.
 - Confirmation includes review of peripheral smear via consultation of a pathologist or hematologist.
- Step 2: Obtain a differential of the WBC count.
 - A manual differential may be required.
 - Distinguishing between myeloid and lymphoid or even blasts contributes to identifying the correct etiology.
 - Myeloid leukocytosis include (1) neutrophilia, which commonly results from bacterial infections; (2) monocytosis; (3) eosinophilia, typically reactive; (4) basophilia, which is rare and suggestive of myeloproliferative neoplasms; and (5) increased blasts, concerning for underlying marrow abnormality.
 - Lymphoid leukocytosis results from viral infections.

ALERT

Beware of any differential that has a high percentage of monocytes or atypical lymphocytes, whether machine generated or manual. Leukemic blasts can be mistaken for these cell types.

- Step 3: Distinguish between reactive and clonal populations.
 - Reactive leukocytosis is heterogenous—pleomorphic, polyclonal, and/or large granular cells are present.
 - Neoplasms such as leukemia/lymphoma are homogenous.
 - May need to use flow cytometry with immunophenotyping and/or

cell receptor gene rearrangements to rule out malignancy, especially in lymphoproliferative disorders

- Step 4: Evaluate other cell lines.
 - Concurrent presence of anemia and/or thrombocytopenia suggests an underlying marrow disorder such as leukemia.
 - Leukocytosis and thrombocytosis may be associated with iron deficiency anemia, sickle cell anemia, LAD type III, and pregnancy.
- Step 5: Use this information in clinical context.

HISTORY

- Evaluate for history or signs of infection.
 - Acute infection is the most common cause of leukocytosis.
 - Fever is nonspecific and may be present in infectious, inflammatory, rheumatoid, or malignant diseases.
- Obtain thorough past medical history.
 - Down syndrome: TMD occurs in ~10% infants and spontaneously resolves in 1 month, although 20–30% of these patients progress to AML. This is a medical emergency if there is organomegaly with cardiopulmonary compromise.
 - Hereditary neutrophilia: autosomal dominant disorder with heterozygous mutation in the CSF3R gene on chromosome 1p34
 - LAD: rare autosomal recessive disorder characterized by recurrent bacterial infections
 - Sickle cell anemia: Leukocytosis likely reflects chronic inflammation and may be associated with increased vaso-occlusive events.
- Comprehensive review of symptoms may indicate malignancy.
 - B symptoms include fever, drenching night sweats, and weight loss of $\geq 10\%$ over 6 months.
 - Persistent bone pain may indicate leukemia and be initially diagnosed as growing pains or worked up for osteomyelitis or JIA.
- Do not forget to obtain history of travel or unusual exposures.
 - Shigellosis enteritis may be seen after travel to areas with suboptimal sanitation and present with leukocytosis and even seizures.
 - Nursing home residents, incarcerated individuals, and health care

- professionals are at higher risk for developing and transmitting TB.
- Reptiles commonly carry Salmonella and rodents commonly carry Hantavirus.
 - Obtain complete family history.
 - Family histories positive for autoimmune disorders may raise suspicion for IBD, JIA, HES, thyroid disease, vasculitis, etc.

PHYSICAL EXAM

- Cardiopulmonary
 - A careful lung examination is necessary, as pneumonia is a common cause of leukocytosis.
 - A new murmur or gallop may be an early sign of bacterial endocarditis.
- Abdominal/lymph
 - If hepatosplenomegaly and/or lymphadenopathy is present, consider acute viral hepatitis, infectious mononucleosis from either EBV or CMV, malignancy, malaria, or lysosomal storage disease.
- Musculoskeletal/dermatologic
 - Arthritis or joint pain and/or rashes may be one manifestation in a constellation that may suggest JIA, rheumatic fever, or Lyme disease.

Imaging

Although universal vaccination with Prevnar (pneumococcal conjugate vaccine [PCV]) has decreased the incidence of pneumonia, clinicians should still strongly consider chest radiography in young, highly febrile children with leukocytosis and no obvious source of infection.

TREATMENT

GENERAL MEASURES

- Isolated leukocytosis may be monitored without intervention.
- If ill-appearing, age-appropriate empiric antibiotics are indicated.
- Consultation with other subspecialties may be necessary.
- Prognosis depends on diagnosis.

ONGOING CARE

In the setting of bacterial infection with appropriate microbial coverage, anticipate resolution of leukocytosis within 4 days.

ALERT

If malignancy is in the differential, consult hematology/oncology prior to initiating steroids.

CODES

ICD10

- D72.829 Elevated white blood cell count, unspecified
- D72.0 Genetic anomalies of leukocytes
- D72.828 Other elevated white blood cell count

FAQ

- Q: Does the degree of leukocytosis correlate to the severity of infection?
- A: Just as the height of fever does not always correlate to the severity of infection, the same is true for the degree of leukocytosis. Even a normal WBC does not rule out bacteremia.
- Q: What is a leukemoid reaction?
- A: A leukemoid reaction is a physiologic response to a stress or infection and is characterized by a WBC of $\geq 50 \times 10^9/L$ with peripheral blood myeloid precursors at all stages of maturity rather

than proliferation of an immature WBC clonal population, which is characteristic of malignancies.

- Q: When is an elevated WBC a clinical emergency?
- A: Leukocytosis or hyperleukocytosis is a clinical emergency when the patient is symptomatic from leukostasis. Hyperleukocytosis is a total WBC count of $\geq 100 \times 10^9/\text{L}$. Clinically significant hyperleukocytosis usually occurs at WBC $\geq 200 \times 10^9/\text{L}$ or $\geq 300 \times 10^9/\text{L}$ in patients with acute myeloid or lymphoblastic leukemia and chronic myeloid leukemia in blast crisis, respectively; however, symptoms may present with a WBC as low as $50 \times 10^9/\text{L}$. Refer to hyperleukocytosis chapter for more information.

LICE (PEDICULOSIS)

Janet Gingold • Linda Fu

BASICS

DESCRIPTION

Infestation of the head, body, or anogenital region by parasitic, wingless insects that feed exclusively on human blood

EPIDEMIOLOGY

- Head lice
 - Spread by head-to-head contact
 - Most common among children 3–12 years old
 - Associated with female gender, warmer weather, crowded living conditions
 - Less common among African Americans
 - Point prevalence estimates range from <1% in some places to >90% in others.
- Body lice
 - Spread by close physical contact with infested persons, clothing, or bedding
 - Associated with poor sanitation, cool climates, homelessness, war, disasters, refugee camps
 - No racial or gender differences
- Pubic lice
 - Usually sexually transmitted
 - Can also spread through contact with clothing or bedding recently used by infested person
 - Most common among young adults

Incidence

- Varies widely with location and living conditions.
- Estimated 6–12 million cases per year in the United States

GENERAL PREVENTION

Humans are the only host for all three types of lice. Recurrences are

common and may be prevented by examining and treating close contacts, especially bedmates.

- Head lice
 - Avoid head-to-head contact with infested persons; don't share brushes, hats, or hair ties. Avoid lying on pillows, furniture, or stuffed toys used by infested person within last 2 days.
 - Wash clothing and bedding used by infested person with hot water ($\geq 130^{\circ}\text{F}$) and set dryer to highest heat setting. Items may also be dry-cleaned or sealed in a plastic bag for 2 weeks. Vacuum furniture and carpet.
 - Environmental insecticide is not helpful.
 - Treatment of pets is not necessary.
 - “No-nit” school policies do not control head lice transmission and are not recommended.
- Body lice
 - Regularly wash clothes.
 - Avoid using clothing or bedding used by infested person.
- Pubic lice
 - Avoid close body contact or sharing clothes with infested person.
 - Not prevented by condom use

PATHOPHYSIOLOGY

- Bites of louse are painless.
- To facilitate blood meal, lice inject enzymes, anticoagulant, and vasodilators. These provoke host inflammatory response causing pruritus.
- Bites characterized by intradermal hemorrhage and infiltrates of eosinophils and lymphocytes
- Excoriation can introduce secondary infections.
- Vector-borne pathogens (body lice only) can cause chronic bacteremia, angiomatosis, or endocarditis.

ETIOLOGY

- Head lice (*Pediculus humanus capitis*)
 - Adults white-to-gray; 2–4-mm long; 6 legs; no wings. Crawl quickly away from threat or bright light. Cannot jump or fly. If

- removed from host, will die within 2 days
- Females lay up to 10 eggs per day over 2–3-week lifespan, attaching egg to base of hair shaft with adhesive.
 - Eggs are very temperature sensitive; hatch in 7–12 days; empty white egg casing remains on hair.
 - Emerging nymphs (instars) die without blood meal within a few hours. Molt 3 times over 9–11 days to become egg-laying adults.
 - Typical infestation includes lice in all stages of development; effect of treatment depends on stage of life cycle.
 - Body lice (*P. humanus corporis*)
 - Morphology and life cycle similar to head lice, but adults are slightly larger
 - Live and lay eggs on clothing and only come to the skin to feed 4–5 times per day
 - Able to live longer off host than head lice
 - Eggs hatch in 6–10 days.
 - Pubic lice (*Phthirus pubis*)
 - Crab-like appearance, with larger talus adapted to coarser hair; predilection for pubic hair
 - May also infest axillary hair, perianal area, eyelashes, beard, and rarely scalp

COMMONLY ASSOCIATED CONDITIONS

- Body lice
 - May act as a vector for epidemic typhus (*Rickettsia prowazekii*), relapsing fever (*Borrelia recurrentis*), and trench fever (*Bartonella quintana*) or plague (*Yersinia pestis*)
- Pubic lice
 - Commonly occurs with other sexually transmitted infections
 - Although pubic lice on children's eyelashes usually result from close contact with infested parent, must also consider sexual abuse

DIAGNOSIS

HISTORY

- Chief complaint is usually pruritus; however, patients may be asymptomatic.
- May complain of disrupted sleep
- Ask about exposure to others with similar symptoms, crowded living conditions, and previous similar episodes.
- Review details of previous treatments to differentiate improper or incomplete treatment, reinfestation, and resistance to pediculicide.

PHYSICAL EXAM

- General points
 - Definitive diagnosis requires visualization of live lice.
 - Bright light and magnification are helpful.
- Head lice
 - Wet combing slows the movement of lice.
 - Use comb to lift and separate hair to visualize scalp and base of hair shafts.
 - Lice and nits (eggs or empty egg casings) most commonly found behind ears, on back of head, and nape of neck
 - Typical case involves 5–10 live lice.
 - Nits are firmly affixed at a characteristic angle to the hair shaft (vs. dandruff). Nits within 1 cm of scalp suggest active infestation. Nits >1 cm from scalp are likely empty egg cases.
 - May see excoriation, oozing, matted hair, or lymphadenopathy with secondary infection
- Body lice
 - Skin exam may reveal erythematous macules and papules from bites; rarely lice
 - Lice and nits may be found along seams on inside of clothing, especially near axillae, inguinal areas, waistband, or collar.
 - In long-standing infestations, may find epidermal thickening, hyperpigmentation, or scaly plaques
 - With secondary infection, may find adenopathy, fever, and malaise
- Pubic lice
 - Small, crab-shaped lice and nits in pubic hair or perianal region; be sure to also check axillae, beard, and eyelashes.
 - May find brownish clumps of louse fecal matter

- With heavy infestation, may find maculae cerulea: 0.5–1-mm bluish macules on the lower abdomen, thighs, or buttocks
- Eyelash infestation may cause blepharitis or conjunctivitis.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

Diagnosis is made by direct visualization of lice or under magnification. Lice will stick to cellulose tape applied to infested area, and tape can then be affixed to glass slide for microscopy. Lice and nits fluoresce yellow green under Wood lamp.

DIFFERENTIAL DIAGNOSIS

- Seborrheic, contact, or atopic dermatitis
- Impetigo
- Scabies
- Xerosis with excoriation
- Hair casts, hair spray or other debris, other insects

TREATMENT

MEDICATION

Head lice

- General issues:
 - Because of different mechanisms of action, effects on different stages of louse life cycle, and potential adverse effects, careful adherence to manufacturers' instructions regarding pediculicide use is essential (preparation of hair, length of application, posttreatment rinsing, combing, and reapplication).
 - Conditioner or excess water on hair can interfere with efficacy.
 - Use enough product to coat all hair and scalp, especially areas behind ears and along hairline at back of neck. After treatment, use fine-toothed comb to remove visible lice and nits.
 - Recheck head daily for lice and nits for 2–3 weeks.
 - Pediculicides irritate mucous membranes; may be toxic if taken internally
- Permethrin lotion 1% (OTC); 5% (Rx)

- Initial drug of choice; resistance increasing
- Minimum age: 2 months
- 10-minute application to damp hair. Reapply 7–10 days later if live lice persist.
- Pediculicidal with some ovicidal activity (acts on insect nervous system)
- Residue on hair kills newly hatching nymphs as they emerge for up to 2 weeks.
- Pyrethrin 1% with piperonyl butoxide (OTC)
 - Resistance varies by geographic location.
 - Minimum age: 2 years
 - 10-minute application to dry hair. Reapply 7–10 days later.
 - Pediculicidal with low ovicidal activity
 - Contraindication: allergy to chrysanthemums or ragweed
- Malathion lotion 0.5% (Rx):
 - Resistance common in United Kingdom but not in the United States where product contains terpineol.
 - Minimum age: 6 years
 - 8–12-hour application to dry hair. Leave uncovered. Reapply 7–10 days later if live lice persist.
 - Pediculicidal and highly ovicidal (organophosphate; cholinesterase inhibitor)
 - Highly flammable: Avoid hair dryers, smoking, and irons during treatment.
- Benzyl alcohol lotion 5% (Rx)
 - Minimum age: 6 months; potential toxicity in younger infants, especially if taken internally
 - 10-minute application to dry hair. Reapply after 7 days.
 - Pediculicidal but not ovicidal (interferes with action of respiratory spiracles)
- Spinosad topical suspension 0.9% (Rx):
 - Minimum age: 4 years
 - 10-minute application to dry hair. Repeat in 7 days if live lice present.
 - Does not require combing for nit removal

- Pediculicidal and ovicidal (neurotoxic to insects; also contains benzyl alcohol; combination prevents resistance)
- Ivermectin lotion, 0.5% (Rx)
 - Minimum age: 6 months
 - 10-minute application to dry hair. Single treatment; do not reapply.
 - Pediculocidal; not ovicidal but few nymphs survive more than 2 days (acts on ion channels in invertebrate nerve and muscle cells)
- Wet combing alone to remove nits and lice may be helpful when medication is ineffective or as an alternative to pediculicide use.
- Controversial and untested treatments:
 - Occlusion: olive oil, mayonnaise, and petroleum jelly do not asphyxiate lice but may slow their movement and facilitate removal with nit comb
 - Shaving: can be effective but not necessary and may not be cosmetically acceptable
 - Trimethoprim-sulfamethoxazole (oral 10-day course): may enhance cure rate of topical permethrin; not FDA-approved for this use
 - Essential oils (e.g., tea tree oil): may have some activity against lice and eggs but are unregulated and may be toxic
 - Hot air: Several mechanical devices deliver hot air to the scalp to desiccate lice and nits, but efficacy is questionable.
 - Lindane shampoo 1%: no longer recommended due to neurotoxicity and increased resistance

Body lice

- Pediculicides are usually not needed if infested clothing and other fomites are appropriately laundered, treated with pediculicide, or destroyed. Oral ivermectin has been used effectively during epidemics.

Pubic lice

- The same OTC pediculicides are used for head lice and pubic lice; resistance less common
- It is important to treat all infested areas and sexual contacts.
- For eyelash infestation, apply petroleum jelly twice daily for 10 days. Remove nits with tweezers.

ALERT

- Pediculicides are oculotoxic. Do not use on eyelashes or eyebrows. If

pediculicide gets in eyes, immediately flush with water.

- Pregnancy risk category varies for pediculicides. Check package insert.

ONGOING CARE

COMPLICATIONS

- Head lice
 - Intense pruritus can disrupt sleep.
 - Stigma associated with infestation can lead to social isolation, teasing, or bullying.
 - Days lost from school or work due to “no-nit” policies impact academic performance and worker productivity.
 - Secondary bacterial infections can result in pyoderma and lymphadenopathy.

- B85.1 Pediculosis due to *Pediculus humanus corporis*

FAQ

- Q: Are people with long hair more likely to get head lice?
- A: No. Longer hair is not associated with greater likelihood of getting head lice. However, removing lice and nits is easier when hair is shorter.
- Q: How long should children with head lice be excluded from school?
- A: The risk of transmission decreases enough to allow children to return to school once they have been treated with a single pediculicide application.
- Q: Given the increase in resistance, should we stop using OTC treatments and use prescription products instead?
- A: Resistance of head lice varies widely by community. Currently, permethrin 1% remains the initial treatment of choice. Prescription products are more expensive and have greater potential for toxicity. Careful adherence to manufacturers' directions and simultaneous treatment of close contacts (especially bedmates) decreases the likelihood of treatment failure and reinfestation.
- Q: How can health professionals allay anxiety and decrease the social stigma of head lice?
- A: Emphasize that head lice infestation is not a sign of poor housekeeping or hygiene. Point out that the benefits of close friendships outweigh the minimal health risks related to head lice. Encourage open communication to facilitate treatment of close contacts.

LONG QT SYNDROME

Ronn E. Tanel

BASICS

DESCRIPTION

Long QT syndrome (LQTS) is characterized by prolongation of the QT interval on the surface electrocardiogram (ECG), syncope, and sudden death as a result of malignant ventricular arrhythmias. The electrical instability is due to an abnormality of ventricular repolarization associated with a cardiac ion channelopathy.

EPIDEMIOLOGY

Prevalence

Prevalence of LQTS is estimated to be approximately 1 in 2,500.

RISK FACTORS

Genetics

- Autosomal dominant (Romano-Ward syndrome)
- Autosomal recessive, sometimes associated with congenital nerve deafness (Jervell and Lange-Nielsen syndrome)
- Genetic linkage analysis studies have demonstrated that >400 genetic mutations among 13 cardiac ion channel genes account for nearly 3/4 of LQTS.
- Genotype-phenotype-based research studies have identified gene-specific electrocardiographic profiles, gene-specific arrhythmia triggers, gene-directed treatment strategies, and gene-specific risk stratification.

GENERAL PREVENTION

- Preventive measures focus on screening for the electrocardiographic abnormality, especially in individuals who appear to be at risk of having the diagnosis.
- Patients who have been diagnosed are advised to avoid exposure to stimulants, medications that are known to prolong the QT interval or

provoke ventricular arrhythmias, and situations that may aggravate the cardiac rhythm or induce torsades de pointes.

PATHOPHYSIOLOGY

Two hypotheses have been proposed to explain the pathogenesis of congenital LQTS syndrome:

- An abnormality or imbalance in sympathetic innervation to the heart, which helps explain the findings of sinus bradycardia, abnormal repolarization, adrenergic dependence of arrhythmias, and response to adrenergic antagonist medications associated with the syndrome
- Intrinsic cardiac ion (potassium and sodium) channel defects appear to be the mechanism responsible for cardiac repolarization abnormalities. Because some identified gene mutations that result in congenital LQTS occur at loci that also encode a cardiac ion channel protein, ion channel dysfunction has been proposed as the intrinsic abnormality that is responsible for abnormal repolarization.

DIAGNOSIS

HISTORY

- Notable findings include the following:
 - Palpitations
 - Presyncope
 - Syncope
- These symptoms may be related to provocative stimuli, especially emotional or physical stress. Any use of medications known to prolong the QTc interval should be noted.
- Most importantly, a thorough family history for arrhythmia, syncope, epilepsy, or sudden unexplained death should be obtained.

PHYSICAL EXAM

Findings are usually normal, but bradycardia may be present.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- The Bazett formula: $QTc = QT / (\text{square root of RR interval})$. Generally,

a QTc >480 msec is considered abnormal, although some clinicians allow a slightly longer QTc for infants <6 months of age.

- Some clinicians believe that the QTc should not be corrected at heart rates <60 beats per minute (bpm). The measurement should be taken in lead II without significant sinus arrhythmia.
- Children frequently have a prominent U wave. It should generally be included in the measurement of the QTc if it exceeds 1/2 the amplitude of the T wave.
- A single measured prolonged QTc interval does not confirm the diagnosis of LQTS.
- T-wave alternans on an electrocardiographic recording is diagnostic.
- Since 2004, genetic testing has been available as a commercial diagnostic test. Unfortunately, only up to 3/4 of all genetic causes of LQTS have been identified, so false-negative genetic testing is possible.
- Clinical scoring systems may help stratify patients into high, moderate, and low probability of having the diagnosis, based on symptoms, family history, and ECG findings.

Imaging

ECG

- Atrioventricular block can be seen on the ECG in infants with relatively rapid heart rates and P waves that occur during the prolonged repolarization period (QT interval) of ventricular refractoriness.

Echocardiogram

- The echocardiogram usually demonstrates normal cardiac structure and function.

Diagnostic Procedures/Other

Other tests that may help confirm the diagnosis include the following:

- 24-hour ambulatory Holter monitoring
 - This recording may disclose asymptomatic ventricular ectopy or arrhythmias, T-wave alternans, or variability in the QTc interval during different periods of the day.
- Exercise stress testing may also be helpful in identifying ventricular arrhythmias or prolongation of the QTc interval, particularly during the recovery phase.

DIFFERENTIAL DIAGNOSIS

- Congenital LQTS is most commonly misdiagnosed as vasovagal syncope or a seizure disorder. All patients who have a syncopal event or who are diagnosed with epilepsy should have a baseline screening ECG.
- Sudden infant death syndrome (SIDS) may be related to congenital LQTS. Some studies have demonstrated that mutations of ion channel proteins that cause LQTS have been found in SIDS victims. QT interval prolongation may be subtle, such that ~10% of affected patients may have a normal result on routine ECG and ~40% may have only borderline prolongation of the QT interval.
- Acquired forms of LQTS should be differentiated from the congenital and inherited form. Acquired LQTS may be due to the following:
 - Electrolyte abnormalities: hypokalemia, hypocalcemia, hypomagnesemia, and metabolic acidosis
 - Toxins: organophosphates
 - Central nervous system trauma
 - Malnutrition: anorexia
 - Primary myocardial disease: myocarditis, ischemia, cardiomyopathy
 - Medication
 - ▢ Cardiac medications: quinidine, procainamide, disopyramide, sotalol, and amiodarone
 - ▢ Antibiotics/antifungals: erythromycin, trimethoprim–sulfamethoxazole, pentamidine, ketoconazole, and fluconazole
 - ▢ Psychotropic medications: tricyclic antidepressants, phenothiazines, and haloperidol
 - ▢ Antihistamines: terfenadine, astemizole, diphenhydramine
 - ▢ Gastrointestinal: cisapride

TREATMENT

MEDICATION

- The primary therapy is β -blockade, most commonly with propranolol or nadolol. Metoprolol and perhaps atenolol are less effective for this diagnosis.

- Class Ib antiarrhythmic medications (e.g., mexiletine) are also used in patients with congenital LQTS, especially in those with documented ventricular arrhythmia.
- Anti-arrhythmic medications generally do not help treat patients with acquired LQTS, but the administration of magnesium sulfate may be beneficial.

ADDITIONAL TREATMENT

General Measures

Patients are usually treated based on symptoms and the clinical severity of the disease.

Additional Therapies

Implantable cardioverter-defibrillators (ICDs) are usually reserved for older children and adolescents who have significant symptoms, documented ventricular arrhythmias, or other significant risk factors for sudden death.

SURGERY/OTHER PROCEDURES

- Occasionally, implantation of a permanent pacemaker is indicated based on the theory that the tachyarrhythmias (e.g., torsades de pointes) are dependent on bradycardia and/or pauses. Rarely, pacemaker implantation may be necessary to support the low heart rate that occurs as a result of β -blocker therapy. Newborns and infants with a very prolonged QT interval, atrioventricular block, and low ventricular rates are historically treated with a pacemaker.
- An ICD may be recommended for patients thought to be at higher risk of developing ventricular arrhythmias.
- Left stellate ganglionectomy is performed to potentially eliminate the hyperactive left sympathetic ganglion output that has been proposed as a mechanism of ventricular arrhythmias. This treatment option is not universally accepted.

INPATIENT CONSIDERATIONS

Initial Stabilization

Most clinicians treat diagnosed asymptomatic children with medications because of a high incidence of sudden death that occurs as the first

symptom.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Follow-up outpatient appointments should review new or recurrent symptoms, including palpitations, near syncope or syncope, and the efficacy and adverse effects of medical therapy.
- ECG may demonstrate a normal or prolonged QTc.
- Follow-up 24-hour ambulatory Holter monitor recordings and exercise stress tests may help assess the adequacy of β -blocker therapy and identify ventricular arrhythmias.
- All family members of the patient should have an ECG as a minimum screening measure.

PROGNOSIS

- Children have a higher incidence of sudden death than adults, which may reflect an inherent bias because adult patients have already survived childhood. The risk of cardiac events is higher in boys before puberty and in women during adulthood.
- Pediatric patients with greatest risk for sudden death are those with QTc >600 msec. Gender, environmental factors, genotype, and therapy are other factors that influence the clinical course.
- A particular clinical phenotype may be caused by different genetic substrates, whereas a single gene can cause very different phenotypes, even within the same family, by acting through different pathways.
- Without treatment, mortality is 21% within 1 year from the first syncope. With proper treatment, mortality has been estimated at 1% during 15-year follow-up. β -blocker therapy has been shown to reduce the incidence of sudden death.
- Current research may lead to the development of therapy specific to the precise ion channel defect.

COMPLICATIONS

- Complications, especially in untreated patients, include the following:

- Ventricular tachyarrhythmias, specifically torsades de pointes
- Syncope
- Sudden death
- In patients with the congenital and inherited form of the condition, asymptomatic family members may be affected.

I45.81 Long QT syndrome

FAQ

- Q: Should activity be restricted in patients with congenital LQTS?
- A: Because sudden rises in serum catecholamine levels may precipitate symptoms, it is appropriate to restrict competitive and vigorous athletics. Symptomatic patients may require greater restrictions.

Documentation of appropriate β -blockade by a lower maximal heart rate at peak exercise on follow-up exercise stress test may be helpful.

- Q: If someone is identified as having LQTS, should family members be evaluated?
- A: Yes, with a high degree of suspicion. Most cases of congenital LQTS are inherited in an autosomal dominant pattern, so that each child of an affected parent has a 50% chance of having the gene. This does not predict severity of symptoms, but parents, all siblings, and children of patients should be examined with an ECG, Holter monitor, and exercise stress test. These studies may help reveal an abnormal QTc interval in suspected family members.

LOWER GI BLEEDING

Michael A. Manfredi

BASICS

DESCRIPTION

- Lower gastrointestinal bleeding (LGIB) is defined as bleeding that occurs distal to the ligament of Treitz.
- Melena and maroon-colored stools can be seen with small bowel bleeding, whereas hematochezia is classically seen with colonic bleeding.
- It is important to recognize that hematochezia can also be a presentation of severe upper gastrointestinal bleeding (UGIB).

EPIDEMIOLOGY

- In a population study of 40,000 admissions to a tertiary care pediatric emergency department, LGIB accounted for 0.3% of all admissions.
- 4.2% of patients with LGIB met criteria for severe life-threatening bleeding.

ETIOLOGY

Causes of LGIB vary by age:

- Neonatal period (birth to 1 month)
 - Allergic colitis
 - Anorectal fissure
 - Necrotizing enterocolitis
 - Enteric infections
 - Upper GI source
 - Duplication cyst
 - Hirschsprung disease enterocolitis
 - Meckel diverticulum
 - Malrotation with volvulus
 - Hemorrhagic disease of the newborn
- Infancy (1 month to 2 years)
 - Allergic colitis

- Anorectal fissure
- Enteric infections
- Intussusception
- Meckel diverticulum
- Malrotation with volvulus
- Lymphonodular hyperplasia
- Upper GI source
- Duplication cyst
- Enterocolitis with Hirschsprung disease
- Vascular malformation
- Preschool age (2–5 years)
 - Anorectal fissure
 - Enteric infections
 - Polyps
 - Parasites
 - Meckel diverticulum
 - Intussusception
 - Lymphonodular hyperplasia
 - Inflammatory bowel disease
 - Hirschsprung disease enterocolitis
 - Hemolytic uremic syndrome
 - Henoch-Schönlein purpura (HSP)
 - Vascular malformation
 - Volvulus
 - Rectal prolapse/rectal ulcer
 - Child abuse
 - Perianal streptococcal cellulitis
- School age (5–13 years)
 - Anorectal fissure
 - Enteric infections
 - Inflammatory bowel disease
 - Intussusception
 - Meckel diverticulum
 - Polyps
 - HSP

- Hemolytic uremic syndrome
- Intestinal ischemia
- Neutropenic colitis (typhlitis)
- Parasites
- Child abuse
- Vascular malformations
- Perianal streptococcal cellulitis
- Adolescent (>13 years)
 - Anorectal fissure
 - Enteric infections
 - Inflammatory bowel disease
 - Hemolytic uremic syndrome
 - Intussusception
 - Midgut volvulus
 - Intestinal ischemia
 - Neutropenic colitis (typhlitis)
 - Polyps
 - Vascular malformations
 - Lymphonodular hyperplasia
 - Parasites
 - Hemorrhoids

DIAGNOSIS

APPROACH TO THE PATIENT

General goals of initial evaluation of patient with LGIB: Determine if patient is actively bleeding, an approximate location of the bleeding and cause, as well as presence or absence of hemodynamic instability, which may indicate need for urgent/emergent clinical resuscitation:

- Phase 1: Determine if there is blood or other cause of bright red or black stools.
- Phase 2: Assess patient to determine etiology; follow history, physical, and laboratory.
- Phase 3: Assess and stabilize patient, decide if emergency treatment is needed or if outpatient referral is required.

HISTORY

- Obtain a detailed history and note if any recently ingested foods resemble blood.
- Evaluate the color of blood:
 - Bright red: Site of bleeding is probably in left colon, rectosigmoid, or anal canal.
 - Darker red stool: right colon
 - Melena or maroon: Bleeding is likely proximal to ileocecal valve.
- Location of blood in the stool:
 - Colitis: Blood will be mixed with stool.
 - Anal fissure/constipation: Blood streaks will be seen on the outer aspect of the stool.
- Consistency of the stool:
 - Diarrhea: suggests colitis
 - Hard stool: may be indicative of fissure and constipation
- Other diagnostic clues:
 - Painful stools: may be consistent with anal fissure, local proctitis, or ischemic bowel
 - Painless rectal bleeding: associated with polyps, Meckel diverticulum, nodular lymphoid hyperplasia of colon, intestinal duplication, intestinal submucosal mass (GIST), or vascular anomaly
 - Abdominal pain: inflammatory bowel disease, other causes of colitis, or a surgical abdomen
- Obtain past medical history for any underlying or known GI disease (i.e., previous GI surgery, past history of colitis, Hirschsprung disease, necrotizing enterocolitis).
- Evaluate for history of jaundice, hepatitis, liver disease, neonatal history: suggestive of portal vein thrombosis (sepsis, shock, exchange transfusion, omphalitis, and IV catheters), portal hypertension, and variceal bleeding.
- Familial history
 - Inflammatory bowel disease, intestinal polyps, and bleeding diathesis (e.g., von Willebrand disease, hemophilia)
- Personal medications: in particular, nonsteroidal anti-inflammatory

medications, heparin or warfarin. In addition, a history of medications in the house should also be obtained due to possible accidental ingestion in younger children.

- Associated symptoms:
 - Mouth ulcers
 - Weight loss
 - Joint pains
 - Fevers
 - Rash
 - Petechiae
 - Renal insufficiency
 - History of ingestion of uncooked meat (hemolytic uremic syndrome [HUS])
 - Purpuric rash (HSP)

PHYSICAL EXAM

- Hemodynamic stability should be assessed immediately.
 - Heart rate: Tachycardia may be an early sign of intravascular volume depletion.
 - Blood pressure: Hypotension is a late sign and may not be present even with significant blood loss because vasoconstriction maintains BP until decompensation occurs.
 - In the setting of normal blood pressure, obtain orthostatic BP.
 - Capillary refill: Delayed capillary refill suggests intravascular volume depletion.
 - Oxygen saturation: may be decreased due to decreased oxygen carrying capacity
 - Evaluate for signs of shock:
 - Vitals signs listed earlier
 - Cool clammy extremities
 - Poor mentation
- Skin
 - Petechiae or purpura: HSP or coagulopathy
 - Ecchymosis: coagulopathy
 - Hemangiomas: vascular anomaly
 - Spider angioma: liver disease or portal hypertension

- Caput medusa: liver disease or portal hypertension
- Palmar erythema: liver disease or portal hypertension
- Jaundice: liver disease or portal hypertension
- HEENT
 - Freckles on buccal mucosa: Peutz–Jeghers syndrome
 - Telangiectasias on buccal mucosa: (Osler-Weber-Rendu syndrome).
 - Mouth ulcers: Crohn disease
 - Icteric sclera: portal hypertension
- Abdomen
 - Hepatosplenomegaly, ascites: liver disease or portal hypertension
 - Isolated splenomegaly: cavernous transformation of the portal vein
- Rectal examination
 - Evidence of perianal disease: inflammatory bowel disease
 - Polyps: Rectal polyps may be detected on digital exam.
 - Hemorrhoids: chronic constipation, portal hypertension

DIAGNOSTIC TESTS & INTERPRETATION

- NG tube lavage
 - No longer recommended in patients with suspected upper or lower GI bleeding for diagnosis, prognosis, visualization, or therapeutic effect
- Stool guaiac
 - May help to distinguish blood in stool from other blood colored substances (i.e., food coloring)

Lab

- CBC should be measured serially.
 - Initial hemoglobin values may be unreliable because a delay in hemodilution may falsely produce near-normal values.
- Iron deficiency anemia: may indicate anemia of chronic disease
 - Leukopenia, anemia, and thrombocytopenia: Consider chronic liver disease and portal hypertension.
 - Anemia with normal RBC indices: truly an acute cause for bleeding
 - RBC indices indicate iron deficiency anemia: Consider mucosal lesion, that is, chronic blood loss.
 - Thrombocytopenia: Consider hemolytic uremic syndrome.

- Coagulation profile
 - If PT and PTT are abnormal, consider liver disease or disseminated intravascular coagulation with sepsis.
- Liver function tests: abnormal in chronic liver disease
- Renal function tests (BUN, creatinine, urine analysis): abnormal in hemolytic uremic syndrome, HSP, acute bleed
- ESR or C-reactive protein (CRP): abnormal in inflammatory disorders or infectious colitis
- Stool tests:
 - Stool culture (Salmonella, Shigella, Campylobacter, Yersinia, Aeromonas, Escherichia coli, Klebsiella)
 - Stool for Clostridium difficile toxin A and B
 - Ova and parasites (Amebae)
 - Stool smears for WBCs (not always positive in colitis) and eosinophils (not always positive in allergic colitis)
 - Stool CMV: Consider in immunocompromised patients.

Imaging

- Abdominal x-ray
 - Can be helpful in evaluating surgical abdomen (dilated bowel, air–fluid levels, and perforation), constipation (presence of excessive stool), colitis (edematous bowel, thumb-printing), pneumatosis intestinalis, and toxic megacolon
- Ultrasound
 - Can show bowel wall thickening consistent with inflammatory bowel disease, Meckel diverticulum, intussusception
- Barium tests:
 - Air-contrast enema is diagnostic and therapeutic in intussusception and diagnostic in mucosal lesions (polyps).
 - Upper GI series with small bowel follow-through is helpful in evaluating anatomy and inflammatory bowel disease.
 - CT scan can show evidence of intestinal inflammation and evidence of bowel obstruction.
- Nuclear medicine
 - Meckel scan: Technetium-99m pertechnetate can detect a Meckel diverticulum when it contains gastric mucosa.

- Bleeding scan: useful in a patient with significant bleeding that precludes endoscopy or in whom endoscopy is nondiagnostic. Technetium-99m–tagged erythrocyte scan detects rapid bleeding at a rate of 0.1–0.5 mL/min; can be performed at 30-minute intervals for up to 24 hours.

Diagnostic Procedures

- Endoscopy
 - Upper endoscopy and colonoscopy is the prime diagnostic and therapeutic tool for upper and lower GI bleeding.
 - Endoscopy can be used to accurately delineate the bleeding site and/or to determine specific cause. It is 90–95% sensitive at locating bleeding site.
 - Upper endoscopy diagnostic in massive UGIB presenting with hematochezia or melena
 - Upper endoscopy and colonoscopy should be performed when the suspicion is high for inflammatory bowel disease.
 - Colonoscopy should be performed when there is a suspicion for polyps.
- Video capsule endoscopy
 - Capsule endoscopy has become 1st-line treatment in adults and children to diagnose obscure causes of GI bleeding in the small intestine.
 - Capsule endoscopy may be limited by ability of the patient to swallow the capsule.
 - The capsule can be placed endoscopically into the small intestine in younger children.
- Enteroscopy
 - Involves the passage of a special endoscope (either by push, single balloon or double balloon) to evaluate the small intestine
 - May be indicated if a lesion is seen on capsule endoscopy that may be amenable to endoscopic therapy
- Angiography
 - Useful in detecting vascular causes of UGIB; can also be therapeutic (i.e., injection of coils into a vascular malformation may occlude it); requires bleeding rate of 0.5–1 mL/min

TREATMENT

GENERAL MEASURES

- Initial management
 - Make patient NPO.
 - Secure stable vascular access (i.e., intravenous line).
 - Obtain blood type, and cross-match RBCs.
 - Stabilize the patient with IV fluids and blood products if necessary (target hemoglobin ≥ 7 g/dL).
 - Target INR < 2.5
 - Consult specialists (pediatric surgery and/or pediatric gastroenterologist).
- Disease-specific therapy
 - Anal fissure
 - ▢ Treat the underlying constipation (mineral oil, lactulose, MiraLax, high-fiber diet, increased water intake).
 - ▢ Local therapy consists of sitz baths, local emollient creams, and steroid suppositories.
 - Polyp: colonoscopy with polypectomy
 - Intussusception: air-contrast enema for confirmation and hydrostatic reduction
 - Parasites: antiparasitic medications
 - Inflammatory bowel disease: referral to pediatric gastroenterologist for therapy

ISSUES FOR REFERRAL

Refer the following patients to a specialist:

- Any patient with significant acute lower GI bleeding after initial stabilization
- Patients with less acute bleeding for whom an easily identifiable cause has not been found or patients with chronic or recurrent lower GI bleeding

SURGERY/OTHER PROCEDURES

In cases of massive or persistent bleeding with no identifiable site, exploratory laparotomy with intraoperative endoscopic evaluation of the

entire bowel to identify mucosal lesions may be required.

HOSPITALIZED PATIENTS

Initial Stabilization

Emergency care

- If patient is critical, stabilize with IV fluids and blood products.
- Order laboratory tests: CBC, PT/PTT, disseminated intravascular coagulation screen, liver function tests, blood type, and cross-match
- Monitor patient's vital signs and hemoglobin.
- Make appropriate diagnosis and institute appropriate therapy.

ONGOING CARE

PATIENT MONITORING

- Monitor hemoglobin in the hospital until patient's condition is stable.
- Send stool studies.
- Refer patients with LGIB that is chronic in nature and hemodynamically stable to specialist for further workup.

DIET

- Consider recommendation of an exclusion diet that restricts (milk and/or soy, egg, wheat, other foods) in breastfeeding mothers of infants consuming breast milk with evidence of allergic colitis.
- Introduce hydrolyzed protein formula in formula-fed infants with suspected cow's milk protein allergy.

CODES

ICD10

- K92.2 Gastrointestinal hemorrhage, unspecified
- K92.1 Melena
- K52.2 Allergic and dietetic gastroenteritis and colitis

FAQ

- Q: What is the most common cause of lower GI bleeding?
- A: In all age groups, fissures are the leading cause, followed by infections.
- Q: What is the most common cause of blood mixed in the stool of an infant?
- A: Allergic colitis. This is an indication to recommend a hypoallergenic diet (exclusion diet in mothers of infants who are breastfeeding, extensively hydrolyzed protein formulas in infants receiving formula).
- Q: What common foods cause stools to be red? Black?
- A: Red: raspberries, cranberries, Kool-Aid, artificial coloring in cereal. Black: bismuth, spinach, blueberries, licorice.

LUPUS ERYTHEMATOSUS

Elizabeth Candell Chalom

BASICS

DESCRIPTION

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease characterized by production of antibodies to various components of the cell nucleus, in conjunction with a variety of clinical manifestations.

EPIDEMIOLOGY

- Age
 - 20% of lupus begins in childhood, but it is very rare younger than 5 years old.
- Female-to-male ratio:
 - Between 3–5:1 (prepubertal) and 9–10:1 (postpubertal)
- SLE occurs about 3 times more often in African Americans than Caucasians. It is also more common in Hispanic, Asian, and Native Americans.

Incidence

- Peak incidence: between ages 15 and 40 years
- Incidence in children is from 10–20 cases/100,000 children per year.

Prevalence

- U.S. estimate: 5,000–10,000 children

RISK FACTORS

Genetics

- Increased frequency in 1st-degree family members of patients with SLE
- 10% of patients have ≥ 1 affected relative.
- Concordance rate of 25–50% in monozygotic twins and 5% in dizygotic twins
- Some major histocompatibility complex antigens are associated with increased incidence of lupus, such as HLA-DR2 and DR3 in whites

and DR2 and DR7 in blacks.

ETIOLOGY

Although exact etiology is unknown, lupus is an autoimmune disease, with genetic, environmental, and hormonal factors playing a role.

DIAGNOSIS

Classification criteria: 4 of the following 11 criteria, developed by the American College of Rheumatology, must be met to classify a patient as having SLE:

- Malar (butterfly) rash
- Discoid rash
- Photosensitivity
- Oral or nasal ulcers
- Arthritis
- Cytopenia
 - Anemia, leukopenia ($<4,000/\text{mm}^3$), lymphopenia ($<1,500/\text{mm}^3$), or thrombocytopenia ($<100,000/\text{mm}^3$)
- Neurologic disease: seizures or psychosis
- Nephritis: >0.5 g/day proteinuria or cellular casts
- Serositis: Pleuritis or pericarditis
- Positive immunoserology (revised 1997): antibodies to double-stranded DNA or Smith nuclear antigen, false-positive serologic test for syphilis, lupus anticoagulant, or antiphospholipid antibodies
- Positive ANA
- Meeting 4 of 11 classification criteria is highly sensitive and specific for diagnosis of SLE.

HISTORY

- History of photosensitivity or malar rash common but not necessary
- Many patients have systemic complaints, such as fever, fatigue, and malaise.
- Many patients complain of joint pain, Raynaud phenomenon, or alopecia.
- Chest pain from pericarditis or pleural effusions may be present.

- Signs and symptoms:
 - Immune complex–mediated vasculitis, which can occur in almost any organ system
 - Cutaneous lesions: very variable; include
 - Erythematous malar or “butterfly” rash
 - Maculopapular rashes (can occur anywhere on body)
 - Periungual erythema
 - Mucosal membrane vasculitis
 - Arthritis: can affect large and small joints; usually symmetric and nonerosive
 - Hematologic pathology includes the following:
 - Hemolytic anemia
 - Anemia of chronic disease
 - Leukopenia
 - Lymphopenia
 - Thrombocytopenia
 - Neurologic symptoms include the following:
 - Headaches
 - Psychosis
 - Depression
 - Seizures
 - Organic brain syndromes
 - Peripheral neuropathies
 - Renal pathology (present in up to 75% children with SLE)
 - Includes mesangial changes and glomerulonephritis (focal, diffuse proliferative, or membranous)
 - First signs of renal disease in lupus patient are often proteinuria and active urinary sediment.
 - Hypertension, nephrotic syndrome, and renal failure can also occur.
 - Serositis: usually seen as pericarditis or pleuritis but peritonitis can also occur
 - Constitutional symptoms are very common: fatigue, weight loss, fever.

PHYSICAL EXAM

- Rash: may be malar, discoid, or vasculitic. Periungual erythema may also be seen.
- Oral or nasal ulcers (usually on hard or soft palate) that are painless and often go unnoticed by patients
- Arthritis of large and small joints
- Pericardial friction rub if patient has pericarditis
- Edema may be present secondary to renal disease.
- CNS changes such as personality changes, psychosis, or seizures

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- ANA
 - Found in >95% of patients with SLE, but a positive ANA can occur in many diseases and in up to 20% of normal population
- Anti-double-stranded DNA and anti-Smith nuclear antigen
 - Very specific to lupus, but not all patients with lupus have these autoantibodies. In many patients, anti-DNA levels vary with activity of disease.
- CBC
 - Anemia, leukopenia, lymphopenia, and/or thrombocytopenia may be seen.
- Urinalysis
 - May show proteinuria or active urinary sediment if there is renal dysfunction
- Complement levels
 - Can fall very low during a lupus flare (C3 and C4)
- PTT
 - Patients may also have prolonged PTT, as result of antiphospholipid (APL) antibodies, often seen in SLE.
 - Patients with APL antibodies are at increased risk for thrombotic events, such as deep venous thrombosis, stroke, and fetal loss during pregnancies.

DIFFERENTIAL DIAGNOSIS

- Systemic-onset juvenile idiopathic arthritis
- Oncologic disease (leukemia, lymphoma)

- Viral or other infectious illness
- Other vasculitic disorders
- Dermatomyositis
- Fibromyalgia
- Drug-induced lupus
- Pitfalls:
 - Avoid overdiagnosis; positive ANA in the absence of clinical signs or symptoms of SLE is not lupus.

TREATMENT

MEDICATION

- NSAIDs
 - May be used for musculoskeletal and mild systemic complaints, although ibuprofen has been noted to cause aseptic meningitis in a small number of patients with SLE.
 - NSAIDs can also exacerbate renal disease in lupus.
- Hydroxychloroquine often used to help control cutaneous manifestations and to help minimize the chance of lupus flares
- Steroids often necessary to control systemic and renal manifestations
- Patients with renal disease often need immunosuppressive agents such as cyclophosphamide (usually given as monthly IV boluses). Mycophenolate mofetil, cyclosporine, or azathioprine may also be used.
- Patients with mainly arthritic symptoms may be treated with weekly methotrexate, PO or SC.
- Patients with antiphospholipid antibodies can be treated with a baby aspirin daily. If they have already had a significant clotting event, they need stronger anticoagulation.
- Angiotensin-converting enzyme (ACE) inhibitors are often used to help prevent renal damage from proteinuria.
- Patients with abnormal lipid profiles that do not respond to diet may need statins.
- Rituximab (anti-CD20 antibody) causes B-cell depletion and is used in SLE, especially for thrombocytopenia.

- Belimumab, a BLyS (B-lymphocyte stimulator) inhibitor, has been approved in adults but not yet in children.
- Antibodies to CD40 and C5 are also being studied
- Plasmapheresis and IVIG have been used as well.

ADDITIONAL TREATMENT

General Measures

Avoid excessive sun exposure and use sunscreen liberally.

ADDITIONAL THERAPIES

For very severe lupus, bone marrow immunoablation or transplantation are options.

ONGOING CARE

PROGNOSIS

- Extremely variable. Renal disease and CNS involvement are poor prognostic signs, whereas systemic complaints and joint findings are not.
- 10-year survival in children presenting with SLE is >90%.

COMPLICATIONS

- End-stage renal disease
- Infections secondary to treatments used to control disease
- Atherosclerosis and myocardial infarctions at a young age
- Libman-Sacks endocarditis, which increases risk of subacute bacterial endocarditis
- Neonatal lupus
 - Neonatal lupus erythematosus (NLE) is due to maternal autoantibodies (usually SS-A or SS-B antibodies) that cross the placenta and can cause rashes, congenital heart block, cytopenias, and/or hepatitis in the newborn.
 - Most symptoms of NLE resolve by 6 months of age, but heart block, if it occurs, is permanent.
 - Many mothers of babies with NLE are asymptomatic and unaware that they have these autoantibodies.

- The rash, erythema annulare, can begin a few days after delivery or within the first few weeks of life.
- Topical steroids can minimize skin lesions.
- Congenital heart block is due to damage of the conducting system of the developing fetal heart.
- Bradycardia may be noted by 22 weeks' gestation, and CHF with nonimmune hydrops fetalis may ensue.

- M32.9 Systemic lupus erythematosus, unspecified
- L93.2 Other local lupus erythematosus

FAQ

- Q: If a patient has a positive ANA but no clinical signs of SLE, how often should the ANA be followed?

- A: A positive ANA will usually remain positive indefinitely, but it has no real significance in the absence of clinical or other laboratory disturbances. Up to 20% of the normal population may have a positive ANA, so there is no need to repeat the test.
- Q: Can SLE patients with end-stage renal disease obtain renal transplants?
- A: Yes, and SLE usually does not recur in the new kidney.

LYME DISEASE

Elizabeth Candell Chalom

BASICS

DESCRIPTION

Multisystemic illness caused by the spirochete *Borrelia burgdorferi*, carried by the deer tick

EPIDEMIOLOGY

- Can affect people of all ages, but 1/3–1/2 of all cases occur in children and adolescents
- Male/female ratio: 1:1 to 2:1
- Onset most often in summer months
- Although Lyme disease can be found anywhere, the majority of the cases in the United States are found in Southern New England and the mid-Atlantic states. It is also seen frequently in California, Minnesota, and Wisconsin.

Prevalence

Has become most common tick-borne disease in the United States, with 29,959 confirmed cases reported in 2009

RISK FACTORS

Genetics

Chronic Lyme arthritis seems to be associated with increased incidence of HLA-DR4 and less so with HLA-DR2.

PATHOPHYSIOLOGY

B. burgdorferi is injected into skin with saliva during bite of *Ixodes* tick. Spirochetes first migrate within skin, forming the typical rash, erythema migrans. Spirochetes then spread hematogenously to other organs, including heart, joints, and nervous system.

ETIOLOGY

The tick-borne spirochete *B. burgdorferi*

COMMONLY ASSOCIATED CONDITIONS

The same ticks that transmit Lyme disease can also transmit Ehrlichia and Babesia, so infections with those spirochetes can occur simultaneously.

DIAGNOSIS

HISTORY

- Tick bite
 - History of tick bite can only be elicited in 1/3 of patients with Lyme disease
 - Most people with tick bites do not develop Lyme disease.
 - Even in endemic areas, risk of developing Lyme disease after tick bite is <5%.
- Rash
 - 50–80% will have or will recall the typical rash
 - Rash is not painful or pruritic but feels warm.
- Other symptoms
 - Many patients will complain of fatigue, headaches, fevers, chills, myalgias, conjunctivitis, and arthralgias early on.
- Joint pain
 - Many patients will complain of painful joints early on and later will develop joint swelling.
- Signs and symptoms
 - Skin: erythema migrans (typical rash)
 - Starts as red macule or papule and then expands to annular lesion up to 30 cm in diameter with partial central clearing
 - The lesion is usually painless and lasts 4–7 days.
 - Musculoskeletal
 - Early on, patient may experience myalgias, migratory joint pain (often without frank arthritis), and painful tendons and bursae.
 - Weeks to months later, 60% of untreated patients will develop monoarticular or pauciarticular arthritis of large joints, especially knees.
 - Joint fluid can have WBC count anywhere from 500–110,000 cells/mm³ and cells are mostly neutrophils.

- Neurologic
 - Several weeks after initial rash, 14% of untreated patients will develop neurologic symptoms including aseptic meningitis, cranial nerve palsies (especially facial nerve palsies), mononeuritis, plexitis, or myelitis.
 - Months to years later, chronic neurologic symptoms may occur, including a subtle encephalopathy: memory, mood, and sleep disturbances.
 - Significant fatigue can occur early or late in the course of Lyme disease.
- Cardiac
 - Several weeks after initial rash, ~5% of untreated patients develop cardiac disease.
 - Most common cardiac lesion is atrioventricular block (primary, secondary, or complete).
- Pericarditis, myocarditis, or pancarditis can also develop.

PHYSICAL EXAM

- May be completely normal early in course of disease
- Rash of erythema migrans, if seen, is virtually pathognomonic for Lyme disease.
- If patient does not have the rash, no physical finding exists that gives definitive diagnosis of Lyme
- Patient may have arthritis, Bell palsy, a cranial nerve palsy, conjunctivitis, or an irregular heartbeat.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab test

- Enzyme-linked immunosorbent assay (ELISA)
 - Can detect antibodies to *B. burgdorferi* several weeks after tick bite. However, it has relatively high false-positive rate and occasionally false-negative results. It remains positive for years after treatment.
- Western blot analysis
 - Much more specific. After 4–8 weeks of infection, ≥ 5 of the following IgG bands must be present for test to be positive: 18, 21,

28, 30, 39, 41, 45, 58, 66, and 93 kd. During first 2–4 weeks of infection, 2 IgM bands may establish diagnosis, but false-positive IgM blots are common.

- Positive ELISA with negative Western blot:
 - Usually means patient does not have Lyme disease and ELISA was a false-positive, but false-positive IgM blots are common.
- Polymerase chain reaction (PCR)
 - PCR testing may be done with synovial tissue or fluid or with CSF. Positive PCR indicates active disease, but negative result does not rule out Lyme.
 - Urine tests for Lyme disease have been shown to be very inaccurate and should not be used.

DIFFERENTIAL DIAGNOSIS

- Viral arthritis/arthralgias
- Septic arthritis
- Juvenile idiopathic arthritis
- Postinfectious arthritis
- Fibromyalgia syndrome
- Systemic lupus erythematosus
- Pitfalls
 - Incorrect diagnosis: Many patients with vague systemic complaints (fatigue, headaches, arthralgias) are incorrectly diagnosed with Lyme disease, even though their Lyme tests are negative (or ELISA mildly positive and Western blot negative).
 - These patients are then treated with multiple courses of oral antibiotics; if they do not respond, they are often treated with IV antibiotics, sometimes for prolonged periods.
 - This situation delays diagnosing true problem and subjects patients to unnecessary risks of long-term antibiotic use and occasionally of central venous lines.

TREATMENT

MEDICATION

- Oral antibiotics
 - Initial therapy for early Lyme disease
 - Specific therapies
 - Patients >8 years old: doxycycline is drug of choice.
 - Younger children or people who do not tolerate tetracyclines: Amoxicillin or cefuroxime is preferred, but penicillin V is also acceptable.
 - Penicillin-allergic patients: Erythromycin may be used but is less effective.
 - Duration of therapy
 - Patients with only skin rash: 14–21 days of oral antibiotics usually sufficient
 - If other symptoms present: 21–28 days recommended
- IV antibiotics
 - Become necessary for
 - Persistent arthritis unresponsive to oral medications
 - Severe carditis
 - Neurologic disease (other than an isolated 7th-nerve palsy)
 - Specific IV therapies
 - Ceftriaxone: drug of choice
 - Penicillin V: may also be used
 - Duration of therapy: 14–21 days
- Prevention
 - Some studies suggest that a single dose of doxycycline after tick bite will prevent Lyme disease.
 - Protective clothing, tick repellants, and checking daily for ticks are good preventive measures.

ONGOING CARE

PROGNOSIS

- In general, it is much better for children than for adults. Only 2% of children have chronic arthritis at 6 months.
- Most of the cardiac manifestations will disappear with or without treatment in a short time (3–4 weeks) but may later recur. Severe

cardiac involvement rarely may be fatal.

COMPLICATIONS

- Chronic arthritis occurs in ~2% of children.
- Other complications arise from treatment, such as
 - Cholecystitis secondary to treatment with ceftriaxone
 - Infections from indwelling catheters used for IV antibiotics
 - Some patients develop what is thought to be a post-Lyme disease syndrome. This syndrome is not well defined and is very controversial. It often consists of arthralgias and fatigue but may include paresthesias and cognitive complaints. Prolonged antibiotics have not been shown to be helpful. Some of these patients present with a fibromyalgia-like syndrome and improve with physical therapy.

CODES

ICD10

- A69.20 Lyme disease, unspecified

- A69.23 Arthritis due to Lyme disease
- A69.21 Meningitis due to Lyme disease

FAQ

- Q: What does the deer tick look like?
- A: The deer tick is flat, very small (about the size of a pin head), and has 8 legs. The adult male is black, and the female is red and black. They can grow to 3 times their normal size when they are engorged with blood.
- Q: Do all bites from infected deer ticks cause Lyme disease?
- A: No. Even infected ticks will not cause Lyme disease if they are attached to the skin for a short period of time. If the tick is attached for <24 hours, the chances of transmitting the disease are exceedingly low. The longer the tick is attached, the higher the probability of disease transmission.
- Q: Should all patients be retested for Lyme disease after a full course of treatment?
- A: No. Lyme titers and the Western blot will remain positive for years after adequate treatment for Lyme disease. If the patient's symptoms have resolved, there is no point in rechecking the titer. If the patient is still symptomatic, titers and a Western blot may be checked before starting IV antibiotic therapy to look for a rising titer and to be sure the patient truly has Lyme disease. If symptoms remain after IV therapy, other diagnoses should be considered.
- Q: Should patients with nontraumatic Bell palsy be tested for Lyme disease?
- A: Bell palsy is seen in association with Lyme disease infections. It is a reasonable indication for testing for Lyme disease.

LYMPHADENOPATHY

Kiran Patel • Morna J. Dorsey

BASICS

DESCRIPTION

- Term used to describe ≥ 1 enlarged lymph nodes >10 mm in diameter (for inguinal nodes, >15 mm; for epitrochlear nodes, >5 mm)
- Any palpable supraclavicular and popliteal lymph node is considered abnormal.

EPIDEMIOLOGY

Incidence

Depends on the underlying process that causes lymph node enlargement

Prevalence

Palpable nodes are present in 5–25% of newborns (cervical, axillary, inguinal) and in $>50\%$ of older children (all areas except epitrochlear, supraclavicular, and popliteal).

PATHOPHYSIOLOGY

- Lymph nodes are often palpable in normal, healthy children.
 - Normal lymph nodes: generally <10 mm
 - They are present from birth, peak in size between 8 and 12 years of age, and then regress during adolescence.
- Lymph nodes drain contiguous areas.
 - Cervical nodes drain head and neck area (up to 15% of biopsied nodes are malignant).
 - Axillary nodes drain arm, thorax, and breast.
 - Epitrochlear nodes drain forearm and hand.
 - Inguinal nodes drain leg and groin.
 - Supraclavicular nodes drain thorax and abdomen.
- Lymphatic flow from adjacent nodes or inoculation site brings microorganisms to lymph nodes.
- Lymph node enlargement may occur via any of the following mechanisms:

- Nodal cells may replicate in response to antigenic stimulation (e.g., Kawasaki disease) or malignant transformation (e.g., lymphoma).
- Lymphocyte proliferation due to immune defect (e.g. primary immunodeficiency disease [PIDD])
- Large number of reactive cells from outside node (e.g., neutrophils or metastatic cells) may enter node.
- Foreign material may be deposited into node by lipid-laden histiocytes (e.g., lipid storage diseases).
- Vascular engorgement and edema may occur secondary to local cytokine release.
- Suppuration secondary to tissue necrosis (e.g., Mycobacterium tuberculosis)
- Many systemic infections (e.g., HIV) cause hepatic or splenic enlargement in addition to generalized lymphadenopathy.

ETIOLOGY

Usually determined by performing a thorough history and physical exam

COMMONLY ASSOCIATED CONDITIONS

Many systemic infections, malignancy, and lymphoproliferative disorders cause hepatic or splenic enlargement in addition to generalized lymphadenopathy.

DIAGNOSIS

HISTORY

- Preceding symptoms (e.g., URI symptoms preceding cervical lymphadenopathy)
- Localizing signs or symptoms (e.g., stomatitis may be associated with submandibular lymphadenopathy)
- Duration
 - Acute (<3 weeks)
 - Subacute (3–6 weeks)
 - Chronic (>6 weeks)
- Constitutional or associated symptoms (e.g., fever, weight loss, or night sweats)

- Exposures
 - Cat exposure (cat-scratch disease)
 - Uncooked meat (Toxoplasmosis)
 - Tick bite (Lyme disease)
- Medications (e.g., phenytoin or isoniazid) or prior treatments
- Travel to or residence in an endemic area should raise suspicion for tuberculosis and Lyme disease.
- History of recurrent, deep seated, or opportunistic infections, family history of PIDD
- Signs and symptoms
 - Localized lymphadenopathy: involves enlarged nodes in any 1 region
 - Generalized lymphadenopathy: involves ≥ 2 noncontiguous regions secondary to a systemic process, such as EBV infection
 - Supraclavicular nodes seen with malignancy: Right-sided supraclavicular node is associated with mediastinal malignancy; left-sided node suggests abdominal malignancy.

PHYSICAL EXAM

- Complete physical exam is imperative to look for signs of systemic disease such as skin, oropharyngeal, or ocular findings or hepatosplenomegaly.
- The child's weight should also be checked to be sure there has been no weight loss.
- If localized lymphadenopathy is suspected, examine the area that the lymph node drains for pathology. For example, an arm papule may be associated with axillary lymphadenopathy in cat-scratch disease.
- Cervical, axillary, and inguinal nodes, as well as liver and spleen, must be palpated to help determine if signs of systemic disease or infection are present.
- Characterize nodes. Be sure to note the following:
 - Location: Be as exact as possible (see above).
 - Size: specify dimensions.
 - Consistency: soft, firm, solid, cystic, fluctuant, rubbery. Firm, rubbery nodes may be associated with lymphomas, whereas soft nodes are generally palpated with reactive lymphadenopathy.

- Fixation: normally freely mobile; infection or malignancy may cause adherence to surrounding tissues or nodes.
- Tenderness: suggests inflammation

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Consider the following tests if ≥ 1 node is persistently enlarged, has increased in size, has changed in consistency or mobility, or if systemic symptoms are present:

- CBC with differential: Consider with generalized lymphadenopathy, or if malignancy is in differential diagnosis.
- ESR or CRP: increased with infection or inflammation
- Lactate dehydrogenase (LDH), uric acid, and liver enzymes: Consider if history and physical exam raise concern for malignancy or hepatomegaly.
- Throat culture: if concern for group A β -hemolytic streptococcal (GAS) pharyngitis
- EBV/cytomegalovirus (CMV) titers: Consider with persistent generalized adenopathy.
- Bartonella henselae titers: Consider with persistently enlarged unilateral node and/or history of cat exposure.
- Purified protein derivative (PPD) testing: Consider with persistently enlarged node (2–4 weeks) or travel to areas where tuberculosis is endemic.
- HIV testing: Consider with persistent generalized lymphadenopathy and failure to thrive.
- Antinuclear antibody (ANA): if other signs of systemic disease to rule out systemic lupus erythematosus (SLE)
- Consider STD testing in adolescents (e.g., RPR).
- Other infectious workup as dictated by history and physical findings (e.g., Lyme titers for bull's eye rash)

Imaging

- Chest radiograph: helpful with supraclavicular nodes, systemic symptoms, or if positive PPD
- Ultrasound: may help differentiate cystic from solid masses

- CT: may help delineate anatomy or extent of the lesion, iliac lymphadenopathy is abnormal

Diagnostic Procedures/Other

- Biopsy should be considered if
 - Nodes are persistently enlarged, especially if accompanied by signs of systemic disease such as hepatosplenomegaly, weight loss, and exanthema.
 - Nodes are fixed to underlying skin.
 - Ulcerations or skin changes are present.
 - Not responsive to conventional therapy
 - Node is supraclavicular, nontender, or increasing in size or firmness.
- Fine-needle aspiration: cost-effective but sometimes nondiagnostic (e.g., unable to assess architecture); may result in fistulous tract
- Open biopsy: often diagnostic but requires general anesthesia

DIFFERENTIAL DIAGNOSIS

Must be carefully differentiated from lymphadenitis, defined as lymph node enlargement with signs of inflammation (including erythema, tenderness, induration, warmth); often treated with antibiotics

- Localized lymphadenopathy
 - Generally occurs as reactive adenopathy in response to local infection
 - Differential diagnosis for localized adenopathy varies depending on affected site.
 - ▢ Cervical adenopathy: includes cystic hygroma, branchial cleft cyst, and thyroglossal duct cyst
 - ▢ Inguinal adenopathy: lower extremity infection (e.g., osteomyelitis) or perineal disease
- Generalized lymphadenopathy: may be seen in many systemic illnesses
 - Viral infections: EBV, CMV, adenovirus, HSV, HIV, enterovirus, rubella, measles virus, varicella virus, viral hepatitis
 - Bacterial infections: Staphylococcus aureus, B. henselae, GAS, Salmonella, Yersinia, brucellosis, tularemia, Mycobacterium tuberculosis, Mycoplasma pneumoniae, rickettsiae

- Primary immunodeficiency diseases: common variable immunodeficiency disease, X-linked lymphoproliferative syndrome, autoimmune lymphoproliferative syndrome, hyper-IgM syndrome
- Malignancy: lymphoma, neuroblastoma, leukemia
- Autoimmune disorders: SLE, juvenile rheumatoid arthritis
- Other infections: parasites (e.g., Chagas disease) or fungal infections
- Medications can cause drug-induced hypersensitivity syndromes (e.g., DRESS): aromatic anticonvulsants, sulfonamides, allopurinol
- Miscellaneous: Kawasaki disease, Castleman disease, Kikuchi-Fujimoto disease (histiocytic necrotizing lymphadenitis), Gianotti-Crosti syndrome (papular acrodermatitis), sarcoidosis, lipid storage diseases (Niemann-Pick, Gaucher, Wolman, Faber diseases)

TREATMENT

MEDICATION

Acute lymphadenitis should be treated with antibiotics directed against *Streptococcus* and *Staphylococcus*.

First Line

- Dicloxacillin 50–100 mg/kg/24 h PO in 4 divided doses; max 4 g/24 h OR
- Amoxicillin-clavulanic acid 45 mg/kg/24 h PO in 2 divided doses, children >40 kg adult dosing
- Consider using clindamycin 30 mg/kg/24 h PO in 3 divided doses OR trimethoprim-sulfamethoxazole (TMP–SMX) 8–10 mg TMP/kg/24 h PO/IV in 2 divided doses in areas with a high prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) in the community.
- Penicillin-allergic patients: clindamycin 30 mg/kg/24 h PO in 3 divided doses or: erythromycin 50 mg/kg/24 h PO in 4 divided doses

Second Line

Consider broader antibiotic coverage for *B. henselae* and atypical mycobacterium: oral: azithromycin 10 mg/kg dose on day 1, followed by 5

mg/kg divided once for 4 more days

ADDITIONAL TREATMENT

General Measures

- Treat underlying disease.
- Close observation, unless history and physical suggest malignancy or lymphadenitis

ISSUES FOR REFERRAL

Refer to surgery or otolaryngology if biopsy or excision required.

SURGERY/OTHER PROCEDURES

Excision for special, prolonged cases

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Localized lymphadenopathy: Observe for several weeks or treat with antibiotics if indicated.
- Serial observation if nodes are persistently enlarged

PROGNOSIS

- Depends on underlying diagnosis
- Excellent for reactive lymphadenopathy

COMPLICATIONS

- Lymphadenitis
- Local infection (e.g., cellulitis)
- Lymph node abscess
- Sepsis via hematogenous spread of inadequately contained infection
- Fistula (e.g., with atypical mycobacteria)
- Fibrosis secondary to purulence or lymphadenitis
- Stridor secondary to enlarged cervical lymph nodes
- Wheezing secondary to enlarged parabronchial mediastinal lymph nodes

CODES

ICD10

- R59.1 Generalized enlarged lymph nodes
- R59.0 Localized enlarged lymph nodes
- P37.1 Congenital toxoplasmosis

FAQ

- Q: When should there be concern about malignancy in a child with lymphadenopathy?
- A: Malignancy should be considered in any child who has lymphadenopathy that does not improve in spite of antibiotic therapy, that has a location of concern (e.g., supraclavicular) or physical exam features of concern (hard, large size [>2 cm]) that persistently enlarges, or if the child shows signs of systemic disease.
- Q: When should a workup of a well child with localized

lymphadenopathy be pursued?

- A: As long as the lymph nodes are soft, mobile, and nontender, the lymphadenopathy is likely to be self-limited. If the cause is unclear, then children should be observed for a couple of weeks. Further workup is needed if the nodes persist or enlarge, if the location is worrisome (e.g., supraclavicular), or if there are signs of systemic disease (e.g., hepatomegaly or weight loss).
- Q: When should a child with lymphadenopathy be referred to a specialist?
- A: Most cases of lymphadenopathy in children are self-limited and can be observed for a few weeks and/or treated with antibiotics, if appropriate. Referral to a surgeon should be considered in any child with persistently enlarged lymphadenopathy (>4 weeks) or immediately if there are signs of malignancy. If there is a history of recurrent or opportunistic infections, referral to an immunologist or infectious disease specialist is warranted.

LYMPHEDEMA

Heidi Engel • Bettina Neumann

BASICS

DESCRIPTION

- Lymphedema is a chronic progressive swelling in subcutaneous tissues, typically in an extremity or the genitals, due to protein-rich accumulation of interstitial fluid from disruption of the lymphatic system. It can be of primary or secondary origin.
- Primary lymphedema has 3 forms, all of which stem from a developmental abnormality of lymphatic flow. Not all primary lymphedemas are clinically evident at birth.
 - Congenital lymphedema, due to anomalous development of lymph system
 - Present at birth
 - Lower to upper extremity ratio: 3:1
 - 2/3 of cases are bilateral.
 - May improve with age
 - Lymphedema praecox (65–80% of primary lymphedema)
 - Usually becomes evident at puberty but may appear between infancy and age 35 years
 - 70% unilateral lower extremity ($L > R$)
 - Lymphedema tarda: presents at age 35 years or older
- Secondary lymphedema is from an acquired abnormality of lymphatic flow, an injury to the lymphatic system.
 - Common causes in children include the following:
 - Postsurgical obstruction
 - Burns
 - Insect bites
 - Infection
 - Scar tissue from radiation
 - Neoplasm
 - Trauma

EPIDEMIOLOGY

- Most lymphedemas in childhood are primary (or idiopathic) lymphedema (96%).
- Congenital lymphedema comprises 10–25% of primary lymphedema cases; lymphedema praecox, 65–80%; and lymphedema tarda, 10%.
- Affected males—most likely congenital and bilateral; affected females—most likely unilateral lymphedema praecox
- Secondary lymphedema is more common in adults and rare in children. In the United States, it is commonly from breast cancer; worldwide, due to filariasis.
- Affects 1.15 of 100,000 in children <20 years

RISK FACTORS

Genetics

- Milroy disease
 - Also known as hereditary lymphedema type IA
 - A rare, autosomal dominant condition that affects lymphatic function
 - Associated with mutations in the FLT4 gene that encodes vascular endothelial growth factor receptor 3
- Meige disease
 - Hereditary lymphedema type II—familial lymphedema praecox
- Fabry disease
 - A serious, X-linked inborn error of glycosphingolipid catabolism associated with progressive renal failure, cardiovascular disease, neuropathy, and angiokeratosis
- Lymphedema-distichiasis
 - An autosomal dominant condition that presents with lymphedema and double rows of eyelashes
 - The condition is associated with mutations in the FOXC2 gene.
- Other genetic conditions prone to lymphedema: Down, Turner, Noonan, yellow nail, Klippel-Trenaunay-Weber, and pes cavus

PATHOPHYSIOLOGY

- Abnormal accumulation of interstitial fluid due to the lymphatic load overwhelming the transport capacity of lymph vessels

- Lymph flow occurs under a low pressure system; unlike generalized edema, capillary filtration remains normal in patients with lymphedema.
- Initially, edema is pitting, whereas chronic edema is generally nonpitting as a result of fibrosis.

DIAGNOSIS

HISTORY

- Unilateral, heavy, often aching lower extremity edema in healthy pubertal female strongly suggests lymphedema praecox.
- Heavy, aching pitting edema distal to site of extremity surgery or trauma suggests secondary lymphedema.
- Sites of previous cellulitis, infection, or insect bites can be associated with secondary lymphedema.

PHYSICAL EXAM

- Heavy, aching pitting edema in unilateral limb is suggestive of lymphedema.
- Lymphedema responds to elevation.
- Risk factors include obesity and inflammatory arthritis.
- Primary lymphedema sites: extremities, usually legs, rare in upper limbs; the foot is always involved in lower extremity lymphedema.
- Chronic inflammation leads to fibrosis and nonpitting or “woody” edema with induration.
- Hair loss and hyperkeratosis of the affected limb develop over time.
- Intense sharp pain in affected limb is uncommon and suggests secondary lymphedema due to thrombophlebitis, cellulitis, or reflex sympathetic dystrophy.
- Global edema suggests other disease states.
- Red streaking of extremity, fever, chills, or nodal enlargement suggests development of cellulitis or lymphangitis.
- History and physical exam are primary source for diagnosis.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Not usually necessary but may be useful to rule out other causes of edema

- Urinalysis for proteinuria as seen with glomerulonephrosis
- Serum total protein and albumin to rule out hypoproteinemia
- Liver function tests to assess functional status
- Pregnancy test

Imaging

Usually unnecessary to make diagnosis but may help to plan or evaluate therapy

- Lymphangiography is no longer used because related dyes caused inflammation and worsening of lymphatic obstruction.
- Radionuclide lymphoscintigraphy, when indicated, is the preferred method of imaging to define anatomy and to evaluate lymph flow and obstruction.
- CT and MRI may be valuable if a malignancy is suspected or to differentiate subcutaneous from adipose swelling.
- Doppler ultrasound may be helpful if deep vein thrombosis is suspected.

DIFFERENTIAL DIAGNOSIS

- Infection
 - Cellulitis
 - Lymphangitis
 - Herpes simplex virus type 2
- Tumors
 - Pelvic mass
 - Multiple enchondromatosis
- Metabolic
 - Cushing disease
 - Hyperthyroidism
 - Lipedema
- Anatomic
 - Venous stasis
 - Deep vein thrombosis
 - Hemihypertrophy
 - Arteriovenous fistula or malformation

- Popliteal arterial aneurysm
- Popliteal cyst (Baker cyst)
- Miscellaneous
 - Heart failure
 - Glomerulonephrosis
 - Cirrhosis
 - Hypoproteinemia
 - Reflex sympathetic dystrophy

TREATMENT

GENERAL MEASURES

- Therapy should be instituted as soon as possible and before fibrosis develops.
- Goals of therapy are to minimize or decrease edema and to prevent infection, fibrosis, and skin changes.
- Compression garments (e.g., Jobst stockings or elastic wraps) is recommended long term but compliance can be a challenge.
- Extremity elevation, especially at night
- Exercise, stay active for a lifetime; muscle contraction assists lymph flow and does not exacerbate swelling.
- Weight control
- Diligent skin care and appropriately fitting shoes to avoid infection
- Manual massage decompression can be helpful for digital edema and for infants who may not tolerate compression garments.
- Automated intermittent pneumatic compression machines shown to facilitate home regimen compliance
- Psychological effects of cosmesis are prominent and should not be overlooked.
- Patient education and support groups can be found through the National Lymphedema Network.

DIET

In children with chylous reflux syndromes, a diet low in long-chain triglycerides may be of benefit.

SPECIAL THERAPY

- Complex decongestive physiotherapy (CDP) is part of a specialized treatment with an initial reductive phase 1 and a maintenance phase 2 provided by a licensed physical therapist or occupational therapist certified in the treatment of lymphedema.
- Treatment is time sensitive and should be instituted as soon as possible to prevent fibrosis developing.
 - Phase 1 consists of manual lymph-drainage therapy, compression therapy specialized bandaging, fitting for appropriate tailored compression garment, and detailed skin and nail care.
 - Phase 2 consists of self-management for drainage techniques, skin care, use and care of compression garments, and exercise advice

MEDICATION

- Diuretics: not generally used in children and adolescents; efficacy for adults is debated
- Prophylactic antibiotic use is indicated for patients with recurrent cellulitis or lymphangitis.

SURGERY/OTHER PROCEDURES

- Microsurgical treatment has been proven to show excellent outcomes in carefully selected patient populations via lymphatic-venous anastomoses or lymphatic-venous-lymphatic anastomoses.
- Traditional surgery has 1 of 2 goals: removal of excess edematous tissue or attempts to restore lymph drainage
 - Both may decrease the rate of infections but have poor cosmetic results.
 - Recommended only for those with uncontrolled swelling with significant disability

ONGOING CARE

PROGNOSIS

- Edema persists throughout life.
- Lymphedema can be staged and monitored via circumferential measurements. Guidelines have been established by the American

Physical Therapy Association.

- Natural history: plateau in severity of edema after an initial few years of progression in 50%, slow constant progression in 50%

COMPLICATIONS

- Cellulitis and lymphangitis are the most common complications and are treated with antibiotics; published series showed 24% of cases developed infection and half of these required hospitalization.
- Poor long-term compliance with compression garments due to uncomfortable nature of therapy
- Lymphangiosarcoma (rare)
- Psychological problems
- Physical limitations
- Chronic inflammation and edema ultimately lead to fibrosis and induration of the involved area.

CODES

ICD10

- I89.0 Lymphedema, not elsewhere classified
- Q82.0 Hereditary lymphedema
- I97.89 Oth postproc comp and disorders of the circ sys, NEC

FAQ

- Q: Is the swelling going to go away?
- A: No, this is a chronic condition requiring long-term management.
- Q: Could this have been prevented?
- A: No, primary lymphedema is typically due to abnormal embryologic development.
- Q: If the lymph channels have been abnormal since birth, why does the swelling present during adolescence?
- A: No one really knows; hormones may play a role in lymphedema.

LYMPHOPROLIFERATIVE DISORDERS

David T. Teachey

BASICS

DESCRIPTION

- Lymphoproliferative disorders are a class of nonmalignant diseases characterized by uncontrolled growth of lymphoid tissues (spleen, bone marrow, liver, lymph nodes).
- Can be congenital or acquired
- Most common in children include
 - Autoimmune lymphoproliferative syndrome (ALPS)
 - Castleman disease (CD)
 - Rosai–Dorfman disease (RDD)
 - EBV-associated lymphoproliferative disorder (ELD)
 - X-linked lymphoproliferative syndrome (XLP)
- Rarer disorders (not discussed in detail)
 - Angioimmunoblastic lymphadenopathy
 - Caspase-8 deficiency syndrome
 - Diansani autoimmune lymphoproliferative disease
 - Kikuchi-Fujimoto syndrome
 - Lymphomatoid granulomatosis
 - Lymphomatoid papulosis
 - Ocular adnexal lymphoid proliferation
 - RAS-associated leukoproliferative disorder

EPIDEMIOLOGY

All uncommon

RISK FACTORS

Often multifactorial with inherited genetic defect and acquired infection

Genetics

- ALPS (80% of patients have identifiable mutation)
 - 60–70% germline mutation in FAS (TNFRSF6)
 - 10% somatic mutation in FAS

- 2% germline mutation in CASP10
- <1% germline mutation in FASL
- XLP
 - Majority of cases mutation in SH2D1A
 - XLP-like syndrome caused by X-linked inhibitor of apoptosis protein (XIAP) mutations

PATHOPHYSIOLOGY

- ALPS
 - Defective FAS-mediated apoptosis leads to abnormal lymphocyte survival with subsequent lymphoproliferation, autoimmunity, and cancer.
- CD
 - Largely unknown but can be triggered by HHV-8 infection, especially in immunocompromised patients
- ELD
 - EBV triggered lymphoproliferative disorder found in patients on chronic immune suppression typically after organ or bone marrow transplant (PTLD) or with inherited immune deficiency
- XLP
 - Mutation in SH2D1A leads to abnormal production of SAP protein in NK and T cells, leading to defective SAP-SLAM signaling and inability to appropriately respond to EBV infection.

DIAGNOSIS

HISTORY

- ALPS
 - Typically presents at young age (average 18 months) with massive lymphadenopathy and splenomegaly
 - Many patients develop secondary autoimmune disease.
 - Most often, autoimmune destruction of blood cells (80% of patients); can be mild to severe
 - Destruction of platelets: See chapter on “[Idiopathic Thrombocytopenic Purpura.](#)”

- Destruction of erythrocytes: See chapter on “[Autoimmune Hemolytic Anemia](#).”
- Destruction of neutrophils: See chapter on “[Neutropenia](#).”
- Can have autoimmune involvement of any organ system, similar to systemic lupus erythematosus
- In young adult years, 10–20% develop lymphoma.
- Lymphoproliferation can improve or worsen with infection. Often progresses through teenage years and improves in adulthood.
- Autoimmune disease is less likely to improve with older age.
- CD
 - Two variants
 - Hyaline vascular: presents with enlarged single lymph node or chain of nodes; >90% with no other symptoms; rarely can have fever, weight loss, fatigue
 - Plasma cell: presents with enlarged single lymph node or chain (unicentric) or diffuse adenopathy (multicentric); often with constitutional symptoms (fever, sweats, lethargy, rashes, neuropathy, arthritis)
- RDD
 - Massive, painless bilateral cervical lymphadenopathy with or without other involved nodal groups
 - Fever
 - Snoring common
 - Can have extranodal invasion of almost any organ (25% of patients have extranodal disease) and signs and symptoms depend on involved organ
- ELD/PTLD
 - Can be mild, with lymphadenopathy, fever, and/or diarrhea, or severe, with massive lymphadenopathy, high fever, night sweats, rash, and pruritus, and organ compression from involved nodes
- XLP
 - Can present as fulminant infectious mononucleosis or aplastic anemia or lymphoma or hematophagocytic syndrome
 - Often critically ill in the setting of EBV infection

PHYSICAL EXAM

- ALPS
 - Massive lymphadenopathy (90% of patients): Can compress vital organs including trachea (rare). Most common site of adenopathy is anterior cervical. Nodes are hard but mobile.
 - Splenomegaly (90% of patients)
 - Hepatomegaly (50% of patients)
 - Other physical exam findings as expected with autoimmune destruction of blood cells and/or end-organ autoimmune disease
- CD
 - Hyaline vascular: single enlarged lymph node or chain; most often cervical or mediastinal; may have shotty diffuse nonpathologic adenopathy
 - Plasma cell: single or multiple pathologically enlarged lymph nodes; abdominal nodes most common; hepatosplenomegaly common. Peripheral edema, ascites, and pleural effusions may be present.
- RDD
 - Massive bilateral anterior cervical lymphadenopathy (90% of patients). Other physical exam findings can vary based on extranodal disease.
 - Hepatosplenomegaly (10% of patients)
- ELD/PTLD
 - Similar to other lymphoproliferative disorders (See “[Epstein-Barr virus](#)” chapter.)
- XLP
 - Similar to other lymphoproliferative disorders, however, far more acutely ill (see also “[Epstein-Barr virus](#)” chapter and [Aplastic Anemia](#)” chapter)

DIAGNOSTIC TESTS & INTERPRETATION

Lab

General

- Complete blood and reticulocyte count for anemia, thrombocytopenia, and neutropenia
- Direct antiglobin test (DAT) to check for autoimmune destruction of red blood cells

- Serum chemistries, uric acid, phosphorus to look for cell turnover (usually normal in lymphoproliferative disorders)
- Liver function tests, PT, PTT, and fibrinogen to measure liver function and for coagulopathy
- EBV, PCR and titers, CMV-PCR
- If acutely ill, consider ESR or CRP and ferritin.
- Quantitative immunoglobulins: often elevated in lymphoproliferative disorders

Diagnostic tests for ALPS

- Mandatory criteria
 - (1) Chronic (>6 months) nonmalignant lymphoproliferation (lymphadenopathy) and/or splenomegaly
 - (2) Elevated peripheral blood double-negative T cells (DNTs): T cells that are CD3+, TCR alpha/beta+, CD4–, and CD8–. DNTs are usually rare in peripheral blood (<1% of total lymphocytes or <2.5% of total T cells). DNTs are elevated and often markedly elevated in ALPS. Slight elevation in DNTs can be found in other autoimmune disorders.
- Major (primary) criteria
 - (1) Genetic mutation in ALPS causative gene (germline or somatic) in FAS, FASL, or CASP10
 - (2) In vitro evidence of defective FAS-mediated apoptosis. This assay requires growing blood cells from patient in culture for weeks and exposing to anti-Fas monoclonal antibody to see if T cells are resistant to death. Only performed in a few labs.
- Minor (secondary) criteria
 - (1) Elevated vitamin B₁₂ (>1,500 ng/L)
 - (2) Elevated IL-10 (>20 pg/mL)
 - (3) Elevated IL-18 (>500 pg/mL)
 - (4) Elevated sFASL (>200 pg/mL)
 - (5) Classic histopathologic findings on lymph nodes or spleen biopsy
 - (6) Autoimmune cytopenias AND elevated serum IgG
 - (7) Positive family history
- Diagnosis

- Definitive: both mandatory and one major criteria
- Probable: both mandatory and one minor criteria (Probable ALPS should be treated the same as definitive ALPS.)

Diagnostic tests for CD

- Castleman syndrome diagnosed by histopathology
- Hypergammaglobulinemia, anemia, high ESR, high IL-6, HHV-8, PCR+

Diagnostic tests for RDD

- RDD diagnosed by histopathology
- Hypergammaglobulinemia, anemia, high ESR, leukocytosis with neutropenia, hematologic autoantibodies

Diagnostic tests for ELD/PTLD

- PTLD after bone marrow graft
- Persistent EBV infection (positive EBV PCR or abnormal seroconversion by titers) in setting of immune suppression or immune compromise
- Diagnosis confirmed with imaging and/or histopathology

Diagnostic tests for XLP

- Persistent EBV infection (positive EBV PCR or abnormal seroconversion on titers)
- Inverted CD4/CD8 ratio
- High IgM and IgA, low IgG
- Defective NK activity
- Secondary hemophagocytic syndrome (elevated ferritin, high triglycerides, low fibrinogen, cytopenias, high fever, splenomegaly, poor NK function, elevated s-IL-2R-alpha, and hemophagocytosis on marrow or node biopsy)
- Diagnosis confirmed by genetic testing for mutations in SH2D1A and XIAP genes, and/or SAP protein quantification

Imaging

- CT scans of head, neck, chest, abdomen, and pelvis with IV contrast is important for all lymphoproliferative disorders at initial diagnosis to define extent of disease.
- It is IMPORTANT to obtain plain chest x-ray on initial presentation in patient with diffuse lymphadenopathy before CT scan to ensure a large

mediastinal mass is not present. If present, it may be unsafe to lie patient flat and/or sedate for CT scan.

- Most lymphoproliferative disorders are very PET-avid.

Diagnostic Procedures/Other

- ALPS and PTLT can be diagnosed without histopathology; however, most patients have a lymph node biopsy.
- Other lymphoproliferative disorders typically require tissue for diagnosis (biopsy, not fine needle aspirate).
- Consider bone marrow aspirate and/or biopsy to rule out marrow disease or other disease processes.

Pathological Findings

- ALPS: DNTs in lymph node and spleen
- CD: hyaline vascular (shrunken germinal centers with eosinophilic expansion of mantle zones with and vessel hyalinization); plasma cell (extensive plasma cell infiltrate in interfollicular regions)
- RD: emperipoiesis (lymphophagocytosis)—hallmark of disease on biopsy; presence of histiocytes
- XLP/PTLD/ELD: EBER+

DIFFERENTIAL DIAGNOSIS

- Other lymphoproliferative disorders
- Lymphoma
- Infection: EBV, CMV, toxoplasmosis, HIV, TB
- Evans syndrome
- Rheumatologic disease

TREATMENT

FIRST LINE

- For ALPS: Corticosteroids or IVIG for acute flares
- For CD localized disease
 - Surgical resection or focal radiation. Steroids may be used to shrink lesions prior to surgery.
- For CD multicentric disease
 - Multiagent therapy (vincristine, prednisone, rituximab,

cyclophosphamide, doxorubicin)

- For RD
 - May self-resolve (20% of patients)
 - If not, consider prednisone, or vinblastine plus prednisone, or mercaptopurine plus methotrexate, or 2CdA.
- For ELD/PTLD
 - Reduce immune suppression or convert immune suppression to sirolimus if possible
 - Consider rituximab, adoptive transfer of EBV-specific cytotoxic T cells
 - If fails or generalized disease, consider multiagent chemotherapy similar to RDD
- For XLP
 - If hematophagocytosis or aplasia: rituximab, etoposide, steroids, and cyclosporine
 - Hematopoietic stem cell transplant is the only cure.

SECOND LINE

- For ALPS
 - Sirolimus or mycophenolate mofetil for chronic disease
 - Sirolimus (rapamycin): pros: improves autoimmune disease and lymphoproliferation and eliminates DNTs. Cons: drug–drug interactions; requires therapeutic drug monitoring; 10% of patients develop mouth sores (most common in first month).
 - Mycophenolate mofetil (CellCept): pros: No drug–drug interactions, no mouth sores, no therapeutic drug monitoring. Cons: not as effective; does not help lymphoproliferation or lower DNTs; GI upset
 - Recommended treatment: Mild to moderate autoimmune disease start with mycophenolate and transition to sirolimus if poor response or side effects. More severe autoimmune disease or clinically significant lymphoproliferation start with sirolimus.

THIRD LINE

- For ALPS
 - Combination therapy: stem cell transplant

- Relative contraindications (AVOID, if possible)
 - Splenectomy: high incidence of pneumococcal sepsis even with antibiotic prophylaxis and immunization
 - Rituximab: can lead to lifelong hypogammaglobulinemia (5–10% of patients)

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Recommended follow-up imaging varies among institutions. Most physicians will repeat imaging if patient's history changes OR to determine response to therapy.

PROGNOSIS

- Prognosis is good to fair for most lymphoproliferative disorders.
- Prognosis is poor in XLP and advanced CD.

CODES

ICD10

- D47.9 Neoplasm of uncertain behavior of lymphoid, hematopoietic and related tissue, unspecified
- D89.82 Autoimmune lymphoproliferative syndrome [ALPS]
- D47.Z1 Post-transplant lymphoproliferative disorder (PTLD)

MALABSORPTION

Sabina Sabharwal

BASICS

DESCRIPTION

- Malabsorption is characterized as a syndrome, as opposed to a disease entity, and is defined as any state in which there is a disturbance of digestion and/or absorption of nutrients across the intestinal mucosa.
- The classical symptoms of malabsorption include chronic diarrhea, abdominal distention, and failure to thrive.

EPIDEMIOLOGY

Depends on the underlying disease causing malabsorption

ETIOLOGY

The most common causes of malabsorption in developed countries are as follows:

- Postenteritis syndrome
- Cow's milk protein intolerance
- Giardiasis
- Celiac disease
- Cystic fibrosis
- Inflammatory bowel disease (IBD)

PATHOPHYSIOLOGY

- Depends on the nutrient affected
 - Carbohydrate
 - Monosaccharide: congenital glucose-galactose deficiency, fructose intolerance
 - Disaccharide: lactase deficiency (congenital or acquired), sucrase-isomaltase deficiency
 - Polysaccharide: amylase deficiency (congenital or acquired)
 - Fat
 - Bile salt deficiency: cholestasis, resection of terminal ileum

- Exocrine pancreatic insufficiency: cystic fibrosis, chronic pancreatitis
 - Inadequate surface area: celiac disease, flat villous lesions
- Protein
 - Protein-losing enteropathy: intestinal lymphangiectasia, congenital heart failure
 - Exocrine pancreatic insufficiency: cystic fibrosis, Shwachman-Diamond syndrome
 - Inadequate surface area: celiac disease
- According to the place where the alteration occurs
 - Mucosal abnormality
 - Anatomic: post-enteritis syndrome, celiac disease, IBD
 - Functional: disaccharidase deficiencies
 - Luminal abnormality
 - Exocrine pancreatic insufficiency: cystic fibrosis, Shwachman-Diamond syndrome
 - Bile salt insufficiency: biliary cholestatic liver disease, ileal resection
 - Anatomic abnormality
 - Short gut: surgical resection
 - Motility disturbance: intestinal pseudo-obstruction

DIAGNOSIS

HISTORY

- GI symptoms
 - Common in patients with malabsorption syndromes
 - Range from mild abdominal gaseous distention to severe abdominal pain and vomiting
 - Chronic or recurrent diarrhea is by far the most common symptom.
 - Abdominal distention and watery diarrhea, with or without mild abdominal pain associated with skin irritation in the perianal area due to acidic stools, are characteristic of carbohydrate malabsorption syndromes.
 - Fat malabsorption can present with bulky, foul-smelling stools that

are oily and thus float in water. Abdominal distention, increased gas, weight loss, and increased appetite are also seen.

- Periodic nausea, abdominal distention, pain, and diarrhea are common in patients with chronic *Giardia* infections.
- Vomiting, with moderate to severe abdominal pain and bloody stools, is characteristic of protein sensitivity syndromes.
- Abdominal pain or irritability (particularly seen in [celiac disease](#))
- Stool characteristics
 - Frequent loose watery stools may indicate carbohydrate intolerance.
 - Bulky, greasy, or loose foul-smelling stools indicate fat malabsorption.
 - In protein malabsorption, stools may be normal or loose.
 - Bloody stools are seen in patients with cow's milk protein allergy, infection, and IBD.
- Other symptoms
 - Failure to thrive caused by malabsorption of carbohydrates, fats, or proteins
 - Anemia, with weakness and fatigue, due to inadequate absorption of vitamin B₁₂, iron, and folic acid
 - Edema, due to decreased protein absorption and hypoalbuminemia
 - Muscle cramping due to decreased vitamin D causing hypocalcemia and decreased potassium levels

PHYSICAL EXAM

- Malabsorption syndromes should be considered during the workup for failure to thrive, malnutrition, poor weight gain, or delayed puberty.
- In particular, they should be suspected in infants with weight loss or little weight gain since birth and in infants with low weight and weight-for-height percentiles.
- Signs of malnutrition, including reduced subcutaneous fat, paleness, angular cheilosis, and muscle weakness
- Abdominal distention, increased bowel sounds
- Rash around mouth and/or anus are commonly seen.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Stool analysis
 - The presence of reducing substances and pH <5.5 indicates that carbohydrates have not been properly absorbed.
 - The level of quantitative stool fat and the amount of fat intake in the diet should be measured and monitored for 3 days using special stains; a coefficient of fat absorption is calculated using the following equation:

$$\frac{\text{Ingested fat (g)} - \text{fat in stool (g)}}{\text{Ingested fat (g)}} \times 100$$

- Normal values for the coefficient of fat absorption: >93% in children and adults, >85% in infants, >67% in premature infants
 - Moderate fat malabsorption ranges from 60 to 80%.
 - Fat absorption of <50% indicates severe malabsorption.
 - The presence of large serum proteins in the stool, such as α_1 antitrypsin, indicates leakage of serum protein. A 24-hour stool collection for α_1 antitrypsin (along with a serum level) serves as a screening test for protein-losing enteropathy.
 - Exam of the stool for ova and parasites or testing for the stool antigen may reveal the presence of Giardia species.
 - If bile acid malabsorption is suspected, quantitative conjugated and unconjugated bile acids may be measured in stool, although this test is not commonly available or used.
- Other laboratory studies
 - CBC
 - May reveal anemia in patients with iron, folate, and vitamin B₁₂ malabsorption
 - Neutropenia is seen in patients with Shwachman-Diamond syndrome.
 - Total serum protein and albumin levels
 - May be lower than reference range in syndromes in which protein is lost or not absorbed, particularly in protein-losing enteropathy and pancreatic insufficiency
 - With fat malabsorption or ileal resection, fat-soluble vitamin levels in the serum are low.

- With bile acid malabsorption, levels of LDL cholesterol may be low.
- Serum calcium may be low due to vitamin D and amino acid malabsorption.
- Serum vitamin A, E, and carotene may be low due to bile salt deficiency and impaired fat absorption.
- Other studies must be performed when a specific disease is suspected (e.g., mucosal biopsy for celiac disease, sweat test for cystic fibrosis, or appropriate workup for IBD).
- Urine analysis should be done to rule out proteinuria in patients with low albumin levels.
- An upper GI radiographic series and/or a lactulose breath test can be performed to look for small bowel dilation due to bacterial overgrowth.
- Genetic testing may be performed for identification of inherited malabsorption syndromes.
- If tissue samples are acquired through a biopsy, ultrastructural analysis may be performed using electron microscopy.

DIFFERENTIAL DIAGNOSIS

- Pancreatic disorders
 - Cystic fibrosis
 - Shwachman syndrome
 - Johanson-Blizzard syndrome
- Chronic cholestasis
 - Biliary atresia
 - Vitamin E deficiency
 - Alagille syndrome
- Infectious diarrhea
 - Giardiasis
 - Cryptosporidiosis
- Mucosal defect
 - Celiac disease
 - Crohn disease
 - Postinfectious diarrhea
- Congenital brush border enzyme deficiencies

- Glucose-galactose transporter deficiency
- Sucrase-isomaltase deficiency
- Microvillus inclusion disease
- Abnormal intestinal lymphatic drainage
 - Primary intestinal lymphangiectasia
 - Secondary intestinal lymphangiectasia

TREATMENT

- Overall, nutritional support is paramount.
- Specific treatment depends on etiology, for example, gluten-free diet for celiac disease, metronidazole for Giardia infection, or removal of the offending agent in a case of food intolerance.

ONGOING CARE

COMPLICATIONS

- Complications of malabsorption vary according to the underlying disease, but malnutrition and its consequences may worsen progressively if the cause is not determined and appropriate treatment prescribed.
- Frequent complications of malabsorption and malnutrition include growth failure, vitamin and micronutrient deficiency (zinc, magnesium, calcium), bone disease, hypoproteinemia and edema, essential fatty acid deficiency, perianal dermatitis, immune dysfunction, and anemia.

CODES

ICD10

- K90.9 Intestinal malabsorption, unspecified
- K90.4 Malabsorption due to intolerance, not elsewhere classified
- K90.0 Celiac disease

FAQ

- Q: Why do patients with malabsorption become anemic?
- A: Patients with malabsorption can become deficient in vitamin B₁₂, iron, and folic acid and in turn can become anemic.
- Q: Why do patients with celiac disease develop symptoms of malabsorption?
- A: Celiac disease leads to inflammation of the small bowel mucosa and villous atrophy. In turn, the absorptive capacity of the bowel is decreased.

MALARIA

Emily M. Schaaf • Chandy C. John

BASICS

DESCRIPTION

- Malaria is a febrile illness caused by the Plasmodium species of protozoan parasites, transmitted by the Anopheles mosquito vector.
- 5 Plasmodium strains infect humans: Plasmodium falciparum, Plasmodium vivax, Plasmodium malariae, Plasmodium ovale, and Plasmodium knowlesi. P. falciparum and P. vivax cause the majority of disease.
- Classic symptoms include stages of chills, followed by high fevers, and then sweating. However, this classic symptom pattern is less likely to be seen in children. Children may manifest initially with only fever as a complaint.

EPIDEMIOLOGY

- High-risk areas of endemic malaria include Africa, parts of Central and South America, Oceania, and tropical regions of Asia.
- P. falciparum is the major species in sub-Saharan Africa. Both P. falciparum and P. vivax are found in India, Southeast Asia, Oceania, and Central and South America, and P. vivax is present in some areas of Africa. P. ovale is usually found in West Africa.
- P. falciparum causes more deaths in children <5 years of age than any other organism.
- WHO reports that 86% of malaria deaths occur in children. Pregnant women are also at high risk.

Incidence

- Worldwide, an estimated 200–300 million cases of malaria occur annually, and 660,000–1.2 million deaths occur from malaria annually.
- ~1,500 cases of malaria are imported into the United States each year. In 2012, almost 2,000 cases of malaria were seen in the United States, the largest number of cases in >40 years.

RISK FACTORS

Genetics

- Sickle cell trait is known to provide protection against malaria.
 - The risk of death of severe falciparum malaria is 60–70% less in children with Hb AS than those with Hb AA.
- Thalassemia and G6PD deficiency also provide some protection against malaria.
- Individuals with a Duffy-negative blood type lack receptors for *P. vivax* merozoite invasion and are typically resistant to *P. vivax*, although recently, cases of *P. vivax* in Duffy-negative individuals have been reported.

GENERAL PREVENTION

- Personal protective measures against mosquito bites are extremely important.
 - Remain in well-screened areas.
 - Wear protective clothing, including pants and long-sleeved shirts.
 - Use insect repellents containing DEET.
 - Use insecticide-treated bed nets.
- Chemoprophylaxis is strongly advised for travelers to endemic areas.
 - Chloroquine may be used in areas with chloroquine-sensitive parasites only (5 mg/kg once a week—max 500 mg).
 - In chloroquine-resistant areas, effective options are atovaquone-proguanil (Malarone), mefloquine, or doxycycline.
 - Malarone can be used in all areas but is contraindicated in severe renal impairment and pregnancy.
 - Dosing: 5–8 kg: 1/2 pediatric tablet daily. 8–10 kg: 3/4 pediatric tab daily. 10–20 kg: 1 pediatric tab (62.5/25) daily. 20–30 kg: 2 pediatric tabs daily. 30–40 kg: 3 pediatric tabs daily. ≥40 kg: 1 adult tab (250/100) daily
 - Mefloquine resistance is present in parts of Asia. Contraindications to mefloquine include seizure disorder, major psychiatric illness, or cardiac disease. It is safe in pregnancy and for young infants.
 - Dosing: ≤15 kg: 5 mg/kg weekly. 15–19 kg: 1/4 tablet weekly. 20–30 kg: 1/2 tab weekly. 30–45 kg: 3/4 tab weekly. >45 kg: 1 tab weekly

- Doxycycline is contraindicated if <8 years of age and in pregnancy.
Dosing: 2.2 mg/kg daily (max 100 mg/day)
- Chloroquine and mefloquine are begun 1 week before travel, continued during the period of exposure and for 4 weeks after leaving the endemic region. Malarone is started 2 days prior to travel and continued 1 week after return. Doxycycline is started 2 days before travel and continued for 4 weeks after return.

ETIOLOGY

- Infection is typically transmitted by the bite of the female *Anopheles* mosquito, but it can also be transmitted through contaminated blood transfusions or acquired congenitally.
- The majority of human disease is caused by *P. falciparum* and *P. vivax*.
 - *P. vivax* and *P. ovale* can cause relapsing disease because of the persistent hepatic (hypnozoite) stage of the infection.
 - Asymptomatic carriage for years may occur due to *P. malariae*.
 - *P. knowlesi* is a primate parasite that can cause severe disease in humans.

COMMONLY ASSOCIATED CONDITIONS

- Severe malaria is most commonly caused by *P. falciparum*.
- Severe malaria is defined as parasitemia >5%, shock, acidosis, severe anemia or signs of CNS or other end-organ involvement such as renal failure, pulmonary edema, respiratory distress (acidotic/irregular breathing), impaired consciousness, seizures, hemoglobinuria, DIC, or hypoglycemia.
- Cerebral malaria is a serious consequence of malaria infection, defined as coma in conjunction with *P. falciparum* parasitemia.
 - Occurs most often in children age 3–6 years in Africa but often occurs in adolescents and adults in Southeast Asia
- Severe anemia is common and can be severe, especially with *P. falciparum*. This is due to high parasitemia, hemolysis, and sequestration.
- Respiratory distress has high mortality, particularly if combined with impaired consciousness.
- Blackwater fever is a complication associated with *falciparum* malaria.

It occurs due to massive hemolysis with resulting hemoglobinuria and acute renal failure.

- Pulmonary edema, renal failure, distributive shock, and progression to coma or death can occur.
- Hyperreactive malarial splenomegaly is seen with chronic exposure to malaria in endemic areas. High levels of malaria IgM are present, and massive hepatosplenomegaly is seen.
- Splenic rupture may occur due to splenomegaly.
- *P. malariae* can cause nephrotic syndrome.

DIAGNOSIS

HISTORY

- History of travel to malaria endemic region
- Poor compliance with malaria prophylaxis
- Signs and symptoms
 - High fevers, headache, chills, and sweats are classic symptoms.
 - Periodicity of fever depends on the Plasmodium species and is less commonly seen in young children and travelers.
 - GI symptoms are common in children. Irritability, anorexia, vomiting, abdominal pain, cough, and arthralgias may be seen.
 - 95% of malaria cases occur within 30 days of return from travel, but malaria may occur as late as months after return.
 - Malaria can cause altered mental status, increased intracranial pressure, seizures, and coma.

ALERT

A high index of suspicion is necessary for the diagnosis of malaria, as failure to diagnose malaria has led to death in some instances. Fever may be the only sign in infants and young children.

PHYSICAL EXAM

- Fever, malaise, ill appearance
- Pallor or jaundice
- Hepatosplenomegaly may be present.
- In severely ill patients, respiratory distress with acidotic, deep

breathing may be seen.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Hemolytic anemia is commonly seen, with severe malarial anemia most common with *P. falciparum*.
- Thrombocytopenia is common.
- Hypoglycemia may occur with *P. falciparum*.
- Peripheral blood smear
 - Thick and thin peripheral smears are required for definitive diagnosis (thick smears provide better sensitivity if the parasitemia is low; thin smears provide for species identification).
 - If initial smears are negative, repeated specimens should be obtained q12–24h over 72 hours to confirm a truly negative result with 3 smears.
 - A parasitemia of >5% of red blood cells, altered mental status, or other organ involvement make the diagnosis of severe malaria and require more intensive therapy.
- Rapid diagnostic tests
 - Rapid tests for antigen detection show excellent sensitivity for *Plasmodium* spp., require a small amount of blood for testing, and provide results in <20 minutes.
 - Rapid tests should complement but not replace microscopy testing, as they do not provide an estimate of parasite density.
- PCR
 - PCR is highly sensitive and can be useful for determining the *Plasmodium* species if it is unclear by blood smear. However, it is time-consuming and costly.

DIFFERENTIAL DIAGNOSIS

- Malaria should be considered in any febrile traveler from an endemic area.
- Other causes of fever in travelers should be considered based on the region of travel are as follows:
 - Dengue
 - Typhoid fever

- Yellow fever
- Hepatitis A
- Influenza
- Measles
- Leptospirosis
- Common causes of fever such as pneumonia and viral illnesses should also be considered.

ALERT

Consider malaria when a patient with fever has a history of travel.

TREATMENT

MEDICATION

Uncomplicated malaria

- Chloroquine can be used for known chloroquine-susceptible *P. falciparum* and *P. vivax* and for all *P. ovale*, *P. malariae*, and *P. knowlesi* infections.
 - Chloroquine is dosed at 10 mg/kg base PO (max 600 mg), then 5 mg/kg PO at 6, 24, and 48 hours (max 300 mg/dose).
 - Susceptible areas include Central America west of Panama Canal, Haiti, Dominican Republic, and parts of the Middle East.
- For chloroquine-resistant *P. falciparum* or if species is unidentified, options are as follows:
 - Atovaquone-proguanil (Malarone). Malarone (mg atovaquone/mg proguanil) is given as one dose daily for 3 days. 5–8 kg: 2 pediatric tabs (62.5/25) per dose. 9–10 kg: 3 pediatric tabs per dose. 11–20 kg: 1 adult tab (250/100) per dose. 21–30 kg: 2 adult tabs per dose. 31–40 kg: 3 adult tabs per dose. ≥40 kg: 4 adult tabs per dose
 - Artemether-lumefantrine (Coartem). Coartem is given for a 6-dose course. The 2nd dose is given 8 hours after the 1st, and then b.i.d. 5–<15 kg: 1 tablet (20 mg artemether/120 mg lumefantrine) per dose. 15–<25 kg: 2 tabs per dose. 25–<35 kg: 3 tabs per dose. ≥35 kg: 4 tabs per dose
 - Mefloquine. Mefloquine is dosed at 15 mg/kg (max 750 mg) PO,

- followed by 10 mg/kg (max 500 mg) PO 8–12 hours later.
- Quinine sulfate (10 mg salt/kg PO t.i.d.) plus doxycycline or clindamycin for 3 days (malaria acquired outside Southeast Asia) or 7 days (malaria acquired in Southeast Asia)
 - For chloroquine-resistant *P. vivax*, options are Malarone, mefloquine, or quinine +doxycycline, all in addition to primaquine.
 - Primaquine is used for the prevention of *P. vivax* and *P. ovale* relapses, in addition to primary treatment. It should not be used in patients with G6PD deficiency or in pregnancy.

Severe malaria

- Quinidine gluconate, 10 mg salt/kg IV initial dose (max 600 mg) over 2 hours followed by 0.02 mg salt/kg/min infusion + doxycycline or clindamycin
- In 2011, WHO guidelines made artesunate the drug of choice for children with severe malaria worldwide. Artesunate IV is available from the CDC under an investigational protocol for severe malaria in the United States.
- Change to an oral agent once parasite density <1% and the patient can take oral medication. The use of exchange transfusion for patients with hyperparasitemia is controversial, as no controlled trial has shown a clear benefit to this treatment.

INPATIENT CONSIDERATIONS

Admission Criteria

Travelers diagnosed with malaria infection should be managed as inpatients.

ONGOING CARE

PATIENT EDUCATION

- Consultation with a travel clinic is advised prior to travel to a malaria-endemic region.
- Chemoprophylaxis and mosquito bite prevention methods are both essential.

PROGNOSIS

- The prognosis depends on the severity of illness, *Plasmodium* species, underlying health conditions, and age of the patient.
- Infants with *P. falciparum* infection account for most of the mortality due to malaria.
- In African children, highest risk of death occurs in children with impaired consciousness and respiratory distress.
- If treated promptly, even *P. falciparum* malaria will likely respond well to treatment.

COMPLICATIONS

- Cerebral malaria has significant morbidity and mortality and can cause long-term neurocognitive impairment.
- Severe malarial anemia is frequent due to *P. falciparum*. However, death rates with adequate treatment are low.
- Chronic relapses can occur from *P. vivax* and *P. ovale* infections.
- Pregnant women are at higher risk for complications from malaria infection.

CODES

ICD10

- B54 Unspecified malaria
- B50.9 Plasmodium falciparum malaria, unspecified
- B51.9 Plasmodium vivax malaria without complication

FAQ

- Q: What drugs are acceptable choices for treatment of malaria in pregnancy?
- A: Options for uncomplicated malaria treatment in pregnant women in the United States include chloroquine (if sensitive), mefloquine, or quinidine + clindamycin.
- Q: Is there a vaccine available to prevent malaria?
- A: No vaccination is commercially available; however, antimalarial vaccines are currently in clinical trials and are showing some efficacy. The RTS,S subunit vaccine is in large-scale trials at this time.
- Q: How can I determine if the area my patient is traveling to has chloroquine-resistant malaria?
- A: The CDC Web site at www.cdc.gov/malaria has extensive information for travelers, including parasite sensitivity patterns and treatment recommendations. A malaria hotline is also available for clinician questions at 770-488-7788.

MALFORMATIONS OF CORTICAL DEVELOPMENT

Jeffrey Bolton • Annapurna Poduri

BASICS

DESCRIPTION

- Cortical malformations are important in clinical neurology, as they are associated with developmental disorders, motor impairments, and epilepsy.
- Defining the underlying malformation has prognostic value for patient's family, as well as possible genetic counseling implications.
- Classification schemes now emphasize the stage of embryogenesis which is disrupted.
- Disorders of neurulation
 - First key step to development of the CNS is neural tube closure around days 21–26 of gestation. Disruptions to rostral closure may lead to encephalocele or anencephaly.
 - Encephalocele: herniation of the intracranial contents through a midline skull defect; may occur frontal (orbit, nose, or forehead), basal, or occipital
 - Anencephaly: congenital absence of both cerebral hemispheres with preserved forebrain and upper brainstem
- Prosencephalic development
 - The prosencephalon is the precursor to the cerebral hemispheres and deep nuclei. Initial development begins at 4 weeks followed by cleavage occurring in weeks 5–6 and midline development from weeks 7–20.
 - Holoprosencephaly: 3 subtypes: (1) Alobar consists of a single spheroid cerebral structure with a common ventricle, fused thalami and basal ganglion, absent corpus callosum, and hypoplastic or single optic nerve. (2) Semilobar consists of anterior fusion with posterior cleavage and less fusion of deep structures. (3) Lobar is least severe, consisting of near total

- separation of the hemispheres with fusion in the most rostral and ventral aspects.
 - Agenesis of the corpus callosum (ACC): Corpus callosum fails to develop, ranging from complete to only mild thinning.
 - Septo-optic dysplasia: optic nerve hypoplasia, hypothalamic and pituitary hypoplasia plus midline and forebrain abnormalities (ACC, absent septum pellucidum)
- Neuronal proliferation
 - Neuronal progenitor cells proliferation peaks during the 1st and 2nd month of human gestation leading to rapid cell growth and differentiation into neurons, astrocytes, oligodendrocytes, etc.
 - Hemimegalencephaly: unilateral enlargement of one cerebral hemisphere, with possible abnormal cortical development in the abnormal hemisphere
 - Megalencephaly: brain measuring >2 SD or $>98\%$ for age
 - Microcephaly: defined as occipitofrontal head circumference >2 SD below the mean for patient's age
 - Tuberous sclerosis complex (TSC): Multiorgan disease with CNS involvement including cortical tubers (discrete areas of dysplastic cortex, paler and firmer in appearance than normal cortex), subependymal nodules, and subependymal giant cell tumors (SEGA).
 - Neurofibromatosis type I: characterized by café-au-lait spots, Lisch nodules in the eye, and benign and malignant tumors in CNS and PNS
- Migration/organization
 - Neurons migrate from the subependymal zone to cortex between 3 and 5 months of human gestation with gyration and organization peaking by 26–28 weeks.
 - Lissencephaly type I: characterized by thickened cerebral cortex with a smooth surface lacking gyral formation. The underlying cytoarchitecture is abnormal, containing less than the normal six layers.
 - Pachygyria: abnormally formed cortex which contains a few coarse gyri

- Subcortical band heterotopia: also referred to as “double cortex”; consists of a circumferential symmetric band of cortex located in the white matter just below typical cortex
- Lissencephaly type II: also known as “cobblestone cortex.” Characterized by lissencephaly with protrusions of neurons over the brain surface into the subarachnoid space. On gross inspection, the surface of the brain has a cobblestone appearance.
- Schizencephaly: consists of a deep cleft extending from cortical surface to the ventricle. The cleft may be lined with polymicrogyria cortex. The cleft may be bilateral or unilateral, with the Sylvian fissure being a common location. Subdivided into open and closed lip, with the former having a wide separation of the cleft wall and the latter having the cleft walls touching.
- Polymicrogyria: defined as a malformation consisting of multiple small placations of the cortical surface in a festoon-like or glandular formation resulting in cortex with numerous small gyri. It may be subdivided depending on location.
- Focal cortical dysplasia: consists of areas of cortex with abnormal lamination with \pm balloon cells
- Heterotopias: defined as collections of neurons in the periventricular or subcortical white matter

EPIDEMIOLOGY

- Incidence of malformations varied depending on specific malformation but overall is quite rare.
- The majority of malformations are associated with an increased incidence of epilepsy, ranging from 50–90%.
- Some malformations, such as anencephaly, have been associated with low socioeconomic status.

PATHOPHYSIOLOGY

- Any disruption to the development of the CNS during the prenatal stage may lead to a malformation.
- These disruptions include genetic mutations, metabolic derangements, infections, and toxic/environmental exposures.

- With infectious and toxic etiologies, the timing of the incident is key in determining the resultant malformation.

ETIOLOGY

- Genetic
 - Holoprosencephaly: trisomy 13 and 18; monogenic mutations including 2p21 (SIX3), 7q36 (SHH), 18q11 (TGIF), and 21q22
 - Microcephaly vera: 1q31 (ASPM), 8p23 (MCPH1), 9q33.2 (CDKL5RAP2), 13q12 (CENPJ), 19q13.12 (WDR62)
 - TSC: TSC1 9q34.13 (Hamartin), TSC2 16p13 (Tuberin)
 - Neurofibromatosis type I: 17q11 AD mutation of neurofibromin gene
 - Hemimegalencephaly: 1q43 (AKT3)
 - Lissencephaly: Miller-Diecker syndrome (lissencephaly, microcephaly, facial dysmorphism, syndactyly) LIS1 gene 17p13.3
 - Lissencephaly with cerebellar hypoplasia: Reelin 7q22
 - X-linked lissencephaly with abnormal genitalia: ARX Xp22.13
 - X-linked lissencephaly and subcortical band heterotopia: DCX Xq22.3-q23
 - Cobblestone cortex: may be seen in Walker-Warburg syndrome, Fukuyama congenital muscular dystrophy (FCMD), or muscle-eye-brain (MEB) disease
 - Walker-Warburg syndrome and MEB: (POMT1) 9q34.13, (POMGnT1) 1p33-34, (FKRP) 19q13.3, (LARGE) 22q12-q13.1
 - FCMD: (FKTN) 9q31.2
 - Schizencephaly w/ microcephaly: 19q13.12 (WDR62)
 - Polymicrogyria (PMG): known association with 22q11 deletions
 - Bilateral frontoparietal PMG: 16q13 (GPR56)
 - Occipital PMG: 9q34.12 (LAMC3)
 - Periventricular heterotopia: Xq28 protein filamin A (FLNA), autosomal recessive 20q11 (ARFGE2)
- Some malformations associated with neurocutaneous syndromes
 - Hemimegalencephaly seen in hypomelanosis of Ito, linear sebaceous nevus syndrome, or Klippel-Trenaunay-Weber syndrome
 - Megalencephaly: Sturge-Weber syndrome, neurofibromatosis, tuberous sclerosis

- Vascular (ischemia or hemorrhage)
 - Microcephaly: may be attributed to chronic placental insufficiency
 - Schizencephaly: often caused by MCA territory prenatal infarcts
 - Polymicrogyria: prenatal hypoxic ischemic injury
- Toxins/exposures
 - Antiepileptic medications (valproic acid [VPA], phenytoin [PHT]): dysraphic states
 - Ethanol, radiation, mercury, retinoids: holoprosencephaly
 - Hyperthermia: encephalocele, anencephaly
 - Maternal diabetes
- Infectious
 - Schizencephaly, microcephaly, anencephaly, polymicrogyria have been associated with various prenatal infections including CMV, toxoplasmosis, rubella, herpes
- Metabolic syndromes
 - Common to see macrocephaly in metabolic disorders, as there may be abnormal metabolite accumulation (Canavan, glutaric aciduria, etc.)
 - PMG has been observed in Zellweger syndrome, Refsum disease, and Menkes disease.

DIAGNOSIS

HISTORY

- A comprehensive family history assessing for members with known syndromes, intellectual disabilities, severe developmental delays, autism, epilepsy, unexplained deaths, frequent miscarriages, or parental consanguinity.
- Close attention should be paid to the pregnancy, inquiring about possible prenatal exposures (ethanol, medications, etc.), infections, or trauma/bleeding.
- Most children with CNS malformations will have developmental delays, thus a detailed developmental history should be obtained.
- Repetitive movements, alterations in consciousness, or other paroxysmal episodes should be asked about as seizures/epilepsy is common in this population.

PHYSICAL EXAM

- At initial presentation, a full physical exam should be performed, paying close attention to head circumference, dysmorphic features, organomegaly, skin findings, and detailed neurologic examination.
- In anencephaly, there is little-to-no overlying skull present. Encephaloceles may be visible as soft, skin-covered protrusions through the skull. In Meckel syndrome, encephalocele is associated with microcephaly, microphthalmia, cleft lip/palate, polydactyly, polycystic kidneys, and ambiguous genitalia.
- Holoprosencephaly may be accompanied by facial anomalies such as absent or malformed nose, single or hypertelorism, in addition to other organ system anomalies such as congenital heart disease, GI, GU, or skeletal defects.
- Skin findings such as hypomelanosis of Ito and linear sebaceous nevus raise concern for hemimegalencephaly.
- Neurofibromatosis type I has characteristic physical findings including macrocephaly, multiple café-au-lait macules, Lisch nodules, axillary/inguinal freckling, and palpable peripheral neurofibromas.
- “Ash-leaf” hypopigmented lesions, facial angiofibromas, and shagreen patches are seen in TSC.
- Miller-Dieker syndrome, associated with lissencephaly, has characteristic facial dysmorphisms including prominent forehead; short upturned nose; thin, protuberant upper lip; and small jaw. Spastic quadriparesis is often noted.

DIAGNOSTIC TESTS & INTERPRETATION

- Many of the malformations can be appreciated on prenatal ultrasound, leading to in utero diagnosis. Many tertiary centers are now able to perform fetal MRI, allowing for a more accurate image of the fetal brain.
- If not diagnosed prenatally, brain MRI should be performed on any patient where there is suspicion for a developmental malformation.
- CT is of little use, as it has low resolution and exposes the child to radiation.
- Once a malformation has been diagnosed via imaging, laboratory investigation should be pursued for known associated genetic

etiologies.

- As mentioned prior, many malformations are associated with monogenic variations. Specific genes are available for testing in certain circumstances (e.g., TSC1 and 2, DCX, and LIS1).
- In the presence of other congenital anomalies, cerebral malformations may be associated with chromosomal changes, thus karyotyping is important in such cases.
- When malformations are known to be associated with metabolic disorders, blood, urine, and CSF should be analyzed.
- When seizures are suspected, video EEG is valuable in assessing for epileptiform activity.

DIFFERENTIAL DIAGNOSIS

- Focal cortical dysplasia may be difficult to distinguish from low-grade glioma on MRI.
- Vascular anomalies and remote infarcts can be mistaken for congenital malformations.

TREATMENT

Most cortical malformations are irreversible. Treatment centers around management of comorbid conditions such as epilepsy, spastic quadriparesis, language delay, and other sequelae.

MEDICATION

- Any child with a malformation and epilepsy should be maintained on appropriate antiepileptic medication in conjunction with an experienced neurologist.
- Spasticity may be treated with antispasmodic agents such as baclofen or diazepam.
- In certain cases, such as TSC, novel agents (mTor inhibitors) are being investigated to halt progression of the disease.

SURGERY/OTHER PROCEDURES

- Cortical malformations often result in medically refractory epilepsy. Some patients may benefit from surgical treatment to cure or palliate

their epilepsy. This process is done very systematically via an experienced epilepsy surgery center.

- More restricted malformations which lead to medically refractory epilepsy may be amenable to resection and result in seizure freedom or reduction.
- More extensive lesions, such as hemimegalencephaly, may be treated with functional hemispherectomy.

ONGOING CARE

- Long-term prognosis varies depending on underlying malformation. The more extensive/severe the malformation, the more neurologic impairment is present.
- Significantly affected children require multidisciplinary care from a host of pediatric specialists including regular neurology visits.
- Families of children with known genetic etiologies should undergo formal genetic counseling to assess risk for other family members.

MAMMALIAN BITES

Margaret Wolff • Jill C. Posner

BASICS

DESCRIPTION

Injury to the human skin and/or subcutaneous tissues caused by bite, causing local, and in some cases systemic, effects

EPIDEMIOLOGY

- Animal bites
 - Approximate frequency
 - Dogs: 90–95%
 - Cats: 3–8%
 - Rodents or rabbits: 1%
 - Raccoons and other animals: 1%
 - 90% of the offending animals are well-known to the victim.
 - Children are the most common victims:
 - Boys are twice as likely as girls to be bitten by dogs.
 - Girls are more likely to be bitten by cats.
- Human bites
 - Most common in children ages 2–5 years
 - In older children, bites may occur accidentally during sports activities or intentionally during altercations or abusive situations.

Incidence

- An estimated 4.5 million dog bites and 400,000 cat bites occur annually in the United States.
- The incidence of human bites is unknown due to underreporting.

GENERAL PREVENTION

- Ensure that children receive routine immunizations against tetanus and hepatitis and that family pets are immunized against rabies.
- Encourage children to avoid contact with wild animals and dead animals.

PATHOPHYSIOLOGY

- Injury associated with bite types:
 - Dog
 - Crush and tear injuries
 - May involve bone
 - Cat
 - Puncture-type wounds
 - Penetrate deeper and carry a higher risk of infection
 - Human
 - Generally only violate skin
 - However, penetration into joint and tendon sheath spaces may occur (especially bites overlying the metacarpal-phalangeal areas).
- Infection
 - Rate of infection
 - Dog bites: 3–18%
 - Cat bites: 28–80%
 - Human bites: 15–20%
 - More recent studies have suggested an incidence of infection after dog and cat bites to be closer to 2–3%.
 - Infections are most commonly polymicrobial with both aerobic and anaerobic organisms.
 - Infected dog and cat bites
 - Pasteurella species are the most frequent isolates.
 - Dog: Pasteurella canis
 - Cat: Pasteurella multocida and Pasteurella septica
 - Common anaerobes include Fusobacterium, bacterioids, Porphyromonas, and Prevotella.
 - Infected human bites
 - Streptococcus anginosus
 - Staphylococcus aureus
 - Eikenella corrodens
 - Fusobacterium species
 - Prevotella species

DIAGNOSIS

HISTORY

- Animal bites
 - Type of animal
 - Apparent health of the animal
 - Provocation for the attack
 - Location of the bite or bites
 - Availability of animal for undergoing observation (i.e., Is it a known animal as opposed to a stray or wild animal?)
 - Rabies immunization status of the animal
- Past medical history
 - Tetanus immunization status of the child
 - Hepatitis B immunization status of child
 - Is patient immunocompromised or asplenic?

PHYSICAL EXAM

- Carefully assess neurovascular integrity.
- Location of bite
 - If bite is located over a joint, assess for violation of joint capsule.
- Examine entire patient to ensure that all wounds are identified and treated.
- Older wounds
 - Assess for signs of infection such as erythema, induration, purulence, regional adenopathy, and elevated temperature.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Blood culture if fever or systemic toxicity is noted
- Aerobic and anaerobic cultures from infected wounds

Imaging

In penetrating injuries overlying bones or joints, consider radiography to evaluate for presence of fracture, foreign body (e.g., tooth), and air within joint.

Diagnostic Procedures/Other

No tests routinely done

TREATMENT

MEDICATION

- Antibiotics: Data are often contradictory. In general:
 - All cat bites should be treated with prophylactic antibiotics, due to high risk of infection with *P. multocida*.
 - Amoxicillin–clavulanic acid PO is drug of choice (50 mg amoxicillin/kg/24 h divided b.i.d. or t.i.d. for 5 days).
 - All human bites should be treated with antibiotic prophylaxis. Amoxicillin–clavulanic acid PO is drug of choice (50 mg amoxicillin/kg/24 h divided b.i.d. or t.i.d. for 5 days).
 - An alternative antibiotic regimen for penicillin-allergic patients is trimethoprim–sulfamethoxazole plus clindamycin.
 - Bites to the hand, face, deep puncture wounds, and wounds in immunocompromised patients may be treated empirically.
 - Skin and soft tissue infections requiring hospitalization:
 - Ampicillin/sulbactam IV 150 mg ampicillin/kg/24 h in 4 divided doses
 - For penicillin-allergic patients, 3rd-generation cephalosporin
 - Antibiotics with poor activity against *Pasteurella* include penicillinase-resistant penicillins, clindamycin, and aminoglycosides.
- Tetanus prophylaxis if indicated
- Rabies prophylaxis if indicated
 - Unknown dog or cat; dogs or cats with unknown immunization status that cannot be observed for 10 days
 - Bites from wild animals, including raccoons, bats, skunks, foxes, coyotes
 - Because bat bites may go undetected, especially by a sleeping child, rabies prophylaxis is recommended after exposure to bats in a confined setting.
 - Rabies is unlikely if the child was bitten by an immunized dog, cat, or other pet (e.g., hamsters, guinea pigs, gerbils).

- Rabies is unlikely if the child was bitten by a small rodent (squirrels, mice, or rats) or rabbit.
- The regimen for patients who have not been vaccinated previously should include both human rabies vaccine (a series of 4 doses administered IM on days 0, 3, 7, and 14; immune-compromised patients should receive a 5th dose on day 28) and rabies-immune globulin (20 IU/kg) administered as much as possible into the wound, the remainder given IM at a site distant from the site used for vaccine administration.
- HIV postexposure prophylaxis (PEP)
 - There are case reports describing transmission of HIV by human bites; however, the risk of transmission due to biting is unknown. It is estimated to be extremely small. Bites with saliva containing no visible blood have no associated risk for transmission and, therefore, are not considered exposures.
 - HIV PEP requires a multidrug regimen administered over 28 days that can be associated with significant toxicity.
 - Decisions to initiate PEP are best made in consultation with local experts or by contacting the National Clinicians Post-Exposure Prophylaxis hotline at 888-448-4911.
 - Hepatitis B has been transmitted from nonbloody saliva. Check the vaccination status of the bitten (or biter if necessary) to consider PEP. Unvaccinated children should begin the hepatitis B vaccine series.
 - The transmission rate of hepatitis C via human bites is unknown and no regimen for PEP currently exists.

ALERT

A bite with a break in the skin is considered low risk, and a bite with intact skin is felt to pose no risk.

GENERAL MEASURES

- Wound care:
 - Copious irrigation with normal saline or tap water to remove visible debris
 - Do not use antimicrobial solutions to irrigate.

- Cleanse, but do not irrigate puncture wounds.
- Human bites over metacarpals (clenched-fist injuries) require orthopedic evaluation for possible surgical exploration and irrigation.
- Debride devitalized tissue.
- The increased risk of infection associated with suturing a potentially contaminated wound must be weighed against the cosmetic effect due to nonclosure:
 - Primary closure of larger wounds or significant facial wounds may be indicated unless wound is old or has evidence of infection.
- Hand wounds may be an exception, due to high propensity for infection.

ISSUES FOR REFERRAL

Local regulations dictate the reporting of animal bites to health departments.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Signs and symptoms of infection
- All patients with significant bites should receive follow-up 48 hours after bite.

PROGNOSIS

Most injury from animal bites is trivial, but infections, and rarely deaths, do occur.

COMPLICATIONS

Human bites over metacarpals (clenched fist) can penetrate tendon sheaths, become infected, and result in a tenosynovitis.

FAQ

- Q: What are the clinical features of Pasteurella infections?
- A: Infections caused by Pasteurella tend to progress rapidly, usually over a 12–24-hour period, and are characterized by tenderness and purulent drainage. The rapid progression of these infections tends to distinguish them from wounds that are infected with *S. aureus* and other pathogens.
- Q: Why are cat bites often more severe than dog bites?
- A: Cat bites are associated with puncture-type wounds and are more likely to involve Pasteurella infection, which is generally more aggressive than other organisms. However, dog bite infections may also be caused by Pasteurella.

MASTOIDITIS

Sadiqa Edmonds Kendi • Frances M. Nadel

BASICS

DESCRIPTION

Infection of the mastoid air cells characterized clinically by protrusion of the pinna and erythema/tenderness over the mastoid process; can range from an asymptomatic illness to a severe life-threatening disease. Acute mastoiditis is defined as the presence of symptoms for less than 1 month.

EPIDEMIOLOGY

- Most patients are between 6–24 months old.
- Male to female ratio of 2:1
- It is unusual to see mastoiditis in young infants because of incomplete pneumatization of the mastoid air cells.

Incidence

- At the start of the 20th century, 20–50% of cases of otitis media developed into coalescent mastoiditis. The routine use of antibiotics for otitis media and aggressive management of treatment failures has decreased incidence to 0.2–0.4%.
- Although some single-site reports have suggested that mastoiditis is on the rise, larger population-based studies demonstrate a stable incidence.

RISK FACTORS

- Age <2 years of age
- Acute otitis media
- Recurrent otitis media

GENERAL PREVENTION

- Appropriate early treatment of otitis media and timely follow-up to identify treatment failures
- Avoid factors that predispose to otitis media, including caretaker smoking and bottle-feeding.

- Early recognition of mastoiditis decreases the risk of intracranial complications.
- Pneumococcal vaccination may help decrease the occurrence of otitis media.

PATHOPHYSIOLOGY

- The mastoid process is the posterior portion of the temporal bone and consists of interconnecting air cells that drain superiorly into the middle ear. Because these mastoid air cells connect with the middle ear, all cases of acute otitis media are associated with some mastoid inflammation.
- Acute mastoiditis develops when the accumulation of purulent exudate in the middle ear does not drain through the eustachian tube or through a perforated tympanic membrane but spreads to the mastoid.
- Acute mastoiditis can progress to a coalescent phase after the bony air cells are destroyed and may then progress to subperiosteal abscess or to chronic mastoiditis.

ETIOLOGY

- Acute mastoiditis is generally caused by an extension of the inflammation and infection of acute otitis media into the mastoid air cells. However, 20–50% of patients may present without evidence of preceding otitis media.
- The bacteria isolated from middle ear drainage or from the mastoid are usually *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Haemophilus influenzae*, or *Staphylococcus aureus*. However, many patients' cultures are sterile:
 - *S. pneumoniae* is the most frequently isolated cause of mastoiditis in pediatric patients. *S. pneumoniae* resistance to penicillin may be as high as 30%, with the 19A serotype being the most common. With the advent of the 13 valent pneumococcal vaccine (which contains the 19A serotype), the epidemiology may change.
 - *Pseudomonas* infection should be suspected if the child has been on antibiotics recently or has a history of recurrent otitis media.
- Chronic mastoiditis is usually caused by *S. aureus*, anaerobic bacteria, enteric bacteria, and *Pseudomonas aeruginosa*:

- Chronic mastoiditis is often a multiple-organism infection.
- Unusual agents of chronic mastoiditis include *Mycobacterium tuberculosis*, nontuberculous mycobacteria, *Nocardia asteroides*, and *Histoplasma capsulatum*.
- Cholesteatomas may contribute to the development of mastoiditis by impeding mastoid drainage or erosion of underlying bone.

DIAGNOSIS

HISTORY

- May include a recent or a chronic history of treatment for otitis media
- Sign and symptoms
 - May include fever, otalgia, otorrhea, and postauricular swelling
 - Children who are already on antibiotics may present with more subtle findings.
 - Intracranial extension should be suspected if there is lethargy, a stiff neck, headache, focal neurologic symptoms, seizures, visual changes, or persistent fevers despite appropriate antibiotic treatment.
 - Labyrinthitis initially presents with tinnitus and nausea, which can progress to vomiting, vertigo, nystagmus, and loss of balance.

PHYSICAL EXAM

- The ear may protrude away from the scalp:
 - In children less than 2 years old, the ear protrudes out and is displaced down. In older children, the ear is displaced up.
- The external ear canal may be edematous or sagging.
- The tympanic membrane often is hyperemic, with decreased mobility, or perforated:
 - The tympanic membranes of children on antibiotics may have a normal appearance.
- The mastoid process is tender, with soft tissue swelling:
 - The overlying skin may be warm and erythematous, with posterior auricular fluctuance.
- In chronic mastoiditis, the fever and posterior auricular swelling are

often not present and the patient presents with ear pain, persistent drainage, or hearing loss.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC with differential: nonspecific
 - May be normal or show a leukocytosis with a neutrophil predominance
- ESR/CRP
 - May be elevated in acute mastoiditis but is usually normal in the chronic stage; more often elevated in complicated mastoiditis
- Purified protein derivative (PPD)
 - Should be done if tuberculosis is suspected
- Middle ear aspirate
 - Gram stain and cultures for aerobic and anaerobic bacteria
 - There is some correlation between middle ear bacterial cultures and mastoid cultures.
 - If possible, drainage prior to antibiotic administration is more helpful in making a microbiologic diagnosis.

Imaging

- X-rays
 - Reveal haziness of the mastoid air cells and can show bony destruction in more advanced disease
 - Are unreliable and can be falsely normal, as well as falsely abnormal
- Contrast-enhanced temporal bone and cranial CT
 - Helpful in the confirmation of the diagnosis, identification of coalescence or a subperiosteal abscess, and evaluation for concomitant intracranial complications
 - Intracranial complications are best seen with MRI.

Diagnostic Procedures/Other

Lumbar puncture must be performed in any child with symptoms of meningitis.

DIFFERENTIAL DIAGNOSIS

- Parotitis
- Posterior auricular lymphadenopathy or cellulitis
- Otitis externa or an ear canal furuncle
- Perichondritis of the auricle
- Neoplastic disease
 - Leukemia
 - Lymphoma
 - Rhabdomyosarcoma
 - Langerhans Cell Histiocytosis
- Branchial cleft anomaly
- Tuberculosis

TREATMENT

MEDICATION

- Parenteral antibiotics are chosen based on the most likely organisms, regional bacterial resistance patterns, and the child's condition.
- Intravenous antibiotics are given for at least 7–10 days followed with oral antibiotics for a total duration of 4 weeks of therapy.
- A third- or fourth-generation cephalosporin such as ceftriaxone or cefotaxime or cefepime is often used with or without vancomycin for empiric treatment.
- Subsequent antibiotic choice should be tailored to antimicrobial sensitivities of the ear aspirate.
- If *M. tuberculosis* is suspected, then antituberculosis therapy should be started.

ADDITIONAL TREATMENT

General Measures

Middle ear drainage is essential; therefore, a myringotomy with or without tube placement should be performed early.

SURGERY/OTHER PROCEDURES

- Indications for surgical intervention include the following:
 - Subperiosteal abscess
 - Coalescence

- Facial nerve palsy
- Meningitis
- Intracranial abscess
- Venous thrombosis
- Persistent symptoms despite adequate antibiotic treatment
- In the preantibiotic era, mastoidectomy was the treatment of choice for mastoiditis. Currently, this therapy is generally reserved for cases complicated by the aforementioned indications.
- Neurosurgical consultation for treatment of intracranial complications may be necessary.

INPATIENT CONSIDERATIONS

Admission Criteria

Admit for IV antibiotics and for ear, nose, and throat (ENT) evaluation for surgical drainage and to ensure response to antibiotics and to rule out complications.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- If patients respond quickly to parenteral therapy, they can complete a 3- to 4-week course with oral antibiotics and weekly follow-up visits.
- Audiograms should be performed later to screen for hearing loss.

PROGNOSIS

- Mastoiditis has a good prognosis if treated early. However, intracranial extension of mastoiditis can lead to permanent neurologic deficits and death.
- Chronic mastoiditis can lead to irreversible hearing loss.

COMPLICATIONS

- The proximity of the mastoid to many important structures can result in serious complications from extension of infection or as a response to the inflammatory process.
- Complication rates may be as high as 16%.

- Intracranial complications include meningitis and extradural, subdural, or brain parenchymal abscesses.
- Venous sinus thrombophlebitis results from extension of disease to the sigmoid or lateral sinus:
 - Sepsis, increased intracranial pressure, or septic emboli may result.
- Facial nerve palsy is usually unilateral and can be permanent.
- Labyrinthitis, petrositis, or osteomyelitis may result from extension of the infection into adjacent bones.
- Subperiosteal abscess
- Hearing loss can occur from destruction of the ossicles or from labyrinthine damage.
- Bezold abscess is a deep neck abscess along the medial sternocleidomastoid muscle that develops when the infection erodes through the tip of the mastoid bone and dissects down tissue planes.
- Gradenigo syndrome
 - Triad of 6th nerve palsy, retro-orbital pain, and otorrhea

- H70.009 Acute mastoiditis without complications, unspecified ear
- H70.099 Acute mastoiditis with other complications, unspecified ear

FAQ

- Q: Do all children with mastoiditis need a CT scan of the head if mastoiditis is suspected?
- A: No. In general, if the child with mastoiditis has mild swelling, no fluctuance of the mastoid, and responds to therapy, no CT scan is needed. A patient who appears toxic or fails to respond to appropriate antibiotic therapy or one who may be a surgical candidate should undergo additional imaging studies.
- Q: Should all children with mastoiditis be admitted to the hospital?
- A: Yes. In general, admission with IV antibiotics and ENT evaluation/drainage is warranted to ensure response to antibiotics and rule out complications.

MEASLES (RUBEOLA)

Jeffrey S. Gerber

BASICS

DESCRIPTION

- An exanthematous disease that has a relatively predictable course, making clinical diagnosis possible
- Because it is rare, cases are often initially misdiagnosed as a nonspecific viral exanthema, drug eruption, or Kawasaki disease.
- Patients are contagious from 1 to 2 days before onset of symptoms (3–5 days before rash) until 5 days after the appearance of the rash. The incubation period is generally 8–12 days from exposure to onset of symptoms and ~14 days until the appearance of rash.
- Types of measles include the following:
 - Typical measles (outlined below)
 - Modified measles: occurs in children with partial antibody protection (after postexposure administration of immunoglobulin or in infants <9 months old with transplacental antibodies)
 - Clinically similar to typical measles but is generally mild
 - The patient may be afebrile, and the rash may last only 1–2 days.
 - Atypical measles: caused by a hypersensitivity reaction to measles infection in those who received killed virus vaccine between 1963 and 1967 and are subsequently exposed to wild-type virus

EPIDEMIOLOGY

- Measles is one of the most highly contagious of all infectious diseases.
- Hospital or clinic waiting rooms (especially pediatric emergency department waiting rooms) have been identified as a major risk, accounting for up to 45% of the known exposures. With adequate immunization (2 doses = 99% effective), measles could be eliminated as a disease.
- Although no longer endemic in the United States, networks of intentionally unvaccinated children have led to several recent U.S. outbreaks originating from measles virus imported from abroad.

- Because 20 million cases of measles occur globally per year (>150,000 deaths), it is critical to maintain high levels of vaccination coverage.

Incidence

- Before the 1963 licensure of vaccine, an estimated 3–4 million people acquired measles in the United States each year; by 1983, there were only 0.7 cases per 100,000 population.
- Delays in immunization facilitated large outbreaks in the United States from 1989 to 1991, peaking in 1990 when 27,672 cases were reported, 89 of which were fatal.
- From 2001 to 2012, the median annual number of measles cases reported in United States was 60, peaking in 2011 (22 cases).
- From January to August 2013, 159 U.S. cases were reported, including the largest U.S. outbreak since 1996 (58 cases). The majority of cases occurred in underimmunized individuals and imported from abroad (including U.S. travelers).

GENERAL PREVENTION

- Vaccine recommendations
 - Routine vaccination against measles, mumps, and rubella (MMR) for children begins at 12–15 months of age, with a second MMR vaccination at age 4–6 years.
 - With the recent resurgence of measles, aggressive employee immunization programs should be pursued for all health care workers.
 - Health care workers born after 1956 who have no documentation of vaccination or evidence of measles immunity should be vaccinated at the time of employment and revaccinated ≥ 28 days later.
- Infection control measures
 - Any inpatient suspected of having measles should be in a negative-pressure respiratory isolation room; health care workers must wear masks, gloves, and gowns (airborne and contact precautions).
 - Isolation is required for 4 days after the 1st appearance of the rash; immunocompromised patients require isolation for the course of the illness.
 - All suspected cases of measles should be reported immediately to

the local health department.

PATHOPHYSIOLOGY

Transmission of measles occurs through direct contact with infectious droplets, less commonly by airborne spread.

ETIOLOGY

Measles is an RNA virus (paramyxovirus, genus Morbillivirus) with only 1 serotype.

DIAGNOSIS

- The disease involves fever, cough, conjunctivitis, and coryza with an erythematous rash, which has a characteristic progression:
 - The rash appears on the face (often the nape of the neck, initially) and abdomen 14 days after exposure. The rash is erythematous and maculopapular and spreads from the head to the feet, often becoming confluent at more proximal sites.
- Pharyngitis, cervical lymphadenopathy, and splenomegaly may accompany the rash.
- Atypical measles
 - This group of young adults (2nd and 3rd decades of life) may become quite ill, with sudden onset of fever from 103° to 105°F and headache. The rash, unlike typical measles, appears initially on the distal extremities, progressing cephalad.
 - Most patients with atypical measles have pneumonia, often with pleural effusions.
 - Diagnosis depends on clinical recognition and by serologic and molecular (RNA) testing.

HISTORY

- Case definition from the CDC includes the following:
 - Generalized rash lasting ≥ 3 days
 - A temperature of $\geq 38.3^{\circ}\text{C}$ (101°F)
 - Cough, coryza, or conjunctivitis
 - Positive testing or epidemiologic linkage to known case

- The mean incubation period is 10 days (range: 8–21 days).
- The prodrome of measles lasts 2–4 days and begins with symptoms of upper respiratory infection, fever up to 104°F, malaise, conjunctivitis, photophobia, and increasing cough.
- During the prodrome, Koplik spots (white spots on the buccal mucosa) appear on most people.
- Following this prodrome, the rash appears on the face (often initially at the hairline) and abdomen (14 days after exposure). The rash is erythematous and maculopapular and spreads from the head to the feet.
- After 3–4 days, the rash begins to clear, leaving a brownish discoloration and fine scaling.
- Fever usually resolves by the 4th day of rash.

DIAGNOSTIC TESTS & INTERPRETATION

- When measles is suspected, laboratory confirmation is important.
- The course of typical measles follows a predictable pattern; therefore, laboratory studies to confirm infection in known contacts might not be required.

Lab

- Serum measles-specific IgM titer (simplest)
 - Sensitivity may be diminished if assay performed <72 hours from onset of rash; repeat if negative. IgM detectable for at least 1 month from onset of rash
 - A comparison of IgG titers obtained during the acute and convalescent stages can be done. Blood samples must be taken at least 7–10 days apart.
 - Culture or RNA (RT-PCR) testing of nasopharyngeal, throat, blood, or urine

DIFFERENTIAL DIAGNOSIS

With a careful history and physical exam, it is usually possible to diagnose measles. The differential diagnosis includes the following:

- Stevens-Johnson syndrome
- Kawasaki disease
- Other viral exanthem
- Meningococcemia

- Rocky Mountain spotted fever (RMSF)
- Toxic shock syndrome

TREATMENT

GENERAL MEASURES

- No specific therapy; supportive care
- Ribavirin is active in vitro but not approved by FDA for treatment of measles.
- Vitamin A treatment of children with measles in developing countries has been associated with decreases in both morbidity and mortality.
 - The World Health Organization recommends vitamin A for all children with measles worldwide.
 - Vitamin A is given once daily for 2 days:
 - 200,000 IU for children ≥ 12 months of age
 - 100,000 IU for infants 6–11 months of age
 - 50,000 IU for infants < 6 months of age
 - The higher dose may be associated with vomiting and headache for a few hours.
 - For children with signs/symptoms of vitamin A deficiency, a 3rd dose at 4 weeks is indicated.
 - Vitamin A is available in 50,000 IU/mL injectable solution and may be given orally.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

In uncomplicated measles infection, clinical improvement and fading of rash typically occur on the 3rd or 4th day.

PROGNOSIS

- Mortality in the modern outbreak of 1989–1990 occurred in 3 of every 1,000 cases in the United States.
- Case fatality rates are increased in immunocompromised children.

COMPLICATIONS

- Complication rate in 1989–1990 outbreaks that occurred throughout the country was 23% and included diarrhea (9%), otitis media (7%), pneumonia (6%), and encephalitis (0.1%):
 - Encephalitis, which can lead to permanent neurologic sequelae, occurs in 1 of every 1,000 cases reported in the United States.
 - Croup, myocarditis, pericarditis, and disseminated intravascular coagulation (black measles) can also occur.
- In 1990, ~18–20% of patients required hospitalization, many for either dehydration or pneumonia.
- In patients with poor nutrition, most common in developing countries, mortality is higher.
- Subacute sclerosing panencephalitis (SSPE) occurs in 1 per 100,000 children with naturally occurring measles:
 - After an incubation period of several years (mean 10.8), a progressive, usually fatal, encephalopathy develops among unvaccinated children.
 - Patients with SSPE are not infectious.

- B05.2 Measles complicated by pneumonia

FAQ

- Q: If a health care worker has had a natural measles infection or measles immunization, should one be concerned about infection following exposure?
- A: Those persons born before 1957 who had wild-type measles virus infection are usually immune from reinfection. However, in a report in 1993, 4 health care workers who were previously vaccinated with positive preillness measles antibody levels developed modified measles following exposure to infected patients. Therefore, all health care workers should observe respiratory precautions in caring for patients with measles.
- Q: During an outbreak of measles, should children <12 months of age be vaccinated?

- A: In an outbreak of measles, public health officials may recommend vaccination of infants ages 6–11 months with a single-antigen measles vaccine; children initially vaccinated before their 1st birthday should be revaccinated at 12–15 months of age. A 2nd dose should be administered during the early school years.

MECKEL DIVERTICULUM

T. Matthew Shields

BASICS

DESCRIPTION

- Meckel diverticulum (MD) is the most common congenital abnormality of the GI tract.
- Derives from the omphalomesenteric duct remnants
- The most common clinical presentation in children of MD is painless rectal bleeding.
- Classically characterized by “Rule of 2’s”
 - Present in approximately 2% of the population
 - Male-to-female ratio 2:1
 - Within 2 feet of the ileocecal valve
 - Can be up to 2 inches in length
 - Symptoms usually present by 2 years of age.

EPIDEMIOLOGY

- MD as an anomaly occurs in ~2% of the population, but only ~4% of patients with MD develop symptoms over their lifetime.
- MD is more common in patients with other malformations including anorectal atresia, esophageal atresia, omphalocele, and cardiac abnormalities.
- MD is considered to be more common in males, with a male/female ratio of 2:1.
- Males are also more likely to have symptomatic diverticula.

PATHOPHYSIOLOGY

- Diverticula with ectopic tissue are more likely to be symptomatic.
- Ectopic tissue in MD is often of gastric origin; can also be comprised pancreatic, duodenal, or colonic tissue as well
- Bleeding occurs when gastric mucosa is present, resulting in peptic ulcerations of the small bowel downstream from the diverticulum (90% of cases).

- Alkaline secretions from ectopic pancreatic tissue can also cause ulcerations with bleeding.
- Obstruction can occur when the diverticulum acts as a lead point for intussusception, when the diverticulum becomes inflamed with subsequent lumen narrowing, or when the diverticulum induces a volvulus.

ETIOLOGY

- True diverticulum (contains all 3 layers of the bowel wall)
- Originates from the antimesenteric border of the bowel in the region of the terminal ileum and proximal to the ileocecal valve
- Remnant of the omphalomesenteric (vitelline) duct which fails to involute completely during the 5th–6th week of gestation as the placenta replaces the yolk sac as the source of fetal nutrition
- MD accounts for 90% of the vitelline duct anomalies. Other anomalies include the following:
 - Omphalomesenteric fistula
 - Omphalomesenteric cyst
 - Fibrous band

COMMONLY ASSOCIATED CONDITIONS

- MD has also been associated with several other congenital anomalies that include the following:
 - Anorectal atresia (affects 11% of patients with MD)
 - Esophageal atresia (12%)
 - Minor omphalocele (25%)
 - Cardiac malformations
 - Exophthalmos
 - Cleft palate
 - Annular pancreas
 - Some central nervous system malformations
- Malignancies have also been reported in association with MD.
 - Can be present within the diverticulum and can cause obstructive symptoms or can be found incidentally
 - Sarcomas are the most common malignancy associated with MD, followed by carcinoids and adenocarcinomas.

DIAGNOSIS

HISTORY

- Rectal bleeding
 - In children, the most common presentation is with painless rectal bleeding, which may range from occult blood to frank bright red blood and hemodynamic instability.
 - The bleeding tends to be self-limiting, because of constriction of the splanchnic vessels secondary to hypovolemia.
 - Bleeding is most commonly seen in children <5 years of age.
- Obstruction
 - Partial or complete small bowel obstruction
 - The clinical symptoms in this setting include recurrent abdominal pain, abdominal distention, nausea, and vomiting.
 - Most common type of presentation in adults and can occur in up to 40% of pediatric patients
 - Intraperitoneal bands, volvulus, or internal herniation may also lead to an obstructive presentation.
- Inflammation/fever
 - Another common presentation for symptomatic MD is inflammation or diverticulitis, which can occur in 12–40% of cases.
 - Patients often present with signs and symptoms consistent with appendicitis, and the diagnosis is made at the time of surgical exploration.
 - In a subset of this group (~1/3), the diverticulum may perforate from infarction or ulceration and lead to a more acute and toxic presentation.

PHYSICAL EXAM

- Physical exam may be normal but will often reflect the type of presenting complication:
 - Bleeding
 - Tachycardia
 - Hypotension
 - Blood in the stool

- Hyperactive bowel sounds
- Obstruction
 - Abdominal pain
 - Vomiting
 - Bilious emesis
 - Abdominal distention
- Inflammation (i.e., diverticulitis, ruptured diverticulum with peritonitis)
 - Fever
 - Abdominal tenderness
 - Symptoms more consistent with acute abdomen

DIAGNOSTIC TESTS & INTERPRETATION

- The diagnosis of symptomatic MD is difficult to make and requires a high index of suspicion.
- This diagnosis should be considered in any patient with recurrent unexplained abdominal pain, nausea and vomiting, or rectal bleeding.

Lab

- The diagnosis of MD cannot be made with laboratory evaluation or plain radiography alone.
- Laboratory analysis may be helpful to determine the degree of bleeding, with a hemoglobin count and a coagulation profile to rule out an underlying coagulopathy.
- Plain radiographs may show evidence of obstruction but are not diagnostic of MD.

Imaging

- Meckel scan (technetium-99m pertechnetate scan)
 - Evaluates for ectopic gastric mucosa within the diverticulum
 - Sensitivity 85%, specificity 95% in children; considerably lower in adults
 - Cimetidine can be used to increase retention of isotope within ectopic gastric mucosa.
- Mesenteric arteriography
- RBC scan with severe bleeding

Diagnostic Procedures/Other

- Surgery
 - In situations in which the Meckel scan is nondiagnostic or in patients with nonbleeding symptoms (but when there is a high index of suspicion for MD), exploratory laparoscopy may be indicated.
- Capsule endoscopy and balloon enteroscopy can establish the diagnosis but are not routinely used.

DIFFERENTIAL DIAGNOSIS

- Allergic colitis
- Infectious colitis
- Polyps
- Inflammatory bowel disease
- Angiodysplasia
- Constipation/anorectal fissure
- Coagulopathy
- Henoch-Schönlein purpura
- Intussusception
- Lymphonodular hyperplasia
- Intestinal duplication

TREATMENT

The treatment for MD that are symptomatic and identified is surgical removal. Surgery involves diverticulectomy or partial bowel resection.

SURGERY/OTHER PROCEDURES

- Initial management should include supportive care.
- Correct any electrolyte abnormalities.
- Initiate proton pump inhibitor (PPI) for gastrointestinal bleeding (PPI will not affect the results of the Meckel scan).
- Nasogastric tube placement for decompression of bowel obstruction
- Surgical intervention of an incidentally found MD is controversial.
 - If it is found during surgical exploration, intervention depends on the size of the diverticulum, age of the patient, and whether fibrous bands are present.
 - If it is found incidentally during radiologic imaging, symptoms

should be monitored closely, but most do not recommend elective surgery.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Bleeding
 - Address issues of anemia and volume status based on vital signs and blood tests.
- Obstruction
 - Evaluate the need for acute management (surgical) and decompression.

CODES

ICD10

Q43.0 Meckel’s diverticulum (displaced) (hypertrophic)

FAQ

- Q: What are various indications for resection of a Meckel diverticulum?
- A: Intussusception, narrowing at base of diverticulum, or presence of ectopic tissue resulting in bleeding
- Q: What is the most common type of ectopic tissue present in Meckel diverticulum?
- A: Gastric
- Q: What is the most common presentation of a Meckel diverticulum?
- A: Intermittent, painless rectal bleeding

MECONIUM ASPIRATION SYNDROME

Hussnain S. Mirza • Thomas E. Wiswell

BASICS

DESCRIPTION

Meconium aspiration syndrome (MAS) is a clinical diagnosis defined as respiratory distress in a newborn delivered through meconium-stained amniotic fluid (MSAF) with no other explanation for clinical symptoms. Severity of MAS can be (a) mild: requiring <0.4 FiO_2 for <48 hours; (b) moderate: requiring ≥ 0.4 FiO_2 for >48 hours with no air leak; and (c) severe: requiring assisted ventilation or if associated with persistent pulmonary hypertension of the newborn (PPHN).

EPIDEMIOLOGY

- Incidence of MSAF: 10–15% of all pregnancies
- 2–9% infants born through MSAF develop MAS (0.1–1.8% of all live births).
- MSAF is rare in premature infants and almost nonexistent before 31 weeks' gestation.

RISK FACTORS

- Postmature gestation
- Small for gestational age (SGA)
- Chorioamnionitis
- Fetal hypoxia (in utero aspiration)
- Thick consistency of meconium
- 1 and 5 minutes Apgar <6
- African American or South Asian ethnicity

PATHOPHYSIOLOGY

Meconium aspiration creates ventilation/perfusion (V/Q) mismatch (by the following variable effects on the airways), leading to hypoxemia, hypercarbia, acidosis, and cardiopulmonary failure.

- Mechanical obstruction of airways

- Complete (atelectasis)
- Partial (hyperinflation and air leaks due to ball and valve phenomenon)
- Meconium-associated pulmonary inflammation
- Inactivation of existing surfactant
- Decreased production of surfactant
- Meconium-induced lung apoptosis
- Coexisting pulmonary hypertension

DIAGNOSIS

HISTORY

- Term or postterm gestation
- Abnormal fetal tracing
- Evidence of MSAF
- Low Apgar score at 1 and 5 minutes
- Respiratory distress at or shortly after birth

PHYSICAL EXAM

- Meconium staining (vocal cords, skin, nails, and umbilical cord)
- Respiratory distress (tachypnea, retractions, grunting, cyanosis, and flaring)
- Barrel-shaped chest (air trapping or air leak)
- Rales and rhonchi
- Systolic murmur (tricuspid regurgitation) due to pulmonary hypertension
- Preductal oxygen saturation $\geq 10\%$ higher than postductal value
- Signs of encephalopathy, particularly if associated with perinatal asphyxia
- Signs of hypoxemia (cyanosis, poor perfusion, hypotension)
- Rarely, green color urine (meconium metabolites may appear in urine)

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC with differential count
 - Leukocytosis with left shift can help to identify secondary infection

or congenital pneumonia; however, a left shift is also common with MAS.

- Peripheral blood culture
 - May help to identify secondary infection, sepsis, or congenital pneumonia
- Arterial blood gas (ABG)
 - Can identify respiratory failure or hypoxemia and guide the need for respiratory support
 - The test is also used to calculate an oxygenation index if the infant is on mechanical ventilation.

Imaging

- Initial chest radiograph
 - Radiographic appearance lags behind clinical symptoms.
 - Frequently, there is no significant association between the extent of radiographic abnormalities and the severity of disease.
 - Initial radiograph can be normal or may have some streaky, linear densities.
- Follow-up chest radiograph
 - As the disease progresses, there can be diffuse patchy densities, hyperinflation, flattening of the diaphragm, pleural effusion, alternating areas of microatelectasis, hyperinflation, and consolidation.
 - Significant air leaks can be noted in 10–30% of infants with MAS.

Diagnostic Procedures/Other

- Pre- and postductal SpO₂ gradient
 - >10% may be associated with PPHN.
- Oxygenation index (OI)
 - After optimizing mechanical ventilation, OI >40 on two serial ABGs performed 4 hours apart could be an indication for extracorporeal membrane oxygenation (ECMO).
 - $OI = (FiO_2 \times \text{mean airway pressure} \times 100) / PaO_2$
- Echocardiography
 - To rule out congenital heart disease and to evaluate for PPHN

DIFFERENTIAL DIAGNOSIS

- Congenital pneumonia
- Transient tachypnea of newborn (TTN)
- PPHN

TREATMENT

MEDICATION

- IV antibiotics
 - In the early stage of the disease, it is difficult to differentiate between MAS and congenital pneumonia. Many clinicians treat empirically while awaiting the results of cultures.
 - Prophylactic antibiotic treatment does not prevent secondary infection in MAS.
- Surfactant bolus treatment
 - Although not specifically FDA approved for MAS, exogenous surfactant replacement may decrease the need for ECMO.
- Steroid therapy
 - Not recommended for routine treatment of MAS
 - Systemic use of steroids has reportedly been associated with shorter duration of mechanical ventilation and with the improved pulmonary function.
- Inhalational nitric oxide (iNO)
 - iNO is used to treat MAS that is associated with PPHN.

ADDITIONAL THERAPIES

- Oxygen therapy
 - The goal is to keep peripheral SpO₂ between 92% and 98% or PaO₂ between 60 and 80 torr (8–10.7 kPa).
 - Oxygen can be provided via oxyhood or nasal cannula. If >0.6 FiO₂ is required to achieve the above-mentioned goal, consider additional respiratory support.
- Continuous positive airway pressure (CPAP)
 - Due to the possible complications (i.e., air trapping, hyperinflation, and air leaks), many clinicians prefer to avoid CPAP. However, CPAP can be cautiously used if air trapping or air leak is not a

major issue.

- Conventional ventilation
 - Used to achieve optimal ventilation and oxygenation. No specific modes have been proven superior.
 - Most clinicians use low positive end-expiratory pressure (PEEP) and prolonged expiratory times in order to prevent hyperinflation, air trapping, and air leaks.
- High-frequency ventilation (oscillator or jet):
 - High-frequency ventilation (HFV) is used as a rescue treatment. No clinical trial has demonstrated clear benefits of HFV over conventional modes in the initial management of MAS. However, in the presence of air trapping or air leaks, jet ventilation may help. Anecdotally, meconium clearance may be increased with high-frequency jet ventilation (HFJV).
- ECMO
 - Indicated for severe respiratory failure manifested by an OI >40 on 2 serial ABGs performed 4 hours apart while on optimal mechanical ventilation
 - Veno-arterial or veno-venous ECMO can be considered in the absence of any vital organ failure, significant congenital anomaly, genetic syndrome, or intraventricular hemorrhage.
- Broncho-alveolar lavage (BAL)
 - BAL with diluted surfactant is an experimental therapy that has been found to produce rapid and sustained improvement in oxygenation, a shorter ventilation course, and decreased need for ECMO.
 - Use of surfactant/dextran mixture for BAL is reportedly helpful in rapid clearance of meconium. However, none of these therapies have been approved for MAS.

GENERAL MEASURES

- ICU care
 - For SpO₂ and continuous cardiopulmonary monitoring, to provide optimal thermal environment, and to ensure minimal handling
- Chest PT is generally not recommended.
- IV fluids

- Required for maintenance of hydration and prevention of hypoglycemia
- IV fluid bolus may be required for hypovolemia or hypoperfusion.
- Inotropic therapy
 - May be required to support the systemic perfusion especially if cardiac output is low due to left ventricular (LV) dysfunction (hypoxia or acidosis), severe PPHN, or decreased venous return
- Sedation
 - May be helpful to decrease agitation, optimize ventilation, and minimize right-to-left shunting. However, routine use of muscle relaxants is controversial, as they may increase the risk for atelectasis and V/Q mismatch.
 - Paralysis is generally not recommended.
- Feeding
 - During acute phase of severe illness, enteral feedings are discouraged to protect the underperfused gut from ischemic injury.
- Sodium bicarbonate therapy: generally not recommended

Preventive Measures

- Prevention of fetal hypoxia
 - Optimal obstetric care is the key for prevention of MAS. The decreased incidence of MAS in the last decade has been attributed to the reduction in postterm delivery and aggressive management of abnormal fetal heart tracings.
- Amnioinfusion: not recommended
- Intratracheal suctioning: recommended only for nonvigorous infants born through MSAF
- Oropharyngeal suctioning: not recommended
- Gastric suctioning: No clinical study had assessed this approach.
- Contraindicated procedures:
 - Attempts to prevent deep inspiration prior to oropharyngeal or endotracheal suctioning by mechanical means (e.g., cricoid pressure, manual blockage of the airway, and thoracic compression)

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Long-term consequences include increased bronchial reactivity and wheezing among the survivors of MAS.
- Infants with severe MAS are at risk for delayed development; they should be followed up in the developmental pediatrics clinic for 2–5 years.

PROGNOSIS

- Severity of lung injury is related to the consistency of meconium (thick meconium is high risk for severe disease) and to the degree of hypoxia and acidosis present at birth.
- Generally, 1/3 of infants with MAS need mechanical ventilation, 15–20% develop PPHN, and 10–30% can have air leaks.
- In spite of appropriate management and clinical care, up to 10% of infants with severe MAS may die.

COMPLICATIONS

- Birth depression
 - Occurs in 20–33% of infants born through MSAF
 - These infants can have neurologic manifestations of hypoxic ischemic encephalopathy (HIE) and needs appropriate treatment.
- SIADH
 - More likely to occur among infants with a history of perinatal asphyxia or air leaks
- PPHN
 - Occurs in 15–20% of infants with MAS
 - PPHN in these infants may be caused by (a) pulmonary vasoconstriction secondary to pulmonary inflammation, hypoxia, hypercarbia, and acidosis and (b) pulmonary vascular remodeling as a result of chronic intrauterine hypoxia.
- Secondary lung infection
 - Meconium provides an excellent growth medium for microorganisms. Meconium may also inhibit polymorphonuclear cells.
- Reactive airway disease
 - Up to 50% of infants who survive severe MAS are at risk to develop

reactive airway disease in the first 6 months of life.

ADDITIONAL READING

CODES

ICD10

- P24.01 Meconium aspiration with respiratory symptoms
- P24.00 Meconium aspiration without respiratory symptoms

FAQ

- Q: What is the composition of meconium?
- A: Meconium is a variable mixture of intestinal epithelial debris, gastrointestinal secretions, bile, mucus, pancreatic juice, blood, swallowed vernix caseosa, and lanugo.
- Q: What are the recommendations for repeated intratracheal suctioning?
- A: If no meconium is retrieved initially, repetitive suctioning is not required. However, if meconium is retrieved and in the absence of bradycardia, intratracheal suctioning can be repeated.
- Q: How to manage vigorous infants born through MSAF?
- A: Asymptomatic infants should be managed like normal newborns. It is important to clinically observe these infants for any signs of respiratory distress for at least 24 hours prior to discharge.
- Q: What are current therapies being considered for the treatment of MAS?

- A: Meconium-resistant surfactant enriched with high proteins, phospholipids, and polymers (e.g., dextran) is waiting for clinical trials. Research has shown potential benefits of the following drugs in the treatment of MAS; however, none of these treatments are approved for clinical use at this point: antioxidants: superoxide dismutase or N-acetylcysteine and angiotensin-converting enzyme (ACE) inhibitors (by suppressing apoptosis).

MEDIASTINAL MASS

Michelle L. Hermiston

BASICS

DESCRIPTION

Space-occupying lesion of the mediastinum

- Anterior mediastinum includes the thymus and other structures anterior to the pericardium.
- Middle mediastinum contains the heart, great vessels, ascending aorta, and aortic arch, as well as lymph nodes.
- Posterior mediastinum contains the tracheobronchial tree, esophagus, descending aorta, and neural structures.

PATHOPHYSIOLOGY

Morbidity is due to compression of adjacent normal structures, particularly large airways, heart, and great vessels.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Congenital/anatomic
 - Large normal thymus in neonate (anterior)
 - Bronchogenic, pericardial, or foregut cyst (middle)
 - Aortic aneurysm and other vascular anomalies (middle)
 - Thoracic meningocele (posterior)
- Infectious (may cause mediastinal adenopathy and/or pulmonary nodules) (middle/posterior)
 - Tuberculosis
 - Histoplasmosis
 - Aspergillosis
 - Coccidioidomycosis
 - Blastomycosis
- Foreign body in the trachea or esophagus

- Sarcoidosis
- Tumor
 - Benign
 - Thymoma (anterior)
 - Teratoma/dermoid cyst (anterior)
 - Lymphangioma/cystic hygroma (middle/posterior)
 - Hemangioma (middle/posterior)
 - Ganglioneuroma (posterior)
 - Neurofibroma (posterior)
 - Malignant
 - Malignant germ cell tumor (anterior)
 - Hodgkin lymphoma (anterior/middle)
 - Non-Hodgkin lymphoma or leukemia (anterior/middle)
 - Neuroblastoma (posterior)
 - Ganglioneuroblastoma (posterior)
 - Ewing sarcoma or osteogenic sarcoma (anterior/posterior)
 - Pheochromocytoma (posterior)
 - Neurofibrosarcoma (posterior)
 - Rhabdomyosarcoma or pleuropulmonary blastoma (any)

APPROACH TO THE PATIENT

Goal is to quickly establish diagnosis and begin treatment as indicated, as condition may rapidly progress and become life threatening. If malignancy is suspected, the child should be immediately referred to an oncologist.

HISTORY

- **Question:** systemic symptoms (fever, weight loss, night sweats, fatigue)?
- Significance: may be associated with infection or malignancy
- **Question:** cough, wheeze, dyspnea on exertion, orthopnea?
- Significance: may indicate early airway compromise
- **Question:** face/neck swelling?
- Significance: suggests superior vena cava syndrome

PHYSICAL EXAM

Focused attention for signs of respiratory distress or cardiovascular compromise. Check for signs and symptoms noted below.

- **Finding:** edema/suffusion of face and neck, jugular venous distension, conjunctival injection, headache, altered mental status?
- Significance: superior vena cava syndrome
- **Finding:** cough (nonproductive), orthopnea or dyspnea, stridor, or wheezing?
- Significance: airway compression
- **Finding:** quiet heart sounds, hypotension, narrowed pulse pressure, or pulsus paradoxus?
- Significance: cardiac tamponade/diastolic dysfunction secondary to mass effect
- **Finding:** lymphadenopathy or hepatosplenomegaly?
- Significance: malignancy or infection. Low cervical, posterior, or supraclavicular adenopathy particularly concerning for malignancy
- **Finding:** pallor, ecchymoses, petechiae, and/or mucosal bleeding?
- Significance: suggest anemia and thrombocytopenia, which are seen in malignant conditions also infiltrating the bone marrow
- **Finding:** Horner syndrome
- Significance: posterior mediastinal mass, most commonly a neuroblastoma

DIAGNOSTIC TESTS & INTERPRETATION

- **Test:** CBC with differential.
- Significance: anemia, thrombocytopenia, and neutropenia noted in malignant diseases infiltrating bone marrow. Circulating blasts frequently noted in leukemia or lymphoma; leukocytosis in infection
- **Test:** lactate dehydrogenase, uric acid, electrolytes, calcium, phosphate, creatinine
- Significance: tumor lysis screen
- **Test:** purified protein derivative (PPD) skin test
- Significance: tuberculosis
- **Test:** urine vanillylmandelic acid (VMA) and homovanillic acid (HVA)
- Significance: elevated in 90% of children with neuroblastoma
- **Test:** alpha-fetoprotein and beta-hCG
- Significance: can be elevated in germ cell tumors
- **Test:** other assays for specific pathogens based on history of exposure

- Significance: For a patient with a large mass or potential cardiopulmonary compromise, goal is rapid diagnosis using least invasive/painful procedure, to minimize need for sedation/anesthesia.
- **Test:** pulmonary function test
- Significance: may be useful to assess pulmonary reserve
- **Test:** bone marrow aspiration/biopsy
- Significance: simplest procedure if CBC is suspicious
- **Test:** lymph node biopsy
- Significance: if adenopathy at easily accessible site
- **Test:** biopsy of mass
- Significance: Consider radiologically guided fine-needle biopsy.
- **Test:** pleurocentesis, pericardiocentesis, or excision of isolated mass
- Significance: may have both diagnostic and therapeutic roles
- **Test:** lumbar puncture
- Significance: may be combined with other procedures if meningitis or hematologic malignancy is suspected

ALERT

Recumbent positioning, sedation, or positive pressure ventilation may lead to catastrophic respiratory or cardiovascular collapse in patients with partial compromise.

- Imaging of airway and consultation with anesthesia, surgeons, and critical care specialists should be obtained prior to any sedation.
- Procedures may need to be done with local anesthesia only with patient sitting upright.

Imaging

- Chest radiograph (lateral film required) to establish size and location of mass
- CT of the chest (if patient can tolerate semirecumbent positioning)
 - To define size, location, and consistency of mass
 - To assess large blood vessels and airways
- Echocardiogram to assess diastolic filling and vascular patency

TREATMENT

- First line
 - Steroids may be given after diagnosis is established to treat hematologic malignancies or decrease edema/inflammation.
 - If leukemia/lymphoma, diagnostic lumbar puncture should be performed prior to steroid treatment if possible.
 - Additional therapy depends on diagnosis (e.g., chemotherapy, antibiotics).

SPECIAL THERAPY

- Radiotherapy
 - May be indicated for emergent management of malignancies

ADDITIONAL TREATMENT

General Measures

- Close monitoring of cardiorespiratory status
- With cardiorespiratory compromise, avoid positive-pressure ventilation, if feasible.
- Definitive therapy will be based on the diagnosis.

ALERT

- Do not treat a patient with wheezing who has no history of asthma with steroids without obtaining a chest radiograph to confirm that there is no mediastinal mass.
- If symptoms are progressing rapidly or there is evidence of superior vena cava syndrome, tracheal compression, or spinal cord compression, emergent steroids or radiation may be required, following rapid diagnostic procedures if possible.

SURGERY/OTHER PROCEDURES

- May be required for diagnostic biopsy
- Excision may relieve acute compression and may be primary therapy for isolated benign mass.

ONGOING CARE

Admission Criteria

- All patients with significant mass, until cardiopulmonary risk defined

- All patients with evidence of significant airway or vascular compression
- All patients with evidence of significant tumor lysis syndrome

Discharge Criteria

Resolution/resection of mass, or clear evidence of cardiopulmonary stability through all activities of daily living (ADLs), including sleep

COMPLICATIONS

- Superior vena cava syndrome
- Tracheal compression
- Spinal cord compression
- Pleural and pericardial effusions
- Secondary infection
- Horner syndrome: ptosis, miosis, and anhydrosis resulting from compression of the cervical sympathetic nerve trunk
- Esophageal narrowing or erosion: may result in feeding difficulty or bleeding
- Tumor lysis syndrome with electrolyte disturbances, kidney failure

CODES

ICD10

- R22.2 Localized swelling, mass and lump, trunk

- Q34.1 Congenital cyst of mediastinum
- D15.2 Benign neoplasm of mediastinum

FAQ

- Q: What should be done if the child is asymptomatic and a mediastinal mass is an incidental finding on chest x-Ray?
- A: Careful history and physical with specific attention to pulmonary, cardiac, and hematologic systems.
 - Vital signs to include temperature and pulse oximetry
 - CBC, differential, ESR, tumor lysis labs
 - PPD, anergy panel if high risk for tuberculosis or initial evaluation is negative
 - CT of chest
 - Referral to oncologist, surgeon, or infectious disease specialist pending above results
- Q: When should an oncologist be consulted?
- A: With any of the following:
 - Rapidly enlarging mass
 - Signs and symptoms of tracheal compression, superior vena cava syndrome, or spinal cord compression
 - Hepatomegaly, splenomegaly, lymphadenopathy, bruises, or petechiae on physical examination
 - Anemia, thrombocytopenia, or leukocytosis suggesting bone marrow involvement
 - Malignant histology demonstrated with biopsy
 - When help is needed in establishing diagnosis

MEGALOBLASTIC ANEMIA

Kieuhoa T. Vo • Elliott Vichinsky

BASICS

DESCRIPTION

- Macrocytosis refers to a blood condition in which red blood cells (RBCs) are larger than normal. It is reported in terms of mean corpuscular volume (MCV). Normal MCV values range from 80 to 100 fL and vary by age and reference laboratory.
- No complications arise from macrocytosis itself as an isolated finding; however, its identification can provide important information regarding the presence of an underlying state.
- In the appropriate clinical setting, MCV values above the upper limit of normal or those that differ significantly from the patient's baseline values may require further clinical and laboratory assessment to determine the underlying cause of macrocytosis.
- Macrocytosis with associated anemia (macrocytic anemia) can be broadly classified as megaloblastic or nonmegaloblastic anemia. This categorization is important and frequently aids in determining the etiology of the anemia.
- Megaloblastic anemia describes an anemic state characterized by the presence of abnormally large RBCs (macro-ovalocytes) and hypersegmented neutrophils in the peripheral blood and bone marrow.

EPIDEMIOLOGY

- The incidence and prevalence is unknown.
- The most frequent causes of megaloblastic anemia are disorders resulting in vitamin B₁₂ (cobalamin) or folate deficiency.

RISK FACTORS

- Premature infants
- Malnutrition
- Strict vegetarians without milk, cheese, or egg intake
- Partial or total gastrectomy, ileal resection

- Infants fed goat's milk
- Bone marrow disorders
- Helicobacter pylori infection
- Crohn disease
- Zollinger-Ellison syndrome
- Orotic aciduria
- Lesch-Nyhan syndrome
- Exocrine pancreatic disease
- Intestinal tapeworm
- Chronic dialysis
- Therapy with certain anticonvulsants
- Therapy with certain HIV antiretroviral medications
- Therapy with certain chemotherapy agents

PATHOPHYSIOLOGY

- Megaloblastic anemia is a direct result of ineffective or dysplastic erythropoiesis caused by a defect in DNA synthesis that interferes with cellular proliferation and maturation.
- When vitamin B₁₂ or folate is deficient, RBC proliferation and maturation result in large erythroblasts with nuclear/cytoplasmic asynchrony. The erythroblasts become large, oval shaped, and contain a characteristic immature, lacy nucleus. These bone marrow features are called “megaloblastic.”

ETIOLOGY

- The most common etiologies of megaloblastic anemia are vitamin B₁₂ or folate deficiencies.
- Medications are another less common cause of megaloblastic anemia.
- Pernicious anemia is a common cause in adults but rare in children. Pernicious anemia is a type of vitamin B₁₂ deficiency anemia and is caused by a decrease in the secretion of intrinsic factor (IF) by gastric parietal cells in the setting of autoimmune atrophic gastritis. IF is a protein essential for absorption of vitamin B₁₂ in the ileum.

DIAGNOSIS

HISTORY

- Pallor, fatigue, poor appetite, irritability
- Malabsorption/diarrhea, steatorrhea, weight loss
- Neurologic symptoms primarily seen in vitamin B₁₂ deficiency:
 - Paresthesias, altered gait, impaired vision, psychiatric symptoms
- Diet history
 - General malnutrition
 - Personal history of strict veganism
 - Infants with vegan mothers
 - Infants fed goat's milk
- Family history of pernicious anemia or autoimmune diseases
- Surgical history of partial or total gastrectomy, ileal resection, splenectomy
- Drug history
 - Anticonvulsants
 - Chemotherapy agents, particularly antimetabolites
 - HIV antiretrovirals
 - Metformin
 - Aminosalicicytes
 - Nitrous oxide, use and abuse

PHYSICAL EXAM

- Pallor, pale conjunctiva
- Glossitis: smooth, tender tongue
- Neurologic findings
 - Muscular weakness
 - Peripheral neuropathy
 - Abnormal position and vibratory sensation
 - Ataxia
 - Positive Babinski test
 - Psychiatric and cognitive changes

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Complete blood count with differential
 - Decreased hemoglobin

- Increased MCV
- Increased red cell distribution width (RDW)
- May have normal or decreased white blood cell count and platelets depending on degree of megaloblastosis
- Peripheral blood smear
 - Macro-ovalocytes
 - Hypersegmented neutrophils
 - Poikilocytosis: abnormally shaped RBCs
 - Anisocytosis: abnormal variation in size of RBCs
- Reticulocyte count: low
- Increased LDH
- Decreased haptoglobin
- Increased homocysteine levels
- Serum vitamin B₁₂ level:
 - <100 pg/mL: vitamin B₁₂ deficiency
 - 100–400 pg/mL: borderline result; check serum methylmalonic acid (MMA) and homocysteine levels to help differentiate between vitamin B₁₂ deficiency and folate deficiency
 - >400 pg/mL: vitamin B₁₂ deficiency is unlikely; check RBC folate level
- RBC folate level: low in folate deficiency
- If the above testing does not reveal an obvious diagnosis, consider further testing:
 - Comprehensive metabolic panel to look for liver and kidney disease, hemolysis, hematologic malignancies or disorders
 - Thyroid-stimulating hormone to look for thyroid disorders
 - Bone marrow examination

ALERT

Coexistent microcytic anemias due to iron deficiency, thalassemias, and chronic disease can obscure the diagnosis of megaloblastic anemia by lowering the MCV. Hypersegmented neutrophils will still persist in the peripheral blood smear and aid in diagnosis.

Imaging

Diagnostic imaging with a barium study may be needed to rule out

gastrointestinal anomalies.

Diagnostic Procedures/Other

- Consider a referral to a hematologist for a bone marrow examination if the diagnosis remains unclear.
- Diagnostic testing for pernicious anemia may include the following:
 - Serum anti-IF antibodies, gastric parietal cell antibodies, pepsinogen (PG) I and II, gastrin
 - Schilling test

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for megaloblastic anemia is large and should include other causes of macrocytic anemia:

- Vitamin B₁₂ deficiency
- Folate deficiency
- Bone marrow disorders (e.g., myelodysplastic syndrome)
- Marked reticulocytosis
- Hemolytic anemia
- Hemorrhage
- Severe hyperglycemia
- Chronic alcohol abuse
- Chronic liver disease
- Hypothyroidism
- Splenectomy
- Chronic lung disease with hypoxia
- Heavy smoking
- Pregnancy
- Medications (as listed in “History”)
- Arsenic poisoning

TREATMENT

ALERT

It is imperative that vitamin B₁₂ deficiency is diagnosed correctly.

Treatment of undiagnosed vitamin B₁₂ deficiency with folate replacement

will not improve the neurologic deficits and may worsen the condition while improving the hematologic parameters.

MEDICATIONS

- Folate deficiency
 - Folic acid 1–5 mg PO daily for 1–4 months or until complete hematologic recovery occurs
 - Long-term treatment is not warranted except in certain cases of malnutrition or ongoing hemolysis.
- Several forms and administration regimens exist for vitamin B₁₂ deficiency:
 - Cyanocobalamin 1,000 mcg/day IM or SQ for 2–7 days based on clinical response, followed by 100 mcg weekly for 1 month, then monthly maintenance doses thereafter
 - Hydroxycobalamin 1,000 mcg IM every 1–3 months is also an effective therapy due to its long half-life in the tissues.
 - Oral cyanocobalamin 1,000–2,000 mcg/day for 1 month, followed by 125–150 mcg/day
 - In some cases, nasal and sublingual cyanocobalamin may also be useful in replenishing vitamin B₁₂ stores.
 - In the majority of patients (e.g., pernicious anemia), treatment is usually lifelong due to abnormal absorption.

ALERT

Hypokalemia associated with vitamin B₁₂ repletion can be life threatening. For severe anemia, a lower initial dose of cyanocobalamin of 0.2 mcg/kg/dose IM or SQ for 2 days followed by the above regimen(s) has been recommended. The clinician should anticipate this complication and provide a potassium supplement if needed.

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Metabolic abnormalities begin to normalize within the first 1–2 days following treatment with parenteral vitamin B₁₂.
- Reticulocytosis occurs about 3–4 days, peaking at 1 week, followed by a rise in hemoglobin within 10 days and a fall in MCV. The

hemoglobin will normalize by 8 weeks. A delayed response suggests the presence of an additional abnormality or an incorrect diagnosis.

- Hypersegmented neutrophils disappear at 10–14 days.
- During this period, the patient might note an improved feeling of well-being, long before there are any changes in the degree of anemia.
- Dementia and depression often respond to therapy, whereas other neurologic abnormalities improve gradually over a period of 6 months and may not return to normal.

PROGNOSIS

- In cases of dietary deficiencies, the prognosis is good.
- Inborn errors of metabolism with associated megaloblastic anemia generally has a poor outcome.

COMPLICATIONS

- Patients with severe anemia may have accompanying heart failure because of the anemia itself and myocardial hypoxia. However, due to its insidious onset, this is a rare finding in megaloblastic anemias.
- Neurologic complications from vitamin B₁₂ deficiency
- Concomitant folate deficiency can complicate the diagnosis of vitamin B₁₂ deficiency.

CODES

ICD10

- D53.1 Other megaloblastic anemias, not elsewhere classified
- D75.89 Other specified diseases of blood and blood-forming organs

- D51.8 Other vitamin B12 deficiency anemias

FAQ

- Q: What are the common dietary sources of vitamin B₁₂?
- A: Red meat, liver, seafood, chicken, dairy products, eggs
- Q: What are the common dietary sources of folate?
- A: Vegetables (especially green, leafy ones), legumes/beans, peanuts, liver. Since 1998, many grain food products have been fortified with folate in the United States and Canada, including breads, cereals, flours, pastas, and rice.

MENINGITIS

Ross Newman • Jason Newland

BASICS

DESCRIPTION

Inflammation of the membranes of the brain or spinal cord, usually caused by viruses or bacteria and, rarely, fungi or parasites

EPIDEMIOLOGY

- Bacterial meningitis
 - Most common agents in children of all ages include *Streptococcus pneumoniae* and *Neisseria meningitidis*.
 - Underlying host factors, age, exposure, and geographic location alter incidence and pathogen.
- Viral meningitis
 - Most common agent in all age groups
 - Most common isolated virus are enteroviruses that tend to occur in outbreaks in summer and early fall.
- Fungal meningitis
 - *Cryptococcus neoformans* is a budding encapsulated yeast-like organism found in soil and avian excreta; associated with immunocompromised patients (especially AIDS), rare cases in healthy children
 - *Candida* species occurs in immunocompromised patients and ill premature infants.
- Tuberculous meningitis
 - *Mycobacterium tuberculosis* (TB) meningitis occurs in 0.5% of untreated primary TB infections.
 - Most common in children aged 6 months to 4 years
 - In ~50% of cases, miliary TB is accompanied by meningitis.

GENERAL PREVENTION

- *Haemophilus influenzae* type b (Hib) vaccine has significantly reduced the incidence of meningitis and other invasive Hib infections by up to

99%.

- 13-valent *S. pneumoniae* protein conjugate vaccine (PCV13) for use in all infants given at 2, 4, 6, and 12–15 months of age
- A tetravalent meningococcal vaccine (MCV4) is recommended for all patients ≥ 11 years of age and select at-risk populations < 11 years. A booster dose is recommended for all patients who receive the first dose of the vaccine between 11 and 15 years of age.

ETIOLOGY

- Bacterial
 - Cause differs depending on age:
 - < 1 month old: group B *Streptococcus*, gram-negative pathogens (*Escherichia coli*, *Citrobacter koseri*, *Cronobacter sakazakii*, *Serratia marcescens*, and *Salmonella* species), *Listeria monocytogenes*, *S. pneumoniae*
 - 1–3 months old: group B *Streptococcus*, *E. coli*, *S. pneumoniae*, Hib
 - 3 months to 5 years old: *S. pneumoniae*, *N. meningitidis*, Hib
 - > 5 years old: *S. pneumoniae*, *N. meningitidis*
 - Consider Hib in unvaccinated patients of any age.
- Viral
 - Herpes simplex virus (HSV) in the neonatal population
 - Enteroviruses: ~ 70 different strains that include polioviruses, coxsackie A, coxsackie B, and echoviruses. Recently discovered enteroviruses are not placed in these 4 groups but are numbered (e.g., enterovirus 68).
 - Other, less common: arboviruses (e.g., West Nile virus), mumps
- Fungal
 - Fungi most commonly isolated include *Candida* species, *Coccidioides immitis*, *Cryptococcus neoformans*, and *Aspergillus* species.
- Aseptic meningitis
 - Agents not easily cultured in the viral or microbiology laboratory can cause meningitis and include *Borrelia burgdorferi* (Lyme disease) and *Treponema pallidum* (syphilis).
- Tuberculous meningitis

- Unusual pathogens more likely in immunocompromised patients

DIAGNOSIS

- Age-specific
- Pain
- Fever
- Nausea and/or vomiting

HISTORY

- Bacterial meningitis
 - Older children may complain of classic meningeal inflammation signs including neck pain, headache, or back pain as well as photophobia, anorexia, and myalgias.
 - Nausea and vomiting are common.
 - In younger children, symptoms are often nonspecific, including fever, hypothermia, irritability, and poor feeding as well as signs of increased intracranial pressure, including seizures and apnea.
 - Attention should be noted to the patient's immunization status, birth history, travel history, trauma, health status, geographic location, and exposure to high-risk contacts.
 - Common chief complaints by the infants' caregivers include the following:
 - Irritable or "sleeping all the time"
 - "Won't take to bottle"
 - "Not acting right"
 - "Cries when moved or picked up"
- Viral meningitis
 - Headache and fever may precede signs of meningitis, such as stiff neck, vomiting, and photophobia.
 - Duration 2–6 days
- Fungal meningitis
 - Cryptococcal meningitis is often indolent, with complaints of worsening headaches and vomiting for days to weeks.
 - Exposure to pigeon or other bird droppings can be a valuable clue.

- Tuberculous meningitis
 - Symptoms are often nonspecific initially, with personality changes, fever, nausea, and vomiting progressing to anorexia, irritability, and lethargy (stage I disease).
 - Stage II disease is characterized by focal neurologic signs (most often involving the cranial nerves III, VI, and VII).
 - Stage III disease is characterized by coma and papilledema.

PHYSICAL EXAM

- Stiff neck in older children. Infants have poor neck muscle tone and this finding is commonly absent.
- Brudzinski and Kernig signs may be present.
 - Brudzinski sign: With the patient supine, flexion of the neck elicits involuntary flexion of the hips or knees.
 - Kernig sign: With the patient supine, the legs are flexed 90 degrees at the hip, extensions of the lower legs are unable to be accomplished beyond 135 degrees.
 - Negative Brudzinski or Kernig sign does not rule out meningitis.
- Younger children may not have nuchal rigidity and Kernig and/or Brudzinski signs.
- Any infant presenting with a sepsis-like picture needs to have meningitis as a consideration.
- Classically, there may be “paradoxical” crying—crying that increases when child is picked up.
- Signs of increased intracranial pressure, including papilledema, asymmetric pupils, bulging fontanelle, diplopia
- Skin exam for erythema migrans from borreliosis (Lyme disease), petechiae, or purpura with invasive meningococcal disease or vesicles in an infant <6 weeks old with HSV

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CSF analysis (cell count with differential, protein measurement, glucose concentration, and measurement of pressure)
- CSF gram stain and culture
- Blood culture

- CBC, platelet count, electrolytes, BUN, creatinine, serum glucose,
- Consider prothrombin time (PT), partial thromboplastin time (PTT), liver function tests, arterial blood gas

Diagnostic Procedures/Other

- Lumbar puncture
 - Contraindicated with cardiopulmonary compromise, uncorrected coagulopathy, signs of increased intracranial pressure, or focal neurologic findings until head imaging can be obtained
- If no etiology is discovered after the first lumbar puncture and the child is not responding to therapy, repeat lumbar puncture at 36–48 hours.
- Opening pressure: normal is <200 mm H₂O in lateral recumbent position
- Depending on the presentation, age, history, and physical exam findings, some or all of the following tests should be requested for CSF analysis:
 - Cell count with differential and Gram stain
 - Bacterial meningitis is characterized by CSF pleocytosis ($>1.0 \times 10^3/\mu\text{L}$) with predominance of neutrophils. Culture is the gold standard for diagnosis.
 - Viral meningitis typically has a lower CSF cell count ($0.05\text{--}0.5 \times 10^3/\mu\text{L}$) compared to bacterial meningitis with a predominance of lymphocytes.
 - Glucose: Compare with serum glucose; normal is >40 mg/dL or 1/2–2/3 of the serum glucose.
 - Protein: normal is 5–40 mg/dL except in newborns, who may have protein levels of 150–200 mg/dL
 - >1.0 g/dL in bacterial meningitis and normal to slightly elevated in viral meningitis
 - Cultures for bacteria, fungi, virus, and mycobacteria
 - 80% of blood cultures are positive in children with bacterial meningitis.
 - Polymerase chain reaction (PCR) analysis for enterovirus, TB, HSV, Epstein-Barr virus
 - *B. burgdorferi* PCR for CSF samples has a diagnostic yield as low as 17%. Antibody studies for neuroborreliosis are

recommended.

DIFFERENTIAL DIAGNOSIS

- Encephalitis
- Toxic encephalopathy
- Epidural abscess
- Cerebral abscess

TREATMENT

GENERAL MEASURES

- Ensure adequate ventilation and cardiac function.
 - Circulation, airway, breathing (CABs)
- Initiate hemodynamic monitoring and support by achieving venous access and treat shock syndrome, if present.
- Prompt initiation of appropriate antimicrobials
 - If a lumbar puncture cannot be obtained or is contraindicated, a blood culture should be obtained and antimicrobials initiated immediately.
- Monitor serum sodium concentrations because syndrome of inappropriate ADH secretion (SIADH) is a frequent complication during the first 3 days of treatment.
- Steroids should be used in the initial therapy of TB meningitis along with anti-TB medication.
- Steroids are indicated for Hib meningitis and can be considered in *S. pneumoniae* meningitis; has been shown to decrease hearing loss and neurologic sequelae but not overall mortality. Consult ID expert for use.
 - If giving steroids, use dexamethasone 0.6 mg/kg/24 h divided into 4 doses and given for 4 days. The first dose should be given before or with the first dose of antibiotic.

MEDICATION

- Antimicrobial agents
 - <1 month of age: ampicillin IV 200–300 mg/kg/24 h divided q6–12h based on postnatal age and weight. If <7 days of age, 200

- mg/kg/24 h divided q8h; if >7 days of age, ampicillin 300 mg/kg/24 h divided q6h and cefotaxime IV 200–300 mg/kg/24 h divided q6h
- >1 month of age: vancomycin IV 60–80 mg/kg/24 h divided q6h; cefotaxime IV 300 mg/kg/24 h divided q6h or ceftriaxone 100 mg/kg/24 h divided q12h (should not be used in infants <2 months of age)
 - Vancomycin IV 60–80 mg/kg/24 h divided q6h should be considered in a patient of any age suspected of *S. pneumoniae*.
 - Alternative therapy for penicillin- or cephalosporin-allergic patients can include carbapenem or a quinolone in addition to vancomycin. Infectious disease specialist input should be considered.
 - Fungal meningitis
 - Amphotericin B with or without 5-flucytosine
 - Tuberculous meningitis
 - Treatment is generally with 4 drugs for 2 months followed by 2 drugs for 10 months.
 - Initially, treat with isoniazid, rifampin, pyrazinamide, and streptomycin.
 - Viral meningitis
 - Enterovirus: supportive care
 - HSV: acyclovir 60 mg/kg/24 h IV divided q8h

ALERT

- Remember that in tuberculous meningitis, up to 50% of children will not react to the 5-tuberculin unit Mantoux tests. Therapy should be started if suspicious; do not rely on the skin testing.
- With the potential for resistant *S. pneumoniae*, vancomycin and cefotaxime or ceftriaxone should be used until antibiotic susceptibility data are available.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Neonatal HSV meningitis should be evaluated with a repeat CSF HSV DNA PCR at day 21 and therapy extended if the PCR remains positive.

- Prophylaxis in Hib:
 - Oral rifampin (20 mg/kg/dose, maximum 600 mg/24 h for 4 days) should be given to all household contacts if 1 member is <4 years of age and is unvaccinated.
- Prophylaxis in N. meningitidis:
 - Oral rifampin (10 mg/kg/dose, maximum 600 mg b.i.d. for 2 days) for all household contacts, day care contacts, and other persons with close contact 7 days prior to onset of illness

Patient Monitoring

- Most children with bacterial meningitis become afebrile by 7–10 days after starting therapy, with gradual improvement in activity with less irritability.
- Evaluation for neurologic sequelae, such as hearing and vision testing, is essential.

PROGNOSIS

- Bacterial meningitis
 - Fatality approaches 100% if untreated.
 - ~500–1,000 deaths each year, or 5–10% of cases
 - Hearing deficits and neurologic damage may occur in up to 30% of children.
- Viral meningitis
 - Prognosis for enteroviral meningitis is good.
- Aseptic meningitis
 - Lyme disease: Prognosis with diagnosis and treatment is good.
- Tuberculous meningitis
 - The long-term prognosis in children with tuberculous meningitis depends on the stage of disease in which treatment is begun.
 - Complete recovery occurs in 94% of those whose treatment was started in stage I but only 51% and 18% for those whose treatment began in stage II or stage III, respectively.

COMPLICATIONS

- Bacterial meningitis
 - Acute complications: SIADH and seizures occur in up to 1/3 of patients, focal neurologic signs occur in 10–15%.

- Long-term complications: neurocognitive defects, hearing defects (most common morbidity among survivors)
- Viral meningitis
 - Acute complications: SIADH in 10%
 - Long-term complications: Complications from viral meningitis are rare. However, neonates (<1 month of age) may develop severe enterovirus disease and older agammaglobulinemic children may develop chronic enterovirus meningoencephalitis.
- Tuberculous meningitis
 - Acute complications: most common are cranial nerve findings, especially 6th cranial nerve palsy affecting the eyes; hydrocephalus
 - Long-term complications: many, including blindness, deafness, and mental retardation

- G00.9 Bacterial meningitis, unspecified
- A87.9 Viral meningitis, unspecified

FAQ

- Q: Is a lumbar puncture required before starting antibiotics in the

patient with suspected meningitis with unstable vital signs requiring resuscitation?

- A: No. In the unstable patient, it is contraindicated to perform a lumbar puncture. Appropriate IV antibiotics should be started. When resuscitated, a lumbar puncture should be performed.

MENINGOCOCEMIA

Andrew P. Steenhoff

BASICS

DESCRIPTION

- A systemic infection with the bacterium *Neisseria meningitidis*, a gram-negative diplococcus that is relatively fastidious. Despite treatment with appropriate antibiotics, this disease may have a fulminant course (i.e., significant complications within hours of presentation) with a high likelihood of mortality.
- 13 serogroups have been described on the basis of capsular polysaccharide antigens; serotypes B, C, and Y account for most of the cases in the United States. Serogroup Y accounted for 30% of cases between 1996 and 1998.

GENERAL PREVENTION

- Isolation of the hospitalized patient; hospitalized patients require respiratory isolation until 24 hours after initiation of appropriate antibiotic therapy.
- Exposed contacts, including household, day care, and nursery school, should receive the following:
 - Rifampin, 10 mg/kg (maximum 600 mg) PO q12h for 4 doses
 - Contacts <1 month of age should receive rifampin 5 mg/kg PO q12h for 4 doses.
 - Alternatively, ceftriaxone is also effective prophylaxis for contacts ≤15 years of age; a single dose of 125 mg IM is recommended.
 - For contacts >15 years old, ceftriaxone 250 mg IM is recommended. Its safety profile is preferred for pregnant women.
- Medical personnel should receive prophylaxis only if they had close contact with respiratory secretions.
- Vaccines for types A, C, Y, and W-135 are available and produce an immune response in 10–14 days.
- A tetravalent conjugate meningococcal vaccine, MCV4, is licensed for use in people in the age range of 2–55 years. It is recommended in all

unimmunized 11–12-year-old adolescents, with a booster dose at age 16 years.

- Serotype B vaccine was recently approved by the FDA and is licensed for use in people 10–25 years of age.
- The Centers for Disease Control and Prevention (CDC) continues to recommend routine adolescent immunization with the exception of persons with a history of Guillain-Barré syndrome (GBS) who are not in a high-risk group for invasive meningococcal disease. An updated fact sheet on GBS and MCV4 is available at <http://www.cdc.gov/vaccinesafety/Concerns/gbsfactsheet.html>. A study published in 2012 did not support an association between GBS and MCV4 vaccination.

EPIDEMIOLOGY

- The rates of meningococcal disease in the United States have remained stable at 0.9–1.5 cases per 100,000 population per year.
- Children <5 years of age are most often affected, with peak incidence between 3 and 5 months of age.
- During epidemics, more school-aged children may be affected.
- The disease occurs most commonly in winter and spring months.
- Increased disease activity may follow an influenza A outbreak.

RISK FACTORS

- Patients with asplenia, deficiencies of properdin C3, or a terminal complement component (C5–C9), and HIV are at increased risk for invasive and recurrent disease.
- Organism virulence factors, such as differences in the bacterial cell wall lipopolysaccharide, play a role in disease severity. Less virulent organisms are more likely in chronic meningococcemia, which has a favorable prognosis.

Genetics

- Inherited deficiency of terminal complement may be found in 5–10% of patients during epidemics. The frequency increases to 30% in patients with recurrent disease.
- A number of other immune function–related genes associated with either susceptibility or protection from infection have been identified.

PATHOPHYSIOLOGY

- Fulminant disease is signified by diffuse microvascular damage and disseminated intravascular coagulation (DIC); see “[Diagnosis](#)” section.
- Death results from effects of endotoxic shock, including circulatory collapse and myocardial dysfunction.

ETIOLOGY

- Colonization and infection of the upper respiratory tract occurs after inhalation of, or direct contact with, the organism, usually in oral secretions.
- Disseminated disease occurs when the organism penetrates the nasal mucosa and enters the bloodstream, where it replicates.

DIAGNOSIS

SIGNS AND SYMPTOMS

- Fever
- Malaise
- Rash
- Petechiae
- Tachycardia
- Delayed capillary fill
- Abnormal mental status
- Bacteremia without sepsis presents with fever, malaise, myalgias, and headache. Patients may clear the infection spontaneously or it may invade meninges, joints, lungs, and so forth.
- Meningococcemia without meningitis occurs after initial bacteremia with systemic sepsis. A rash erupts, which may be nonspecific maculopapular, morbilliform, or urticarial. Progression to petechiae or purpura signifies evolution of disease.
- Fulminant disease can manifest within 1–2 hours of onset of signs or symptoms and is signified by hypotension, oliguria, DIC, myocardial dysfunction, and vascular collapse. Death occurs in 15–20% of these patients.

HISTORY

Time of onset of fever, malaise, and rash

PHYSICAL EXAM

- Physical examination of a child with fever should include careful evaluation of the skin for petechiae and signs of early shock (tachycardia, delayed capillary refill, abnormal mental status, etc.).
- Recognition of abnormal vital signs and lethargy is necessary.
- Nuchal rigidity, lethargy, and irritability should be carefully but expeditiously evaluated.

DIAGNOSTIC TESTS & INTERPRETATION

The organism can be cultured from blood, CSF, and skin lesions.

Lab

- Gram stain of CSF or scraped petechial lesion (pressed against a glass slide) revealing gram-negative diplococci will give a presumptive diagnosis.
- Rapid test for antigen detection
 - Supports diagnosis if found in CSF but not sensitive for serogroup B
- CBC
 - One study showed that 94% of children show abnormalities in 1 or more of the following parameters: abnormalities in absolute neutrophil count ($\leq 1,000/\text{mm}^3$ or $\geq 10,000/\text{mm}^3$), immature neutrophil count ($\geq 500/\text{mm}^3$), and/or immature-to-total neutrophil ratio (≥ 0.20).

Diagnostic Procedures/Other

Lumbar puncture: antigen detection although culture remains the gold standard

DIFFERENTIAL DIAGNOSIS

- Meningitis due to *N. meningitidis* is indistinguishable from that of other causes, except for 1/3 of children who have a petechial rash.
- Sepsis from other microbial causes (e.g., *Streptococcus*, Rocky Mountain spotted fever, viruses) may have a very similar clinical presentation, including the petechiae or purpuric rash.

TREATMENT

GENERAL MEASURES

- Because of the rapidly progressing nature of meningococemia in some, patients with acute onset of petechial rash and fever should receive a prompt initial dose of antibiotics (if possible and practical, after blood culture or lumbar puncture).
- Close monitoring of vital signs and clinical status should follow, preferably in an ICU setting.

MEDICATION

- Cefotaxime or ceftriaxone can be initiated as presumptive therapy. After sensitivity is confirmed, penicillin is preferred.
- After isolate is proven sensitive to penicillin, treatment of choice is aqueous penicillin G IV at a dose of 300,000 IU/kg/24 h q4–6h (max, 12 million U/24 h) for 5–7 days.
- In penicillin-allergic patients, 3rd-generation cephalosporins, or chloramphenicol are acceptable alternatives.

ISSUES FOR REFERRAL

Public health officials should be notified of *N. meningitidis* cases.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Patients with bacterial meningitis should have a hearing test as a follow-up.

PROGNOSIS

- Fatality rate of meningococemia is 15–20%, even when recognized and treated.
- Fatality rate of meningococcal meningitis is 5%. The most severe cases often have a rapid progression from onset of symptoms to death over a matter of hours. At the time of hospital admission, the following signs predict poor survival:

- Lack of meningitis
- Shock
- Coma
- Purpura
- Neutropenia
- Thrombocytopenia
- DIC
- Myocarditis

COMPLICATIONS

- Complications may result directly from the infection or be classified as allergic immune complex mediated.
- Meningococcemia may be complicated by myocarditis, arthritis, hemorrhage, and pneumonia; digit or limb amputation, and skin scarring.
- Meningococcal meningitis is most commonly complicated by deafness in 5–10% of survivors.
- Other complications of meningitis include seizures, subdural effusions, and cranial nerve palsies.
- Immunologic complications include arthritis, vasculitis, pericarditis, and episcleritis.

- A39.2 Acute meningococcemia

FAQ

- Q: How long should antibiotic therapy be given to a patient with septic shock?
- A: 7 days
- Q: Is MCV4 meningococcal vaccine indicated for all adolescents?
- A: Yes, MCV4 is now recommended in all previously unimmunized adolescents at the doctor visit from 11 to 12 years or at high school entry, whichever comes first. A booster dose is recommended at age 16 years.
- Q: How does 1 approach MCV4 immunization of adolescents who previously received MPSV4?
- A: If 3–5 years have elapsed since their MPSV4 vaccination, then MCV4 immunization is indicated.
- Q: When should 1 test for complement deficiency?
- A: In patients with recurrent disease
- Q: Which hospital personnel should receive prophylaxis?
- A: Only those with direct exposure to index patient's secretions.

MESENTERIC ADENITIS

Adrienne M. Scheich

BASICS

DESCRIPTION

Mesenteric adenitis is defined as inflammation of the mesenteric lymph nodes. The inflamed nodes are usually clustered in the right lower quadrant (RLQ) small bowel mesentery or are located ventral to the psoas muscle.

EPIDEMIOLOGY

- Age related, most common in patients <15 years of age
- Affects males and females equally
- History of recent sore throat or upper respiratory tract infection found in 20–30% of subjects
- Most common cause of acute abdominal pain in young adults and children
- Self-limiting condition
- Most common cause of inflammatory adenopathy (more common than tuberculosis)
- Mesenteric adenitis in childhood is related to a decreased risk of ulcerative colitis in adulthood.

PATHOPHYSIOLOGY

- Lymph nodes involved are those draining the ileocecal area. Lymph nodes absorb toxic products or bacterial products secondary to stasis.
- Nodes are enlarged up to 10 mm; discrete, soft, and pink; and with time become firm. Calcification and suppuration are rare.
- Cultures of the nodes are negative.
- Reactive hyperplasia: Adenitis results from a reaction to some material absorbed from the small intestine, reaching the intestine from the blood or lymphatic system.
- Hypersensitivity reaction to a foreign protein

ETIOLOGY

- Viral
 - Adenovirus, echovirus 1 and 14, coxsackieviruses, Epstein-Barr virus (EBV), cytomegalovirus (CMV), human immunodeficiency virus (HIV)
- Bacterial
 - Tuberculosis, Streptococcus species, Staphylococcus species, Escherichia coli, Yersinia enterocolitica, Bartonella henselae (cat-scratch disease)

DIAGNOSIS

Can be difficult to differentiate from acute appendicitis clinically, and many patients may undergo laparotomy before diagnosis

HISTORY

- Abdominal pain
 - Dull ache as well as colicky pain occurs due to stretch on the mesentery.
 - May initially be in the upper abdomen/RLQ or generalized
 - If generalized, eventually becomes localized to RLQ
 - Patients often have difficulty localizing the exact point of the most intense pain, in contrast to appendicitis, where pain is often localized to RLQ.
- Intermittent spasms: Between spasms, the patient feels well.
- Signs and symptoms:
 - Abdominal pain (RLQ)
 - Anorexia and fatigue are common.
 - Nausea and vomiting usually precede abdominal pain.
 - Fever
 - Diarrhea

PHYSICAL EXAM

- Often febrile to $>38^{\circ}\text{C}$ (100.4°F)
- May have associated upper respiratory tract infection symptoms, such as rhinorrhea or hyperemic pharynx

- Presence of peripheral lymphadenopathy
- Abdominal examination
 - Tenderness of the RLQ: may be a little higher, more medial, and less severe than acute appendicitis
 - Point of maximal tenderness may vary from one examination to the next.
 - Voluntary guarding with or without rebound tenderness and without rigidity
- Rectal tenderness

DIAGNOSTIC TESTS & INTERPRETATION

- Mesenteric adenitis is a diagnosis of exclusion.
 - It can only be diagnosed accurately at laparoscopy or laparotomy.
 - Ultrasound or CT scan may demonstrate enlarged mesenteric lymph nodes.
- See “[Differential Diagnosis](#).”

Lab

Complete blood count and C-reactive protein may be increased but are not specific.

Imaging

- Abdominal ultrasound
 - Differentiates among acute appendicitis, pelvic inflammatory disease, ovarian pathology, and mesenteric adenitis
- Contrast-enhanced CT scan of the abdomen and pelvis shows enlarged mesenteric lymph nodes, with possible ileal or ileocecal wall thickening, normal appendix
- MRI

Diagnostic Procedures/Other

- Laparoscopic surgery
- Laparotomy

DIFFERENTIAL DIAGNOSIS

- Infection
 - Acute appendicitis: 20% of patients treated for possible acute appendicitis had mesenteric adenitis.

- Infectious mononucleosis: associated lymphadenopathy more generalized
- Associated splenomegaly: can screen for positive EBV titers
- Tuberculosis: associated intestinal involvement, positive purified protein derivative (PPD) test, elevated erythrocyte sedimentation rate (ESR)
- Pelvic inflammatory disease: should be considered in sexually active adolescents, and pelvic exam may be helpful
- Urinary tract infections/pyelonephritis: Urinalysis and urine culture are helpful.
- Abscess: related to missed acute appendicitis or inflammatory bowel disease (IBD)
- *Y. enterocolitica* infection: bloody diarrhea, arthropathy present; stool culture is diagnostic.
- Typhlitis: Transmural inflammation of the cecum is seen in patients with neutropenia
- Tumors
 - Lymphoma: Adenopathy can be more generalized.
 - CT scan of the abdomen and/or laparotomy to confirm the diagnosis
- Trauma
 - Hematomas of the abdominal wall and intestines
 - History of trauma
- Metabolic
 - Acute intermittent porphyria
 - Cyclic episodes of acute abdominal pain and vomiting
 - Appropriate metabolic workup diagnostic
- Congenital
 - Duplication cysts: may present with abdominal pain due to rupture, bleeding, intussusception, or volvulus
 - Meckel diverticulum: may present with diverticulitis or act as a lead point for intussusception
- Miscellaneous
 - Crohn disease: associated mesenteric adenitis and intestinal involvement
 - Intussusception: acute abdominal pain with “currant jelly” stools;

barium/air enema is diagnostic and therapeutic.

- Ovarian cysts: may need abdominal/pelvic ultrasound to differentiate between the two
- Chronic mesenteric ischemia

TREATMENT

Most patients recover completely without any specific treatment.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Watch for

- Increasing abdominal pain
- Vomiting
- Fevers
- Toxic appearance
- Severe tenderness that is persistent
- Guarding
- Rigidity
- Decreasing bowel sounds

PROGNOSIS

- Most patients recover completely without any specific treatment.
- When to expect improvement: Acute symptoms may take days to resolve and generally last a few days after the associated viral symptoms have resolved.

COMPLICATIONS

- Suppuration
- Intussusception (enlarged lymph nodes can be a lead point for intussusception)
- Rupture of lymph nodes
- Abscess formation

- Peritonitis
- Death (very rare) from abscess and peritonitis

CODES

ICD10

I88.0 Nonspecific mesenteric lymphadenitis

FAQ

- Q: Can one differentiate clinically between acute appendicitis and nonspecific mesenteric adenitis?
- A: Yes, but the differences can be subtle. Patients with nonspecific

mesenteric adenitis generally cannot localize the exact point of the most intense pain, unlike those with appendicitis, who can localize their pain to the RLQ. Abdominal examination in patients with mesenteric adenitis is characterized by increased tenderness of the RLQ that is a little higher, more medial, and less severe than that in acute appendicitis. Point of maximal tenderness may vary between examinations in patients with nonspecific mesenteric adenitis. There is no rigidity on abdominal examination in patients with nonspecific mesenteric adenitis. However, it is clinically difficult to differentiate the two entities.

- Q: Which investigations can be diagnostic for RLQ pain?
- A: An ultrasound or CT scan of the RLQ can differentiate between acute appendicitis, ovarian pathology, and lymphadenopathy. An upper gastrointestinal series with small bowel follow-through or a magnetic resonance enterography study can be diagnostic for IBD.

METABOLIC DISEASES IN ACIDOTIC NEWBORNS

Leah Fleming • Hilary Vernon

BASICS

DESCRIPTION

- Metabolic acidosis is a common acute presentation of an inborn error of metabolism (IEM), particularly in the presence of elevated anion gap. Acidosis can also be seen as a result of hypoperfusion, congenital heart disease, sepsis, liver failure, toxic ingestion, and diabetic ketoacidosis (DKA).
- IEMs are generally defects of protein, fat, or carbohydrate metabolism or of the mitochondrial respiratory chain that result in either accumulation or deficiency of a metabolite.
- IEMs should be considered early in the workup of a child with metabolic acidosis in order to detect those conditions that are treatable prior to development of permanent neurologic sequelae. Sequelae can be related to duration and severity of exposure. Basic evaluation for IEMs should be undertaken concurrently with other diagnostic evaluations.

ALERT

Infants with IEMs are at increased risk for decompensation and acute presentation in cases of infection, fever, fasting, or other causes of catabolism.

RISK FACTOR

Genetics

Autosomal recessive with exception of pyruvate dehydrogenase deficiency (X-linked dominant), ornithine transcarbamylase (X-linked), and some diseases of the mitochondrial genome(maternally inherited).

GENERAL PREVENTION

- Avoid propofol if possible (anecdotal increase in pancreatitis).

- Avoid prolonged fasting or nutritional deprivation.
- Avoid use of systemic steroids whenever possible.

PATHOPHYSIOLOGY

Metabolic acidosis is often a downstream effect of the primary metabolic abnormality. A block in normal metabolism can result in dysfunction of the mitochondrial respiratory chain, buildup of toxic intermediates, disordered or reduced energy production, buildup of waste nitrogen in the form of ammonia and specific amino acids, and through conjugation of the acids with carnitine, lead to carnitine depletion. These events can lead to multi-organ dysfunction including the following:

- CNS toxicity: edema, neurologic effects of hypoglycemia, toxic encephalopathy
- Cardiac: arrhythmias, left ventricular noncompaction, cardiomyopathy
- Liver: hepatosplenomegaly, elevation of liver function tests, prolonged hyperbilirubinemia
- Hematologic: bone marrow suppression
- Renal: proximal tubule dysfunction, kidney failure (later onset)

ETIOLOGY

Multifactorial. Primary metabolic disease is typically due to a genetic defect that causes a block in metabolism resulting in buildup of toxic intermediates or absence/reduction of necessary downstream products.

COMMONLY ASSOCIATED CONDITIONS

- Maternal HELLP, fatty liver of pregnancy, preeclampsia: associated with specific fetal disorders of fatty acid oxidation
- Metabolic stroke: stroke affecting the basal ganglia (not ischemic or hemorrhagic in character)

DIAGNOSIS

HISTORY

- Pregnancy history: maternal hypertension, elevated liver enzymes, low platelets (HELLP) syndrome; acute fatty liver of pregnancy; preeclampsia; reduced fetal movements; IUGR; fetal bradycardia

- Family history of consanguinity, siblings with unexplained severe childhood illness, sudden infant death syndrome (SIDS), developmental delay, Reye syndrome, or death
- Deterioration after a symptom-free interval (typically at least several days required for toxic metabolic buildup)
 - Classic presentation is of poor feeding, vomiting, and alterations in neurologic status (irritability, hypotonia, encephalopathy).
 - Without treatment, this will progress to lethargy, temperature instability, seizure, coma, and death.
- Diet history including frequency of feeds, vigor, whether breast milk or formula and, if formula, the type of formula (low protein may delay onset of symptoms)
- Fits, cycling movements
- Associations with IEMs
 - Gram-negative sepsis (galactosemia)
 - Cerebral or pulmonary hemorrhage (urea cycle disorder)
 - Severe, prolonged, unexplained hypoglycemia in term neonate (suggests organic acidemia or defect of gluconeogenesis)
 - Mild respiratory alkalosis (hyperammonemia)
 - Ketosis (organic acidemia, congenital lactic acidosis)
 - Coagulopathy, jaundice (mitochondrial, hemochromatosis, fatty acid oxidation disorders, hereditary fructose intolerance, tyrosinemia, galactosemia)

PHYSICAL EXAM

- Vital signs: tachypnea, hypotension. Look for Cushing triad.
- General
 - Dysmorphic features (may be present in mitochondrial and peroxisomal disorders and some fatty acid oxidation disorders)
- HEENT: bulging fontanelle (cerebral edema), maple syrup urine disease (MSUD)
- Eye: cataracts, dislocated lens, corneal clouding, retinal changes
- Skin: jaundice, rashes
- Cardiac
 - Cardiomyopathy (fatty acid oxidation, propionic acidemia), pericardial effusion (congenital disorder of glycosylation),

cardiomegaly

- Respiratory: tachypnea, Kussmaul breathing, apnea
- Hepatosplenomegaly (disorders of gluconeogenesis, storage disorders, galactosemia)
- Neurologic: reflexes, tone, seizure
- Odor
 - Sweet: MSUD (urine and ear cerumen)
 - Sweaty feet: isovaleric acidemia
 - Fruity: methylmalonic acidemia, propionic acidemia
 - “Tom Cat” urine odor: multiple carboxylase deficiency
- Growth parameters
 - Typically normal in newborn period but may have IUGR or delayed return to birth weight (BW)

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Initial evaluation (concurrently with sepsis evaluation)
 - Complete blood count with differential
 - Blood gas including pH and lactate
 - Serum urea, creatinine, glucose, electrolytes (anion gap), AST, ALT
 - Ammonia (place on watery ice, run immediately)
 - Creatine kinase
 - CRP
 - Urinalysis, urine-reducing substance
 - Obtain copy of newborn screen report.
- CSF: if obtained in course of complete sepsis evaluation
 - Consider freezing a tube for later use.
 - May send lactate, lactate-to-pyruvate ratio
- Should be sent for definitive diagnosis:
 - Plasma amino acids (PAA), acylcarnitines, urine organic acids, urine orotic acid (if ammonia is elevated), urine ketones
- Treatment should not be delayed in the case of presumptive IEM.
- In case of death, obtain the following:
 - Urine: deep frozen
 - Blood: EDTA for DNA analysis
 - Skin: sterile, for fibroblast culture; store at 4–8°C

- Liver, muscle: snap frozen
- CSF if possible (for amino acids and neurotransmitters)
- Plasma: heparinized
- Blood spot: for acylcarnitine profile

Imaging

- Echocardiogram to evaluate for structural heart disease and cardiac function
- Consider head ultrasound (ventriculomegaly seen in pyruvate dehydrogenase complex deficiency)

Diagnostic Procedures/Other

- Ammonia ($>200 \mu\text{mol/L}$) very strongly implies metabolic disease. Up to $65\text{--}100 \mu\text{mol/L}$ is normal in a healthy neonate.
- Calculate anion gap: High anion gap implies excessive acid production or retention.
- If not previously performed, secondary testing should include acylcarnitine profile, free fatty acids and 3-hydroxybutyrate, osmolality, plasma amino acids, lactate and pyruvate ratio, and urine organic acids.
- Ophthalmology exam
- Confirmatory testing is by specific enzyme analysis or genetic testing.

DIFFERENTIAL DIAGNOSIS

In neonates, inborn errors of metabolism present with similar symptoms and can easily be confused with other serious diseases.

- Sepsis
- Birth asphyxia
- Ductal-dependent congenital heart disease
- Neonatal withdrawal syndrome
- Endocrine abnormalities (adrenal insufficiency)
- IEM resulting in metabolic acidosis can be divided into the lactic acidoses, those that cause a ketoacidosis, and the organic acid disorders.
 - Lactic acidosis
 - Pyruvate dehydrogenase deficiency
 - Pyruvate carboxylase deficiency

- Phosphoenolpyruvate carboxykinase deficiency
- Defects in tricarboxylic acid cycle enzymes
- Mitochondrial diseases or other conditions affecting oxidative phosphorylation
- Severe disorders of gluconeogenesis (e.g., glucose-6-phosphatase deficiency)
- Multiple carboxylase deficiency, biotinidase deficiency
- Disorders of fatty acid oxidation
- Ketoacidosis
 - Disorders of ketone use (e.g., β -ketothiolase deficiency)
 - Ketosis can also occur in lactic acidosis syndromes (above) and organic acidemias (below).
- Other organic acid disorders
 - MSUD
 - Branched-chain organic acidurias (methylmalonic acidemia, propionic acidemia, isovaleric acidemia)
 - Others: In some cases, other abnormalities (e.g., lethargy, hyperammonemia) may occur prior to severe acidosis.

TREATMENT

GENERAL MEASURES

- Stop feeding.
- Provide 6–10 mg/kg/min dextrose (typically as D10 at twice maintenance).
 - If considering pyruvate dehydrogenase deficiency, use lower dextrose infusion rate, typically D5.
- Admit to intensive care unit.
- Consult biochemical genetics team.
- Consider early continuous venovenous hemodialysis to remove toxin and decrease ammonia. Peritoneal dialysis is less effective but can be used.
- Correct hypothermia, dehydration, electrolyte disturbance, etc.
- Consider sodium bicarbonate.
 - Start at 1 mEq/kg.

- Often, the patient will require large doses due to ongoing acid production.
- Insulin as needed for iatrogenic hyperglycemia.
- Resume nutritionally complete feeding as soon as possible under guidance of biochemical genetics team. This may include specialized iTPN or formula.

ADDITIONAL THERAPIES

- Nitrogen scavenger such as sodium benzoate and sodium phenylacetate if urea cycle overwhelmed or primary urea cycle disorder
- Carnitine promotes excretion of organic acids. Administer 50 mg/kg/dose IV every 6 hours. Use is controversial in disorders of fatty acid oxidation; not to be used in LCHAD (theoretical arrhythmia risk)
- Specific supplementation
 - Biotin (holocarboxylase deficiency) 10 mg PO/NG
 - Hydroxocobalamin (cobalamin-responsive methylmalonic academia) 1 mg IM
 - Pyridoxine (pyridoxine-dependent seizure)
 - Pyridoxal phosphate (pyridoxine-5'-phosphate oxidase deficiency)
 - Glycine (isovaleric acidemia)
 - Nitroisoleucine (tyrosinemia)
 - Arginine (urea cycle)
 - Thiamine (MSUD, some forms of congenital lactic acidosis) 50 mg PO/NG daily to b.i.d.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Refer to a biochemical genetics team for ongoing evaluation and management.
- Generally, patients will require frequent monitoring in the newborn period and throughout life; however, this varies with the diagnosis.
- Specific treatment based on correct diagnosis of IEM

COMPLICATIONS

- Prognosis varies based on disease.
- For some disorders, appropriate treatment dramatically improves morbidity and mortality (especially the fatty acid oxidation disorders and vitamin responsive disorders); for others, there is improved survival but still significant morbidity.
- Long-term complications are becoming better understood with improved survival (e.g., risk of pancreatitis and renal failure in the branch chain acidurias). As in other chronic pediatric illnesses, such as diabetes, recurrent episodes are often triggered by stress, noncompliance, or illness and may increase in frequency during the teen years.
- Severity of neurologic complications increases with frequency and duration of episodes of metabolic decompensation and/or frequency and duration of elevated ammonia. Neurologic complications can include metabolic stroke (basal ganglia), herniation, seizure disorder, and intellectual impairment.
- There may be progressive impairment of the heart, liver, or kidney; chronic bone marrow suppression; as well as effects of malnutrition and hyperglycemia (due to frequent D10 infusions).

- E88.89 Other specified metabolic disorders

- E72.29 Other disorders of urea cycle metabolism

FAQ

- Q: What factors determine developmental outcome in children with inborn errors of metabolism?
- A: The specific diagnosis and patient mutation, how rapidly appropriate therapy is initiated, frequency of decompensating, and compliance with chronic management all contribute to developmental outcome.
- Q: If the newborn screen (NBS) was normal, can the infant still be affected by an IEM?
- A: Many IEMs are not included on the NBS, and there can also be false negatives.
- Q: Do IEMs only affect infants?
- A: No. An individual can present with an IEM at any point in his or her life, depending on the level of enzyme deficiency/threshold for catabolic stress.

METABOLIC DISEASES IN HYPERAMMONEMIC NEWBORNS

Stephan Siebel • Ada Hamosh

BASICS

DESCRIPTION

- Inborn errors of metabolism are inherited defects in biosynthesis, catabolism, or transport of lipids, amino acids, or carbohydrates. The first presentation of an inborn error of metabolism can be at any age, with most cases manifesting during states of metabolic catabolism and/or increased dietary intake of an offending metabolite.
- Clinical findings can range from acute life-threatening crises to milder, nonspecific clinical episodes of malaise, emesis, lethargy, anorexia, or even acute neuropsychiatric abnormalities.
- Some inborn errors of metabolism present with elevated levels of ammonia ($>100 \mu\text{M/L}$). Ammonia is highly neurotoxic, and elevated levels can lead to encephalopathy and death. Maintaining a high degree of clinical suspicion in sick neonates is essential.

EPIDEMIOLOGY

- Incidence and prevalence vary among different types of inborn errors of metabolism. Collectively, approximately 1 in 500 newborns are affected by one of the various inborn errors of metabolism.
- Estimated incidence of urea cycle defects is 1:18,000. Incidence of organic acidemias is 1:1,000 and of medium-chain acyl-CoA dehydrogenase (MCAD) deficiency ranges from 1:4,900 to 1:17,000.

RISK FACTORS

Genetics

Inheritance of most inborn errors of metabolism is autosomal recessive. Ornithine transcarbamylase deficiency (the most common urea cycle defect) is X-linked.

PATHOPHYSIOLOGY

- Nitrogen is an essential building block of amino acids and a major source of ammonia from protein degradation. Ammonia is highly toxic, especially to the central nervous system (CNS). A major mechanism for ammonia detoxification is the urea cycle, which converts ammonia in the liver to water-soluble urea. Urea is then excreted by the kidneys.
- Inborn errors of metabolism causing hyperammonemia interfere with urea cycle function, either directly through primary enzymatic defects of the urea cycle or indirectly, caused by liver failure, decreased production, increased use, or defective transport of a urea cycle intermediate as seen in aminoacidopathies, organic acidemias, fatty acid oxidation defects, and defective carbohydrate metabolism.

ETIOLOGY

Any biochemical defect that alters the amount of ammonia or that interferes with the detoxification of ammonia

DIAGNOSIS

HISTORY

- Evidence of systemic disease: A variety of systemic newborn illnesses, including sepsis, can be complicated by secondary hyperammonemia.
- Family history of poorly explained pediatric death, developmental disability, or neuropsychiatric disorders should raise suspicion for a genetic disorder, such as an inborn error of metabolism. Diagnoses to ask about:
 - Sepsis or recurrent infections (opportunistic organism or no organism identified)
 - Sudden infant death syndrome
 - Cardiomyopathy
 - Uncontrollable seizures
 - Coma
 - Liver failure
- Current diet and feeding schedule: In urea cycle defects, hyperammonemia is exacerbated by protein intake.

- Failure to wake and feed spontaneously is a sign of CNS dysfunction in neonates.
- Perinatal hypoxia can cause temporary liver dysfunction and reduced urea cycle capacity. Relative immaturity of the urea cycle can cause hyperammonemia in premature infants.

PHYSICAL EXAM

- ABCs and vital signs: Cushing triad (apnea, bradycardia, hypertension) should prompt immediate evaluation for elevated intracranial pressure, a complication of hyperammonemia.
- Head, eyes, ears, nose, and throat: macrocephaly, bulging fontanelle (elevated intracranial pressure)
- CVS: dilated or hypertrophic cardiomyopathy in some organic acidemias and fatty acid oxidation defects
- Respiratory: hyperpnea (rapid deep breathing that will lead respiratory alkalosis which is different from the rapid shallow breathing of transient tachypnea of the newborn)
- GI: Hepatomegaly occurs in some of these disorders (argininosuccinate lyase deficiency, fatty acid oxidation, galactosemia).
- Skin: Jaundice is not typical in urea cycle defects but occurs in other inborn errors of metabolism associated with hepatotoxicity.
- Neurologic: extrapyramidal signs, encephalopathy, myoclonic jerks, hyper-/hypotonia, obtundation, and coma

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Initial labs for a presumptive diagnosis in a patient with hyperammonemia:
 - Dextrose stick
 - Electrolytes, BUN, creatinine
 - CBC, blood culture, serum ketones
 - Blood gas with lactate
 - Liver function tests and PT/PTT
 - Urinalysis for ketones, reducing substances
 - Frequent ammonia levels (q4–12h), obtain as free-flowing samples, placed on wet ice and immediately transport to the lab for

processing

- Review state newborn screen.
- Suspected disorders and follow-up testing:
 - Urea cycle defects: plasma amino acids and urine orotic acid
 - Organic acidemias: urine organic acids, plasma amino acids, and acylcarnitine profile
 - Fatty acid oxidation defects: creatine phosphokinase, urine organic acids, plasma acylcarnitine profile
 - Galactosemia: urine galactitol, red blood cell galactose-1-phosphate uridyltransferase (GALT) activity
 - Open ductus venosus: low urea and glutamine
 - Definitive diagnosis may require enzyme testing or mutation analysis.

Imaging

Brain MRI/CT may show demyelination; circumscribed brain atrophy; cerebellar hypoplasia or aplasia, symmetric and/or fluctuation; and abnormalities of brainstem, basal ganglia, thalamus, and/or hypothalamus, especially in “cerebral” organic acidurias.

DIFFERENTIAL DIAGNOSIS

- Neonatal hyperammonemia not caused by inborn errors of metabolism
 - Sepsis or other severe illness
 - Liver failure (drugs, toxins, others)
 - Transient neonatal hyperammonemia (e.g., open ductus venosus)
 - Perinatal depression/hypoxia
 - Iatrogenic (valproic acid, asparaginase)
- Inborn errors of metabolism
 - Urea cycle defects (N-acetylglutamate [NAG] synthetase deficiency, carbamoyl phosphate synthase deficiency, ornithine transcarbamylase deficiency, argininosuccinate synthetase deficiency, argininosuccinate lyase deficiency)
 - Organic acidemias (isovaleric acidemia, propionic acidemia, methylmalonic acidemia, etc.)
 - Fatty acid oxidation defects (medium-chain acyl-CoA dehydrogenase deficiency, etc.)

- Hyperornithinemia, hyperammonemia, homocitrullinemia (HHH) syndrome
- Pyruvate carboxylase deficiency
- Hepatopathy (due to galactosemia, hereditary fructose intolerance)
- Hyperinsulinism-hyperammonemia syndrome (HIHA; glutamate dehydrogenase deficiency)

TREATMENT

Presumptive treatment should not await a definitive diagnosis but should be based on clinical suspicion and initial labs. Delays in treatment can be fatal and will cause brain damage.

GENERAL MEASURES

- Many patients will require admission to an intensive care unit and may require ventilator support.
- Obtain IV access.
- Promote renal ammonia excretion through increased maintenance fluids.
- Immediately discontinue exogenous protein intake, which exacerbates ammonia production.
- Enhance anabolism with calories from high-rate dextrose infusion (10 mg/kg/min) with insulin (0.1–1 IU/kg/h) and intralipids (0.5–1 g/kg/24 h) (exclude long-chain fatty acid disorder).
- Consider total parenteral nutrition or semi synthetic amino acid formulas during crises.
- Nitrogen-scavenging agents enable ammonia to bind to amino acids which yield products that can be excreted in the urine:
 - Sodium benzoate (250 mg/kg/24 h)
 - Sodium phenylacetate (250 mg/kg/24 h) intravenously when ill, or
 - Sodium phenylbutyrate (400–600 mg/kg/24 h) orally when well.

Note that high levels (or serum concentrations) of sodium benzoate and sodium phenylbutyrate can be toxic, >2 mmol/L and >4 mmol/L, respectively. Monitor sodium and potassium levels when using these scavengers.

- Arginine (180–360 mg/kg) or citrulline therapy to supplement residual urea cycle function
- L-carnitine supplementation (100–200 mg/kg/24 h) to support mitochondrial metabolism (unless urea cycle defect is identified as the cause)
- Administration of N-carbamyl-L-glutamic acid (Carbaglu) (100–200 mg/kg/24 h) has been shown to reduce ammonia levels in NAG synthetase deficiency, CPS1 deficiency, and the organic acidemias.
- Antiemetics (e.g., ondansetron)
- Metronidazole (10–20 mg/kg/24 h for 10 days every month) to decrease bacterial gut flora as a major source of ammonia and propionate
- Dialysis in severe hyperammonemia ($>250 \mu\text{mol/L}$) if unresponsive to IV scavengers
- Monitor ammonia, electrolytes, and neurologic status closely during a crisis.

ONGOING CARE

Specific therapies are best carried out under the supervision of a metabolic specialist and a metabolic nutritionist. Goal of every long-term treatment is to achieve a protein-sparing anabolic effect of an optimal diet that limits the episodes of acute crises and promotes adequate growth:

Adjust diet to underlying metabolic defect by restricting metabolites prior to their respective enzymatic block and/or their precursors from the diet, for example:

- Urea cycle defects
 - Restrict natural protein; protein elimination during times of stress during illness/stress; avoid fasting
 - Chronic therapy with nitrogen-scavenging agents
 - Amino acid supplements when indicated (e.g., citrulline in ornithine transcarbamylase deficiency; arginine in citrullinemia, argininosuccinate lyase deficiency)
 - Long-term therapy may involve an orthotopic liver transplant.
- Fatty acid oxidation disorders

- Low-fat, high-carbohydrate diets with frequent feeds; avoid fasting
- Organic acidemias
 - Protein restriction, semisynthetic amino acid formulas lacking the offending amino acid; protein elimination during times of stress during illness/stress; and avoidance of fasting; intermittent metronidazole in propionic acidemia to eliminate intestinal propionate production; liver and/or kidney transplant
- Provide vitamins, minerals, trace elements, cofactors, and calories in accordance to the Recommended Daily Allowance (RDA) to promote adequate growth and an anabolic state because catabolism may trigger acute crises, especially in urea cycle defects and organic acidemias, to assess adequate nutritional therapy; measure height, weight, and head circumference; and obtain CBC, plasma protein and albumin, plasma amino acids, iron and ferritin, lipid panel, renal and hepatic function test, as well as calcium and phosphorus levels frequently
- Dietary protocol for treatment of intercurrent illness at home
- Emergency letter/protocol and bracelet
- Early treatment of infection
- Routine vaccination

COMPLICATIONS

- Recurrent episodes of hyperammonemia
- Malnutrition → growth retardation, osteoporosis
- Elevated intracranial pressure
- Intellectual disability
- Vision loss due to optic neuropathy
- Nephropathy, cardiomyopathy
- Coma, metabolic strokes, early death

CODES

ICD10

- E88.89 Other specified metabolic disorders
- E72.20 Disorder of urea cycle metabolism, unspecified
- E72.4 Disorders of ornithine metabolism

FAQ

- Q: Can females have ornithine transcarbamylase deficiency?
- A: Ornithine transcarbamylase is an X-linked gene, and females are generally asymptomatic carriers. However, due to “skewed” X inactivation of the OTC, affected female may exhibit symptoms after increased protein intake or states of catabolism.
- Q: Can any of these disorders present outside of the newborn period?
- A: Disease severity depends in large part on a patient’s enzyme activity. Therefore, hyperammonemia can occur at any age during a period of metabolic stress.
- Q: What determines developmental outcome in children with inborn errors of metabolism?
- A: Outcome depends on prompt diagnosis, residual enzyme activity, early treatment, and compliance with long-term treatment.

METABOLIC DISEASES IN HYPOGLYCEMIC NEWBORNS

Stephan Siebel • Ada Hamosh

BASICS

DESCRIPTION

- Hypoglycemia is a frequent finding in the neonatal period, which results from the imbalance between carbohydrate intake, endogenous glucose production, and tissue usage.
- Neonates stabilize their serum glucose levels by about 12 hours after birth to 45 mg/dL (2.6 mmol/L). In a healthy state, glucose homeostasis underlays tight regulation through glucose-lowering hormones (insulin) and counterregulatory, glucose-mobilizing hormones (cortisol, growth hormone, and others) by acting on glycolysis, gluconeogenesis, glycogenolysis, and many other metabolic pathways involved in the biosynthesis, catabolism, or transport of carbohydrates, lipids, and amino acids.
- Hence, many inborn errors of metabolism can present with episodes of hypoglycemia during metabolic crises, which can be life threatening if not treated promptly.
- First presentation of an inborn error of metabolism can be at any age, with most cases presenting during times of metabolic stress or transition, as in infancy, illness, and dietary changes. Therefore, it is prudent to quickly establish a tentative diagnosis and initiate treatment in a sick neonate.

EPIDEMIOLOGY

- Incidence of hypoglycemia is estimated at 1–3/1,000 live births.
- Incidence of inherited forms is estimated at 1/50,000 live births in sporadic populations and higher in Ashkenazi Jews.
- The incidence of medium-chain acyl-CoA dehydrogenase (MCAD) deficiency ranges from 1:4,900 to 1:17,000 live births.
- Incidence of familial hyperinsulinism is 1 in 2,500 live births.

Genetics

Almost all inborn errors of metabolism causing hypoglycemia are autosomal recessive. Congenital hyperinsulinism can be autosomal dominant or recessive. Glycerolkinase deficiency is X-linked.

PATHOPHYSIOLOGY

- Through glycolysis and oxidative phosphorylation, glucose is a major source of cellular energy (ATP). Failure to produce ATP is probably the main source of hypoglycemia-associated tissue dysfunction.
- The brain preferentially uses glucose metabolism to produce energy and is particularly sensitive to hypoglycemia.
- A long list of metabolic disturbances in a variety of pathways can result in hypoglycemia.
- Neonates are at particular risk for hypoglycemia because they use glucose more rapidly than adults and have immature ability to obtain energy from other sources (glycogen, muscle protein, adipose tissue).

ETIOLOGY

- Inherited defects in biochemical pathways affecting metabolism of fats, amino acids, or carbohydrates
- Mutations in genes known to be involved in glucose metabolism, for example, congenital hyperinsulinism (ABCC8, KCNJ11, GLUD1, CAK, HADH, SLC16A1, HNF4A) and Fanconi-Bickel syndrome (GLUT2, SCLA2)

DIAGNOSIS

HISTORY

- Family history: Because inborn errors of metabolism are genetic disorders, patients may have a family history of poorly explained pediatric death. Diagnoses to ask about include the following:
 - Sepsis (was an organism identified?)
 - Sudden infant death syndrome
 - Cardiomyopathy
 - Uncontrollable seizures
 - Coma

- Liver failure
- Unexplained developmental delay or hypoglycemia in older siblings
- First hypoglycemia after introducing different foods (e.g., milk, fruits, etc.)
- Complications with the pregnancy:
 - Maternal diabetes
 - Certain disorders of fatty acid oxidation are associated with fatty liver of pregnancy or HELLP (hypertension, elevated liver enzymes, low platelets) syndrome.
 - Small for gestational age/intrauterine growth retardation/prematurity: may present with transient hypoglycemia
- Results of newborn screen: Children are tested for a variety of inborn errors of metabolism through newborn screening programs. Some of these disorders predispose to hypoglycemia and have specific therapies.
- Current diet and feeding schedule: Timing of hypoglycemia helps form differential diagnosis:
 - Hypoglycemia occurring shortly after feeding (0–4 hours) is suggestive of hyperinsulinism or inability to process carbohydrates (hereditary fructose intolerance).
 - Hypoglycemia between 2 and 10 hours after feeding is concerning for glycogen storage diseases, defects in gluconeogenesis, or counterregulatory hormone deficiencies.
 - Hypoglycemia after fasting (>6 hours) is suggestive of ketotic hypoglycemia, defects in gluconeogenesis, or fatty acid oxidation defects.

PHYSICAL EXAM

- ABCs and vital signs: Tachycardia, irritability, and weakness are commonly seen in hypoglycemia.
- Facies: Decreased interpupillary diameter or other midline anomalies occur in association with abnormalities of the pituitary.
- Skin: Diaphoresis is an effect of the catecholamine surge that accompanies hypoglycemia.
- CVS: cardiomyopathy (fatty acid oxidation defects, glycogen storage disorders, organic acidemias)

- Respiratory: Tachypnea may be the result of either respiratory compensation of metabolic acidosis or hyperammonemia.
- Hepatomegaly
- Occurs in many inborn errors of metabolism causing hypoglycemia and is a key feature in differentiating possible diagnoses.
- May be due to abnormal accumulation of lipid (e.g., in fatty acid oxidation defects) or glycogen (e.g., glycogen storage disease).
- Renal: nephropathy/tubulopathy (organic acidemias, Fanconi-Bickel syndrome)
- GU:
 - Virilization in congenital adrenal hyperplasia
 - Micropenis in hypopituitarism
- Neurologic: Every neonate with a suspected inborn error of metabolism needs a complete neurologic exam to evaluate for level of consciousness, tone, unusual movements, and reflexes. Symptoms of neuroglycopenia include the following:
 - Tremulousness
 - Polyphagia
 - Seizures
 - Irritability
 - Weakness
 - Hypotonia
 - Stupor and coma occur if hypoglycemia is not reversed
- Growth parameters:
 - Infants with Beckwith-Wiedemann syndrome, familial hyperinsulinism, or infants of diabetic mothers may be large for gestational age.
 - Beckwith-Wiedemann syndrome may also present with additional physical stigmata (hemihypertrophy, visceromegaly, macroglossia, abdominal wall defects) and hyperinsulinism.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

The goal of the initial lab evaluation is to make a presumptive diagnosis. In many cases, definitive diagnosis requires specialized and time-consuming tests.

- Initial labs for a presumptive diagnosis in patient with hypoglycemia:
 - Dextrose stick
 - Urine dipstick: glucosuria (glucose transporter defects)
 - Electrolytes, BUN, creatinine, anion gap
 - CBC, blood culture
 - Serum and urinary ketones
 - Arterial blood gas with lactate
 - Liver function tests and PT/PTT
 - Urinalysis for reducing substances: positive in fructose intolerance, galactosemia
 - Plasma ammonia levels (obtained as free-flowing samples without tourniquet): Sample must be placed on wet ice and immediately transported to the lab for processing.
 - Review state newborn screen.
- Suspected disorders and follow-up testing:
 - Familial hyperinsulinism: high insulin levels, low/absent serum/urinary ketones
 - Adrenal insufficiency, hypopituitarism: low cortisol, growth hormone, epinephrine/norepinephrine levels
 - Defects of fatty acid oxidation or ketogenesis: plasma acylcarnitine profile, free fatty acids+ 3-hydroxybutyrate/ketones (low)
 - Organic acidemias: urine organic acids, acylcarnitine profile
 - Factitious hypoglycemia/Munchausen syndrome by proxy: elevated C-peptide levels, toxicology screen: sulfonylureas, ethanol
 - Urea cycle defects: plasma amino acids, urine orotic acid
 - Galactosemia: urine galactitol, red blood cell galactose-1-phosphate, uridyltransferase (GALT) activity, total galactose
 - Defects of gluconeogenesis/glycogen storage disease: arterial blood gas with lactate (lactic acidosis), +/- elevated creatine kinase (CK), specific enzyme testing or mutation analysis
 - Prolonged fasting: elevated free fatty acids+ 3-hydroxybutyrate
 - Gene testing for specific disorders (Beckwith-Wiedemann syndrome)

DIFFERENTIAL DIAGNOSIS

Hypoglycemia is caused by increased glucose use or decreased glucose

availability. Examples of disorders causing each:

- Increased glucose use
 - Sepsis increases metabolic demand and is a leading cause of neonatal hypoglycemia.
 - Familial hyperinsulinism: suspect when required glucose infusion rate (GIR) >10–20 mg/kg/min to maintain normoglycemia
 - Increased insulin production: Beckwith-Wiedemann syndrome
 - Decreased insulin counterregulatory hormones (glucagon, cortisol, growth hormone) due to adrenal insufficiency, hypopituitarism
- Decreased glucose availability/production
 - Infants of diabetic mothers
 - Small for gestational age: low energy stores, immaturity of glucose-regulating pathways
 - Liver failure/disease from ingested carbohydrates: galactosemia, hereditary fructose intolerance
 - Glycogen storage diseases
 - Glycerol kinase deficiency, glycerol intolerance
 - Decreased gluconeogenesis: phosphoenolpyruvate carboxykinase deficiency, fructose-1, 6-diphosphatase deficiency, pyruvate carboxylase deficiency
 - From decreased efficiency of pathways providing alternate energy sources: organic acidemias, fatty acid oxidation defects
- Disorders of glucose transporter:
 - GLUT1 or 2 deficiency
 - SGLT1 or 2 deficiency
- Various toxins or medications interfere with pathways needed to maintain glucose homeostasis, including salicylates, valproate, β blockers, ethanol, and exogenous insulin.

TREATMENT

Presumptive treatment should not await a definitive diagnosis but should be based on clinical suspicion and initial labs.

GENERAL MEASURES

- A well-appearing neonate with a low dextrose stick should be fed immediately. If feeds are contraindicated or not tolerated, obtain IV access.
- In children with associated physical or laboratory findings consistent with an inborn error of metabolism or other serious illness (e.g., vital sign instability, lethargy, acidosis), IV access should be obtained.
- A dextrose bolus (e.g., 5 cc/kg D10) rapidly corrects hypoglycemia in most cases. Infants requiring high glucose infusion rates to maintain normoglycemia are suspicious for hyperinsulinism.

ADDITIONAL THERAPIES

Specific therapies vary according to the diagnosis and are best carried out by metabolic specialists:

- Hyperinsulinism
 - May require continuous glucose administration of 7–10 mg/kg/min (IV or via continuous gastric feeds)
 - Medical therapies including diazoxide and octreotide
 - Pancreatectomy
- Deficiencies in counterregulatory hormones: hormone supplementation
- Galactosemia, hereditary fructose intolerance: Eliminate offending agent from diet.
- Fatty acid oxidation disorders, glycogen storage disease type I, defects in gluconeogenesis: frequent feeds, fasting avoidance, increase caloric intake during stress. Some children may benefit from cornstarch supplementation before bedtime to prevent nocturnal hypoglycemia.

ONGOING CARE

COMPLICATIONS

Recurrent and severe hypoglycemic episodes affect neurocognitive development.

ICD10

- P70.4 Other neonatal hypoglycemia
- E88.9 Metabolic disorder, unspecified
- E88.89 Other specified metabolic disorders

FAQ

- Q: Why is hypoglycemia dangerous?
- A: Glucose is a crucial source of rapidly available energy for many tissues, especially the brain. Prolonged hypoglycemia causes CNS damage.
- Q: Why are the critical labs so important?
- A: In some metabolic disorders, the biochemical disturbance is apparent only during hypoglycemic episodes. Collecting this panel of informative labs during an episode greatly increases the chance of making a diagnosis.
- Q: If an infant dies before a diagnosis is made, what can be done to provide information for family members regarding future pregnancies?
- A: A postmortem exam can be helpful. A skin biopsy can yield fibroblasts for genetic and biochemical assays to investigate defects in specific pathways, and a muscle biopsy can be used to investigate mitochondrial disorders. Follow specific protocol for obtaining biopsies.

METABOLIC SYNDROME

Michele Mietus-Snyder • Sheela N. Magge

BASICS

DESCRIPTION

- A systemic disorder of energy regulation associated with ectopic fat deposition, immune activation, insulin resistance, and increased risk for cardiovascular disease (CVD) and type 2 diabetes mellitus (T2DM)
- Recognized by central adiposity, dyslipidemia, hypertension, and abnormal glucose tolerance
- These metabolic parameters change with age, gender, race, and ethnicity, so no established pediatric thresholds have been defined.
- Extrapolation from adult criteria permits diagnosis when ≥ 3 of the following 5 elements are present (approximate levels):
 - Waist circumference >90 th percentile (waist to height ratio >0.6)
 - Low high-density lipoprotein cholesterol (HDL-c) <10 th percentile (<40 mg/dL)
 - High triglycerides (TG) >90 th percentile (>90 mg/dL to age 9 years, then >110 mg/dL)
 - Hypertension: systolic and/or diastolic BP >95 th percentile for age, height, and gender
 - Elevated fasting blood sugar (>99 mg/dL)

EPIDEMIOLOGY

Prevalence

- Uncommon in children of normal weight
- Up to 60% of obese children meet criteria for the metabolic syndrome.
- Rates correlate with visceral, ectopic fat depot.
- Highest rates in Hispanics $>$ non-Hispanic (NH) Whites and \sim Asians $>$ NH Blacks
- More prevalent with age and in males than females

RISK FACTORS

- Prenatal and postnatal stressors

- Family history of T2DM and/or CVD
- Diet high in processed foods, added sugars, and trans fats
- Sedentary lifestyle
- Smoking or passive smoke exposure

Genetics

Sequence and epigenetic modification of genes involved in energy regulation have been implicated in disease progression, including adipose tissue differentiation, insulin signaling, and circadian clock genes as well as the mitochondrial genome.

PATHOPHYSIOLOGY

- Subcutaneous adipose capacity (which varies in individuals for both genetic and environmental reasons) is exceeded.
- Deposition of fat in hypertrophied adipose cells within nonadipose depots, notably visceral, hepatic, and muscular
- Triglyceride-engorged adipocytes trigger major histocompatibility complex (MHC) II response and immune activation. Antigen presentation may be endotoxin from microbial translocation.
- Stimulated monocyte/macrophage infiltration into ectopic adipose depots release TNF alpha, IL-6, and MCP-1
- Chronic low level inflammation
- Mitochondrial dysfunction and excessive intracellular oxidative stress
- Insulin resistance and systemic consequences

ETIOLOGY

- Decreased mitochondrial reserve with age and physical inactivity
- Excessive caloric load, particularly a diet high in refined carbohydrate and/or trans fat
- Genetic and epigenetic predisposition

COMMONLY ASSOCIATED CONDITIONS

- Nonalcoholic fatty liver disease (NAFLD)
- Disordered sleep ± obstructive sleep apnea
- Polycystic ovarian syndrome (PCOS)
- Low vitamin D level

DIAGNOSIS

HISTORY

- Prenatal stress
 - Small or large for gestational age
 - Maternal gestational diabetes or eclampsia
 - Maternal or pregnancy-related overweight
- History of accelerated weight gain
 - Age at which weight gain started (Physiologic insulin resistance of peripubertal years is a common trigger.)
 - Previous difficulty losing weight (difficult to lose weight if hyperinsulinemic)
- Psychosocial stressors: teasing, food insecurity
- Family history: early CVD and T2DM
- Lifestyle
 - Eating behavior
 - Sugared beverage consumption
 - Frequency and content of processed snacks
 - Poor produce and whole grain intake
 - Aberrant eating structure (skipping breakfast, lack of balanced meals)
 - Physical activity
 - Increased hours of screen time
 - Low sports and activity participation
 - Poor sleep hygiene
- Parenting skills
 - Ability to set boundaries
 - Lifestyle role modeling
- Smoke exposure and smoking history
- Signs and symptoms
 - Obese patients with metabolic syndrome are usually asymptomatic but may have
 - Easy and rapid weight gain
 - Excessive hunger, carbohydrate craving
 - Snoring, gasps during sleep (OSA)

- Fatigue, disinterest in activity
- Headaches (may be symptom of OSA or pseudotumor cerebri)
- Thickened, darkened skin in flexures, notably at the nape of the neck and axillae (suggestive of acanthosis nigricans) and skin tags
- Polydipsia, polyuria, nocturia (concerning for diabetes)
- Depression, bullying, teasing
- Abnormal menses, male-pattern hair growth, acne (concerning for PCOS)

PHYSICAL EXAM

A complete physical should be done on all patients. Special attention should be paid to the following:

- Weight, height, and BMI
- Waist circumference and waist to height ratio
- Blood pressure
- Papilledema
- Tanner stage
- Abdominal striae
- Hepatomegaly
- Acanthosis nigricans and skin tags
- Hirsutism, acne
- Affect, mood

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Metabolic screening (preferably fasting specimens) should be done on all obese patients:

- Fasting lipid profile: total cholesterol, HDL-c and TG. Metabolic syndrome is a condition of hypertriglyceridemia not increased cholesterol. LDL-c is typically unremarkable; but in the presence of high TG, LDL particles are smaller and less well cleared so they are more numerous, whereas HDL particles, also smaller, are less stable and decreased in number and thus HDL-c is low.
- Nonfasting lipid profile: non-HDL-c elevation
- Fasting glucose and insulin: Compensatory hyperinsulinism suggests

(although not definitive) insulin resistance; homeostasis model assessment – insulin resistance (HOMA-IR) = (fasting insulin × FBG)/405: measure of insulin resistance

- Hemoglobin A1c (HbA1c): may be a helpful indication of chronic caloric overload in nonfasting state; potential screen for diabetes
- Liver function tests (LFTs): ALT and AST elevation are nonsensitive indicators of NAFLD.
- Thyroid function tests: may find very mild elevations of TSH with normal T4
- 25-OH vitamin D level: often low
- 2-hour OGTT: suggested when fasting blood sugar >99 mg/dL, elevated HbA1c (>5.6% but can use clinical judgment), and/or symptoms of diabetes (polydipsia, polyuria, nocturia) to assess for impaired glucose tolerance and T2DM
- Abnormal lab tests should be repeated after a trial of weight management.

Imaging/Additional Studies

- All patients with hypertension should have an ECG to evaluate for LVH; ambulatory BP monitoring can also be useful.
- Patients with elevated ALT or AST (particularly ALT) could have a 2-D echo to assess for hepatic fat infiltration of NAFLD.
- MRI is currently the gold standard for ectopic/visceral fat evaluation.
- A history of disordered sleep and heavy snoring, especially with pauses in breathing, warrants a sleep study (polysomnogram).

DIFFERENTIAL DIAGNOSIS

The full cardiometabolic constellation of findings is unique to this syndrome, but individual features may present in other conditions:

- Hereditary combined dyslipidemia
- Hereditary hypertriglyceridemia
- Essential hypertension
- Type 1 diabetes mellitus
- Lipodystrophies

TREATMENT

MEDICATION

There are no pharmacologic treatments approved for the treatment of metabolic syndrome as a whole. Medications can be used to treat individual components. See “[Additional Therapies](#).”

GENERAL MEASURES

Comprehensive behavioral modification through both improved diet and increased physical activity is the first-line treatment for metabolic syndrome. It decreases body weight, improves body composition and insulin sensitivity, and can positively affect CVD risk factors even if weight loss is not achieved due to redistribution of fat from ectopic to subcutaneous depots and/or a favorable shift to lean muscle weight.

- Physical activity: ≥ 60 minutes per day of moderate to vigorous physical activity (can be in short intervals) defined as a level of effort that increases heart rate and produces heavier than at-rest breathing.
- Diet: upgrade carbohydrate and fat quality
 - Avoid/limit sugar-sweetened beverages, specifically juice and soda. Limit sugar substitutes. Encourage water.
 - Primary dairy beverage for 2–21 years old: low-fat or fat-free unflavored milk
 - Increase fiber intake
 - ≥ 5 servings of whole fruits and vegetables per day
 - Increase whole grains in diet; avoid grains with < 3 g fiber/serving.
 - Limit foods containing high-fructose corn syrup; limit added sugars; aim for total sugar to fiber ratio < 5 , ideally < 3 .
 - Fat content
 - Total fat, 25–30% of daily kcal/estimated energy requirement (EER)
 - Saturated fat, 8–10% of daily kcal/EER
 - Avoid trans fat
 - Monounsaturated and polyunsaturated fat (PUFA) up to 20% of daily kcal/EER
 - Favor omega-3 PUFA
 - Cholesterol < 300 mg/day
- Sedentary activity/screen time

- Includes television, video games, texting, or computer not related to school
- Limit to ≤ 2 hours per day for children older than 2 years (no screen time if < 2 years)
- No TV in bedroom or screens after bedtime
- Smoking
 - Explicitly counsel about the dangers of smoking and advocate smoking cessation.
 - Counsel to avoid secondhand smoke.

ADDITIONAL THERAPIES

For individual elements of the metabolic syndrome

- Dyslipidemia: ≥ 10 –21 years of age
 - LDL-c will not exceed 190 mg/dL with metabolic syndrome alone.
 - LDL-c > 160 mg/dL unusual in metabolic syndrome but hypercholesterolemia may coexist (See “Hyperlipidemia” chapter.)
 - LDL-c 130–159 mg/dL + 2 high-level risk factors OR 1 high-level + ≥ 2 moderate-level risk factors OR clinical CVD
 - Risk factor algorithm helps identify risk for small dense LDL and a higher LDL particle burden.
 - HMG-CoA reductase inhibitors (statins)—pravastatin or rosuvastatin preferred. Note side effects; needs monitoring.
 - TG ≥ 110 –499, non-HDL-c ≥ 145 (mg/dL)
 - Restrict refined carbohydrate intake.
 - Consider daily fish oil over-the-counter preparations with ~ 400 mg DHA + EPA.
 - TG > 500 –700 mg/dL and > 10 years of age
 - Consider adjunct fibrate (off label).
 - TG $\geq 1,000$ mg/dL
 - Not likely in metabolic syndrome alone; rule out primary hypertriglyceridemia
- Hypertension: stage 1 with no response to lifestyle changes $\times 3$ to 6 months and stage 2
 - Rule out primary renal etiology (check U/A, BUN, creatinine, renin)
 - ACE inhibitors, angiotensin receptor blockers, diuretics, and

vasodilators are used most commonly in pediatrics. Note side effects and needs monitoring.

- T2DM
 - OGTT: fasting blood glucose ≥ 126 mg/dL or 2-hour ≥ 200 mg/dL or HbA1c $\geq 6.5\%$
 - Metformin or metformin XR are the only oral agents approved for the treatment of T2DM in children.
 - To minimize GI distress, titrate up over weeks to 1,000 mg PO b.i.d. with meals.
 - Common side effects: nausea, bloating, diarrhea, and gas, which often resolve within 2 weeks
 - Rare side effects: lactic acidosis, megaloblastic anemia; prophylax with a daily multivitamin
 - Monitor LFTs, creatinine, and Hb/Hct.
 - Discontinue 48 hours prior to contrast administration or surgery.
 - Counsel to use contraceptive methods to avoid pregnancy.
 - Insulin injections—refer to endocrinology
- Prediabetes
 - Impaired fasting glucose: 100–125 mg/dL
 - Impaired glucose tolerance: 2-hour glucose on OGTT, 140–199 mg/dL
 - HbA1c, 5.7–6.4% (debated whether synonymous with prediabetes)
 - Consider OGTT to rule out prediabetes and diabetes.
 - No consensus on the use of metformin in prediabetic states but some evidence of efficacy

ISSUES FOR REFERRAL

- Referral to pediatric lipid specialist for LDL-c ≥ 130 and/or TG ≥ 200 (mg/dL)
- Referral to pediatric endocrinologist for diabetes, prediabetes, or PCOS
- Referral to pediatric gastroenterologist for ALT > 2 times normal to rule out NAFLD
- Referral to pediatric hypertension specialist for stage 1 hypertension not responsive to lifestyle or stage 2 hypertension
- Consider referral to multidisciplinary pediatric weight management

clinic for intensive lifestyle counseling.

SURGERY/OTHER PROCEDURES

Bariatric surgery is a potential weight loss treatment for extreme obesity with cardiometabolic complications in older adolescents with potential for significant insulin sensitization. Refer to a pediatric center experienced in bariatric surgery.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Ongoing weight management
- Children ≥ 10 years of age with BMI from 85th–94th percentile: Check lipid profile at least every 2 years; if other risk factors are present, include glucose and LFTs.
- Children ≥ 10 years of age with BMI ≥ 95 th percentile: Check fasting lipid panel, glucose, and AST/ALT at least every 2 years and other tests as indicated.

PROGNOSIS

Multiple studies have shown that without aggressive intervention, cardiometabolic risk factors track from childhood to adulthood, increasing lifetime risk for T2DM and CVD.

ICD10

E88.81 Metabolic Syndrome

FAQ

- Q: Why is it important to diagnose metabolic syndrome?
- A: Although obesity increases metabolic risk, not everyone who is obese develops complications; those at the greatest cardiometabolic risk need additional screening and intervention.
- Q: Do children with the metabolic syndrome have it when they become adults?
- A: If children with the metabolic syndrome do not use diet and exercise to treat it, they will likely have it as adults.
- Q: Does cardiovascular risk improve if these children lose weight?
- A: Yes, 5–10% body weight loss can result in improvement of CVD risk factors due to preferential weight loss from the ectopic visceral fat depot.

METHEMOGLOBINEMIA

Kevin C. Osterhoudt

BASICS

DESCRIPTION

- Methemoglobin is dysfunctional hemoglobin in which the deoxygenated heme moiety has been oxidized from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state.
- Methemoglobinemia is an undue accumulation of methemoglobin within the blood.

EPIDEMIOLOGY

- Toxic methemoglobinemia, resulting from exposure to oxidant chemicals or drugs, is the most common cause of methemoglobinemia among children older than 6 months of age.
- Enteritis-associated methemoglobinemia is the most common cause among children younger than 6 months of age:
 - As many as 2/3 of infants with severe diarrhea have methemoglobinemia.

PATHOPHYSIOLOGY

- Hemoglobin in the allosteric configuration of methemoglobin cannot carry oxygen.
- Methemoglobin increases the oxygen affinity of normal heme moieties in the blood and results in impaired oxygen delivery to tissues.
- NADH-dependent cytochrome b5 methemoglobin reductase is the major source of physiologic reduction of methemoglobin.
- A normally dormant NADPH-dependent methemoglobin reductase is the site of action for antidotal methylene blue therapy.

ETIOLOGY

- Toxic methemoglobinemia
 - Dietary or environmental chemicals: chlorates, chromates, copper sulfate fungicides, naphthalene, nitrates, and nitrites

- Industrial chemicals: aniline and other nitrogenated organic compounds
- Drugs: amyl nitrite, benzocaine, dapsone, lidocaine, metoclopramide, nitric oxide, nitroprusside, phenazopyridine, prilocaine, many others
- Methemoglobinemia is a common iatrogenic complication of drug therapy.
- Enteritis-associated methemoglobinemia is multifactorial in origin:
 - Intestinal nitrate and nitric oxide promotes methemoglobin formation.
 - Innate enzymatic methemoglobin reduction systems may be underdeveloped during infancy.
 - Acidemia further inhibits enzymatic methemoglobin reduction systems.
 - Methemoglobinemia is also reported with nitrite-producing bacterial infections of the intestines or urinary tract.
- Congenital methemoglobinemia (rare)
 - Hemoglobin M: Heterozygotes for autosomal dominant hemoglobin M will exhibit lifelong cyanosis.
 - NADH-dependent methemoglobin reductase deficiency: Homozygotes for this autosomal recessive enzyme will have lifelong cyanosis; heterozygotes may have increased susceptibility to oxidative hemoglobin injury.

COMMONLY ASSOCIATED CONDITIONS

- Heinz body hemolytic anemia
 - Oxidant stress on the globin protein may cause hemolysis.
- Sulfhemoglobinemia
 - Oxidant stress on the hemoglobin porphyrin ring may cause sulfhemoglobinemia.

DIAGNOSIS

HISTORY

- Age of onset

- New onset of cyanosis in children older than 6 months of age is unlikely to be due to congenital or enteritis-associated methemoglobinemia.
- Source of water
 - Well water may be contaminated with nitrates.
- Drug or chemical exposure
 - May suggest a source of toxic methemoglobinemia
- Diarrhea
 - May suggest enteritis-associated methemoglobinemia

PHYSICAL EXAM

- Cyanosis
 - Cyanosis becomes apparent in the presence of 1.5 g/dL of methemoglobin (in contrast to 4–5 g/dL of deoxyhemoglobin).
- Heart murmur
 - May suggest right-to-left intracardiac shunting rather than methemoglobinemia
- Abnormal lung auscultation:
 - May suggest cyanosis due to pulmonary disorder
- Signs and symptoms
 - Malaise
 - Fatigue
 - Dyspnea
 - Tachycardia
 - Cyanosis

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Oxygen saturation
 - Oxygen saturation measured by pulse oximetry is artificially low, but oxygen saturation calculated from arterial blood gas is normal (a “saturation gap”).
- Co-oximetry
 - Multiple-wavelength co-oximetry is the standard for quantifying methemoglobin in the blood.
- Hemoglobin quantitation

- The percent methemoglobin concentration must be considered in relation to the total hemoglobin.
- Anemia may suggest concurrent hemolysis.
- Serum bicarbonate
 - Metabolic acidosis is relatively mild in cases of <40% toxic methemoglobinemia.
 - Metabolic acidosis is typically profound in cases of enteritis-associated methemoglobinemia.
- Glucose-6-phosphate dehydrogenase (G6PD) assay
 - G6PD deficiency does not predispose to methemoglobinemia and should not be routinely ordered.
- Hemoglobin electrophoresis
 - Hemoglobin M is rare and does not respond to therapy.
 - This test should not be routinely ordered.

Diagnostic Procedures/Other

- Pulse oximetry may be inaccurate in the setting of methemoglobinemia or methylene blue therapy.
- Blood may have a “chocolate brown” appearance despite exposure to air.

DIFFERENTIAL DIAGNOSIS

- Environmental hypoxia
- Cardiovascular disease
- Pulmonary disease
- Sulfhemoglobinemia
- Factitious skin discoloration

TREATMENT

MEDICATION

- Consider administration of 1% methylene blue.
 - Dose: 1–2 mg/kg IV over 5 minutes, repeated as necessary (caution above 4–7 mg/kg total)
 - Indications: signs of tissue hypoxia, CNS depression, >30% methemoglobinemia

- Contraindications (relative): known, severe G6PD deficiency
- Methylene blue therapy may be ineffective if
 - Patient is G6PD deficient.
 - Ongoing drug or chemical absorption or biotransformation leads to continuing methemoglobin formation.
 - Sulfhemoglobin is present.
 - Hemoglobin M is present.
 - High doses of methylene blue add to, rather than ameliorate, the oxidant stress.

ADDITIONAL TREATMENT

General Measures

- Acquired methemoglobinemia
 - Administer 100% oxygen.
 - Decontaminate or remove from toxic source of oxidative stress.
 - Alleviate enteritis with IV fluids or elemental formulas.
 - Treat identified bacterial infections.
 - Exchange transfusion is a consideration of last resort.
- Congenital methemoglobinemia
 - No beneficial therapy exists for hemoglobin M.
 - Oral methylene blue or ascorbic acid may provide alternative reduction pathways for patients with NADH-dependent reductase deficiencies.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Toxic methemoglobinemia
 - Consider consultation with a medical toxicologist.
 - May require environmental investigation
- Enteritis-associated methemoglobinemia
 - Careful formula rechallenge warranted if possibility exists for milk protein allergy or other dietary intolerance
- Congenital methemoglobinemia
 - Consider consultation with a hematologist.

PROGNOSIS

- Toxic methemoglobinemia
 - Full recovery with recognition, removal of oxidant stress, and appropriate therapy
- Enteritis-associated methemoglobinemia
 - Methemoglobinemia may be prolonged and relapsing until enteritis healed.
- Congenital methemoglobinemia
 - Lifelong cyanosis expected

COMPLICATIONS

- >10% methemoglobinemia
 - Cyanosis
- >30% methemoglobinemia
 - Malaise, fatigue, dyspnea, tachycardia
- >50% methemoglobinemia
 - Somnolence, tissue ischemia
- 60% methemoglobinemia
 - Potential lethality

CODES

ICD10

- D74.9 Methemoglobinemia, unspecified

- D74.8 Other methemoglobinemias
- D74.0 Congenital methemoglobinemia

FAQ

- Q: Can methemoglobinemia be diagnosed by the color of the blood?
- A: The “chocolate brown” blood of methemoglobinemia is most easily noted when compared to “control” blood on a white filter paper background. In contrast to deoxygenated blood from patients with cardiopulmonary disease, methemoglobin-darkened blood does not redden on exposure to room air.
- Q: Is methemoglobin responsible for the profound metabolic acidosis often found in diarrheal infants?
- A: Benzocaine-induced methemoglobinemia rarely causes acidosis in infants. In contrast, infants with enteritis-associated methemoglobinemia often have a profound acidemia with a relatively narrow anion gap. Acidosis should be considered a contributing or coexisting factor, rather than a result, of methemoglobinemia among infants with diarrhea.

MICROCYTIC ANEMIA

Tannie Huang • James Huang

BASICS

DESCRIPTION

Microcytic anemia is hemoglobin 2 standard deviations (SD) below the mean as well as an abnormally low mean corpuscular volume. Use of age-based norms for both indices is critical.

EPIDEMIOLOGY

- In pediatrics, the most common cause of microcytic anemia is iron deficiency anemia (IDA).
- IDA incidence by age:
 - 1–2 years, 14%
 - Adolescent females, 9%
- Hemoglobinopathies causing microcytic anemia are common in Mediterranean countries, Southeast Asia, China, Africa, and India. Incidence in the United States is currently increasing due to increasing immigration.

RISK FACTORS

Prematurity, breastfeeding, lower socioeconomic class, and overweight infants are more likely to have IDA. Certain ethnic groups such as African Americans and Hispanics have higher rates of iron deficiency. These groups also have a higher incidence of hemoglobinopathies, which can complicate the clinical picture.

PATHOPHYSIOLOGY

- Iron homeostasis in the body is primarily regulated through mechanisms of iron absorption.
- Iron is absorbed through duodenal enterocytes and then transported to the liver. Hepcidin is synthesized by the liver and is the major regulator of iron absorption. The amount of dietary iron that is absorbed is relatively low but varies depending on the patient's iron

stores.

- The body loses about 1–2 mg/day of iron through loss of intestinal epithelia. This amount is higher in menstruating females.
- IDA usually develops from absorption that is inadequate to compensate for excretion and the demands required for growth (in children).
- Hemoglobin is made up of two alpha globin chains and two beta globin chains. Abnormalities in the production of these chains can lead to microcytic anemia. Anemia can develop either through inadequate production of one of these chains or through increased clearance of red blood cells (RBC) with mutated globin chains.

ETIOLOGY

- The most common cause of microcytic anemia is iron deficiency.
- Hemoglobinopathies are the next most common cause in childhood. Of the hemoglobinopathies, hemoglobin E and alpha- and beta-thalassemias most commonly cause microcytic anemia.
- Rarely, disorders of heme synthesis such as dyserythropoietic anemias and sideroblastic anemia can be a cause of microcytic anemia.
- Anemia of chronic disease can occasionally be microcytic, although more frequently is normocytic.

DIAGNOSIS

HISTORY

- Age of onset: Iron deficiency is most common in infancy and menstruating females. A teenage male with iron deficiency anemia should be a red flag and an alert to look for ongoing occult blood loss.
- Ethnic background
- Dietary history, including
 - Breast- versus formula-fed in infancy
 - Daily milk consumption of greater than 24 oz is associated with IDA.
 - Lack of red meat consumption
 - Pica
- Lead exposure (often paint in older homes, mini blinds, ceramic

dishware, or toys)

- GI symptoms including diarrhea/constipation
- Blood loss (can be from GI, urinary, epistaxis, menstruation, and rarely pulmonary causes)
- Weight loss/fever/malaise or other symptoms of systemic disease
- Family members who have needed transfusions. In pubertal females, a maternal menstrual history may be informative.
- Special questions: Children with behavioral problems, including breath-holding spells, have higher rates of iron deficiency.

PHYSICAL EXAM

- Most children with iron deficiency are well appearing with a normal physical exam. They may be somewhat irritable.
- Frontal bossing or malocclusion of the teeth can be seen in children with thalassemia due to expansion of the bone marrow compartment.
- Pallor is the most common finding.
 - Evaluate in the face, conjunctiva, gums, and nail beds. Palmar crease becomes pale with a hemoglobin less than 7 g/dL.
- Blue sclera can be occasionally observed in iron deficiency. Scleral icterus may be seen in patients with hemoglobinopathies.
- Glossitis may be seen in patients with chronic iron deficiency.
- Cardiovascular examination
 - Auscultate for tachycardia and flow murmurs. However, often, children with chronic IDA may not have tachycardia.
 - Cardiac instability is rare but does occur.
- Splenomegaly: The spleen enlarges in some patients with thalassemia as a site of extramedullary hematopoiesis. This is a rare finding in IDA, although it has been reported.
- Nail abnormalities: Spoon nails (koilonychia) can be seen in long-standing iron deficiency.

DIAGNOSTIC TESTS & INTERPRETATION

- No single test identifies all the causes of microcytic anemia. Children are often identified through routine screening at well-child exams.
- CBC: low hemoglobin level and low mean corpuscular volume for age (lower limit of normal can be estimated by 70+ age in years)

- Red cell distribution width (RDW) is increased in IDA and normal in thalassemia.
- RBC count is elevated in thalassemia. Mentzer index: MCV/RBC count in millions: <13 points, toward thalassemia; >13 points, toward IDA
- Reticulocyte count: reticulocytopenia in IDA, reticulocytosis in hemoglobinopathies
- Thrombocytosis is often seen in IDA (can appear prior to microcytosis). In severe, prolonged iron deficiency, thrombocytopenia eventually develops.
- Peripheral blood smear
 - ▢ Hypochromia and bizarre forms in IDA
 - ▢ Target cells are seen in patients with thalassemia.
 - ▢ Basophilic stippling with lead poisoning
- Iron studies: Ferritin, serum iron, transferrin saturation, and TIBC must be interpreted together. In the face of iron deficiency, the body's iron stores are first mobilized. It is only once these iron stores are depleted that microcytosis develops.
 - Ferritin
 - ▢ Decreased in iron deficiency
 - ▢ Most sensitive index for iron deficiency. A ferritin of less than 30 is over 90% sensitive and specific for IDA.
 - ▢ As a measure of iron stores in the liver, it is one of the earliest indices to change in IDA.
 - ▢ May be elevated out of proportion to iron stores because it is an acute-phase reactant and will rise with infection, inflammation, malignancy, or liver disease
 - ▢ Can be increased in patients with thalassemia who have not received transfusion because ineffective erythropoiesis leads to increased GI absorption of iron
 - Serum iron
 - ▢ Measures transferrin-associated ferric iron and fluctuates with daily iron intake
 - ▢ Normal in thalassemia (unless chronically transfused, which leads to increased iron levels)

- Normal or reduced in infection or inflammatory states
- TIBC
 - Elevated in IDA but can be normal to decreased in anemia of chronic disease
 - Oral contraceptives can increase TIBC.
 - Liver disease and malnutrition can decrease TIBC.
- Transferrin saturation
 - Calculated value ($\text{serum iron/TIBC} \times 100$)
 - Low in IDA
- Soluble transferrin receptor
 - Newer test used to determine iron status. It is increased in iron deficiency anemia and also in thalassemia syndromes but not with the anemia of chronic disease.
 - Unlike ferritin, it is not an acute phase reactant and does not increase with inflammation or infection.
 - Should not be used routinely in patients in the evaluation of IDA but only in patients with other illnesses that make the interpretation of ferritin levels difficult
- Lead level and free erythrocyte protoporphyrin (FEP) are both elevated in lead intoxication. Lead poisoning and IDA can exist together.
- Hemoglobin electrophoresis with quantitation

ALERT

Results of hemoglobin electrophoresis are only reliable in patients with normal iron stores. If patients have abnormal iron studies, repeat hemoglobin electrophoresis after adequate period of iron supplementation.

- Decreased hemoglobin A and increased hemoglobin A2 in beta-thalassemia trait
- Normal hemoglobin electrophoresis in patients with one (silent carrier) and two (trait) alpha-globin thalassemic mutations
- Hemoglobin H consists of tetramers of beta globin chains and is seen in patients with three alpha-globin mutations.
- If a patient has been transfused or labs cannot be drawn, labs on the parents may be helpful. A CBC, peripheral smear, and a hemoglobin electrophoresis are usually sufficient.

Diagnostic Procedures/Other

- Bone marrow aspirate is rarely indicated but can be performed if malignancy or disorders of heme synthesis are in the differential.
- Recurrent iron deficiency despite treatment raises suspicion for ongoing blood loss. Hemoccult stools to look for occult GI bleeding, common in children with milk protein allergy. Urinalysis for evidence of renal RBC loss. Pulmonary hemosiderosis can present as recurrent pneumonias.

DIFFERENTIAL DIAGNOSIS

- Iron deficiency
- Hemoglobinopathies
- Chronic lead poisoning
- Anemia of chronic disease
- Sideroblastic anemia

TREATMENT

MEDICATION

- Ferrous sulfate or ferrous gluconate at 6 mg/kg of elemental iron per day in divided doses. Iron salts should be taken with orange juice, as ascorbic acid increases absorption. It should NOT be taken with milk. Milk intake should be stopped completely. Patients on proton pump inhibitors may have decreased absorption.
- Intravenous iron is reserved for patients with malabsorption. Iron sucrose, ferric gluconate, and iron dextran are available in the United States. Anaphylaxis is the primary adverse reaction; iron sucrose and ferric gluconate have lower rates of anaphylaxis.

GENERAL MEASURES

- Many patients are identified on routine well-child screening. Consider therapeutic trial of iron supplementation without further workup if history is suspicious.
- Oral iron supplementation and altered dietary practices improves anemia in almost all patients.
- Parents should be able to report seeing dark black iron in the stool. Iron

can cause nausea, GI discomfort, and constipation. Stool softeners can help.

- Transfusion of RBCs is rarely indicated and is only needed in patients with cardiovascular instability.
- Treatment of lead intoxication is achieved through chelation and removal of environmental exposures.
- In patients with microcytic anemia from hemoglobinopathies, but normal iron indices, iron therapy is not indicated.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Repeat laboratory evaluation can be done in 1 month. Reticulocyte count is the first laboratory value to change and begins to increase within a week after the initiation of iron therapy. Hemoglobin levels take at least 2–3 weeks to respond. MCV is the last index to improve.
- Poor adherence to therapy is the most common cause of treatment failure.
- Children with IDA are more likely to have more difficulties with learning and behavioral problems.
- Children with other hemoglobinopathies should be referred to a hematologist. They do not need further treatment with iron.

- D50.8 Other iron deficiency anemias

MILIA

Jennifer DiPace • Brooke I. Siegel

BASICS

DESCRIPTION

- Common benign, keratin-filled cysts that present as white pinpoint papules most typically on the face but may occur elsewhere on the body (palate, gingiva, penis)
- Subtypes include primary and secondary milia.
 - Primary: spontaneous
 - Secondary: secondary to trauma, medications, or another disease
- Milia en plaque—rare type of primary milia which typically occurs in the posterior auricular area as an erythematous plaque

EPIDEMIOLOGY

- Congenital milia is the most common form of primary milia.
 - Approx. 40% of newborns have milia.
 - Less common in premature infants
 - No gender or racial predilection
- Secondary milia can occur in all age groups.

RISK FACTORS

- Full-term newborns
- Any bullous condition increases the risk of secondary milia, particularly epidermolysis bullosa and porphyria.

GENETICS

- No known genetic predisposition for primary congenital milia, the most common type of milia encountered in pediatrics
- Milia may be a major feature of rare genetic diseases of the skin (Loeys-Dietz syndrome, oral-facial-digital syndrome type 1, Rombo syndrome, or Bazex-Dupré-Christol syndrome).

GENERAL PREVENTION

There are no known preventative measures for primary milia.

PATHOPHYSIOLOGY

Retention of keratin and sebaceous material within the pilosebaceous duct, eccrine sweat duct, or sebaceous collar surrounding fine vellus hair

ETIOLOGY

- Most commonly spontaneous in newborns
- May be related to trauma or blistering conditions in older children

DIAGNOSIS

HISTORY

- Primary congenital milia
 - Asymptomatic
 - Typically present at birth or in the first few days of life
- Secondary milia
 - Recent trauma or burns
 - History of blistering diseases

PHYSICAL EXAM

- 1–2 mm pinpoint, white, pearly smooth papules without surrounding erythema or inflammation
- Distribution is most often on nose, cheeks, chin, and forehead in congenital milia.
- Other places to consider
 - Oral mucosa: Epstein pearls on midline palate, Bohn nodules at gum margins
 - Glans penis cysts

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

The diagnosis of milia can be made by history and physical exam alone. No further diagnostic testing is needed.

DIFFERENTIAL DIAGNOSIS

Other considerations in the newborn period are as follows:

- Sebaceous gland hyperplasia: secondary to exposure to maternal hormones. Lesions are yellowish, follicular papules typically on nose,

cheeks, upper lip, and forehead.

- Neonatal acne: inflammatory, erythematous, papulopustular rash on the face and scalp; usually appears after 1–2 weeks of life, although it may be present at birth
- Erythema toxicum: benign rash in the neonatal period. It is characterized by erythematous macules, often with a central pustule or vesicle.

TREATMENT

- Primary congenital milia require no treatment. Milia are benign, asymptomatic, and self-limiting in this condition.
- Treatment may be indicated in the following settings:
 - Diffuse or persistent milia in older children
 - Milia in areas of trauma or burn leading to cosmetic concern
- Treatment could include topical retinoid or manual extraction.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

No specific monitoring or follow-up is necessary in congenital milia.

PROGNOSIS

- Natural history of primary congenital milia is that the majority of cases will resolve spontaneously within 2–4 weeks without scarring or recurrence.
- In infants or children with diffuse or persistent milia, consider further evaluation for genodermatoses. Such conditions include Loeys-Dietz syndrome, oral-facial-digital syndrome type 1, Rombo syndrome, or Bazex-Dupré-Christol syndrome.

COMPLICATIONS

Cosmetic concerns based on location of milia are usually the only complicating factor.

CODES

ICD10

- L70.2 *Acne varioliformis*
- L85.1 *Acquired keratosis [keratoderma] palmaris et plantaris*
- K09.8 *Other cysts of oral region, not elsewhere classified*

FAQ

- Q: Are milia painful or pruritic?
- A: No. Milia are asymptomatic. If there is pain, pruritus, fever, or other constitutional symptoms, the diagnosis of milia should be reconsidered.
- Q: Are milia contagious?
- A: No, they are not transmitted from person to person. In the case of congenital milia of the newborn, the parent should be reassured that the lesions are not infectious.
- Q: Are milia and miliaria the same condition?
- A: No. Both are benign skin conditions of childhood. However, miliaria is a disorder of the eccrine sweat glands, not of the pilosebaceous duct. Miliaria is characterized by sweat retention and subsequent vesicle formation, usually after prolonged perspiration. Miliaria is thought to occur because of sweat duct obstruction.

MULTICYSTIC DYSPLASTIC KIDNEY

Kelly A. Benedict • Paul Brakeman

BASICS

DESCRIPTION

- Multicystic dysplastic kidney disease (MCDK) is the most severe type of cystic renal dysplasia and is characterized by multiple, noncommunicating cysts which are divided by dysplastic tissue.
- In general, there is no functioning renal tissue in a multicystic dysplastic kidney.
- Involutates over time (usually within the first 5 years)

EPIDEMIOLOGY

- Incidence is 0.3–1 in 1,000 live births.
 - Most cases are detected antenatally.
- Affects boys > girls
- Left kidney > right kidney
 - Usually unilateral but can be bilateral

PATHOPHYSIOLOGY

- Initial growth of the ureteric bud is normal, but renal development halts at a later stage.
- Histology shows disordered renal tissue with areas of undifferentiated mesenchymal cells, abnormal differentiation (i.e., cartilage), rare nephrons

COMMONLY ASSOCIATED CONDITIONS

- Associated anomalies of contralateral GU tract include the following:
 - Vesicoureteral reflux, most common, occurs in ~25%
 - Renal hypoplasia
 - Ureterocele
 - Ureteropelvic junction (UPJ) obstruction
 - Genital anomalies

DIAGNOSIS

HISTORY

Commonly diagnosed by antenatal ultrasound

PHYSICAL EXAM

- Blood pressure at each visit to monitor for hypertension
- Evaluate height and weight
- Neonates: Palpable flank mass may be present.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Creatinine
 - If unilateral kidney is normal, serum creatinine should be normal.
 - One strategy is to monitor serum creatinine at 1 month, 18 months, 5 years, and when growth complete to detect reduced function in remaining kidney.
- Urinalysis to check for proteinuria to evaluate for hyperfiltration in remaining kidney.
- Urinalysis and urine culture, if the patient has any symptoms of UTI or unexplained fever

Imaging

- Renal ultrasound
 - To confirm diagnosis of MCDK and evaluate the contralateral kidney
 - Usually no detectable Doppler flow
 - Useful to follow involution of MCDK and hypertrophy of contralateral kidney
 - 50% will have complete involution by 5 years.
 - Should be done after birth and at 1 month, 2 years, 5 years, and 10 years of life
- Voiding cystourethrogram (VCUG)
 - To evaluate for urinary reflux is controversial.
 - Although rate of VUR is high, most is low-grade and would not require prophylactic antibiotics.

- Patients with febrile UTI should have a VCUG.
- Mercaptoacetyl-triglycine (Mag3) scan
 - To confirm diagnosis and rule out a kidney with severe hydronephrosis

DIFFERENTIAL DIAGNOSIS

Hydronephrotic kidney with poor function

ALERT

If contralateral kidney is abnormal, renal function should be evaluated, and the patient requires ongoing nephrology follow-up.

TREATMENT

MEDICATION

Occasionally, these patients may require antihypertensive medication, an ACE-inhibitor for proteinuria, or urologic evaluation if they suffer from severe VUR or recurrent UTI.

GENERAL MEASURES

- No specific treatment is needed for MCDK.
- Previously, nephrectomy was treatment of choice; however, given low risk of hypertension and malignancy, currently, routine nephrectomy of MCDK is not recommended.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Blood pressure monitoring
 - Anecdotally, these patients were thought to be at risk for hypertension.
 - However, more recent studies show no increased risk.
- Patients may be at increased risk for developing Wilms tumor in MCDK.
 - Risk 3–10 per 10,000
 - Monitored with periodic renal ultrasound and abdominal exam

- Periodic urinalysis to evaluate for proteinuria and serum Cr to monitor renal function

PROGNOSIS

- Patients with contralateral anomalies are at greater risk for developing chronic kidney disease (CKD).
- Patients with normal contralateral kidneys may have hyperfiltration (~30%) and proteinuria (~10%).
- Risk of developing Wilms tumor
 - May be as high as 3–10 times higher than the general population (1 in 10,000)
 - This estimate is controversial, however, as a systematic review of 1,041 children with unilateral MCDK found no cases of Wilms tumor

ADDITIONAL READING

CODES

ICD10

- Q61.4 Renal dysplasia
- Q61.3 Polycystic kidney, unspecified

FAQ

- Q: What can be done to preserve contralateral renal function?
- A: Well-controlled blood pressure, treatment of proteinuria, and quick treatment of UTI may decrease the progression of CKD.
- Q: Are patients with MCDK at an increased risk for developing a UTI?
- A: No. Risk of UTI is ~5%, consistent with general pediatric population. However, if a patient with MCDK has a febrile UTI, a VCUG is recommended to evaluate for VUR.
- Q: Can patients with unilateral MCDK live a normal life?
- A: Yes, if the contralateral kidney is normal. Patients should be encouraged to live a healthy lifestyle. If the patient has hypertension or diabetes, they should be tightly controlled.
- Q: How is this different than polycystic kidney disease?
- A: Polycystic kidney disease (PKD) tends to affect both kidneys and is a progressive disorder. Infants with PKD have relatively normal kidneys at birth and cystic disease develops over time. MCDK is not progressive and usually affects one kidney. PKD is an inherited condition, whereas MCDK is usually not inherited.

MUMPS/PAROTITIS

Kathleen Gutierrez

BASICS

DESCRIPTION

Centers for Disease Control and Prevention (CDC) clinical case definition for mumps: illness with acute onset of unilateral or bilateral, tender, self-limited swelling of the parotid or other salivary gland, lasting ≥ 2 days, without other apparent cause

EPIDEMIOLOGY

Incidence

- In the prevaccine era, 90% of all children contracted mumps virus infection by 14 years of age.
- Incidence of this once very common disease has declined dramatically since the advent of universal childhood immunization.
- Outbreaks, however, continue to occur.
- 200–300 cases per year reported in the United States since 2001
- In early 2006, a large epidemic broke out in Iowa and neighboring states:
 - 11 states reported $>2,500$ cases.
 - Largest epidemic since 1988
 - Median age of patient was 21 years (mostly college students)
 - Led CDC and American College Health Association to recommend 2 doses of MMR vaccine to be a requirement for college entry
- In 2006, 81–100% of children entering United States schools had received 2 doses of mumps vaccine.
- In 2009–2010, an outbreak of mumps occurred in a highly vaccinated population in the northeastern United States. Intense exposure facilitated transmission. Previous vaccination appeared to limit the severity of disease.
- Seroprevalence of antibody to mumps virus in the United States population (1999–2004) is estimated at 90%.

GENERAL PREVENTION

- 2 combination mumps vaccine are used:
 - MMR: Measles, mumps, rubella
 - MMRV: Measles, mumps, rubella, varicella
- A single 0.5-mL SC injection of live mumps vaccine (MMR or MMRV) is recommended at 12–15 months.
- A second vaccination is recommended between 4 and 6 years of age.
- The efficacy of 2 doses of vaccines is estimated at approximately 80–90%.
- Primary vaccine failure and waning vaccine-induced immunity have been reported.
- Some have suggested the need for a 3rd vaccination to mitigate waning immunity. Preliminary studies indicate no increase in adverse effects after a 3rd vaccination.
- The 1st dose of MMR vaccine sometimes causes fever and rash:
 - These symptoms occur 7–12 days after immunization.
 - Measles component is usually the culprit.
- Both MMRV and MMR vaccines, but not varicella vaccine alone, are associated with increased outpatient fever visits and seizures 5–12 days after vaccination in 12- to 23-month-olds, with MMRV vaccine increasing fever and seizure twice as much as the MMR + varicella vaccine.
- Vaccine should not be administered to children who are immunocompromised by disease or pharmacotherapy, as well as to pregnant women.
- If a child has recently received immune globulin, administration of MMR vaccine should be delayed (for 3–11 months depending on the dose of IG).
- Children with HIV infection who are not severely immunocompromised should be immunized with the MMR vaccine.
- 1 attack of mumps (clinical or subclinical) usually confers lifelong immunity.
- Links of the MMR vaccine to autism by Andrew Wakefield MB, BS in a 1998 Lancet publication have now been exposed as fraudulent.

PATHOPHYSIOLOGY

- The virus is spread by contact with respiratory secretions.
- The mumps virus enters via the respiratory tract, and a viremia ultimately ensues.
- The virus spreads to many organs, including the salivary glands, gonads, pancreas, and meninges.
- Period of communicability: 7 days before to 9 days after onset of parotid swelling
- Most communicable period: 2–3 days before to 5 days after onset of parotid swelling
- Incubation period: 12–25 days after exposure
- Humans are the only known host for mumps.

ETIOLOGY

- Epidemic parotitis is caused by mumps, an RNA virus in the Paramyxoviridae family.
- Other viral causes of parotitis include Epstein-Barr virus, cytomegaloviruses, influenza, parainfluenza, and enteroviruses
- Parotid enlargement can be an initial sign in HIV-infected children.
- Bacterial cases are usually secondary to *Staphylococcus aureus* (suppurative parotitis).
- Streptococci, gram-negative bacilli, and anaerobic infections are also possible.
- Rare childhood cases may be secondary to an obstructing calculus, foreign body (sesame seed), tumors, sarcoid, Sjögren syndrome, or various drugs (antihistamines, phenothiazines, iodine-containing drugs/contrast media).

COMMONLY ASSOCIATED CONDITIONS

- Salivary adenitis
 - Most common manifestation of mumps
 - 1/3 of cases occur subclinically
- Epididymo-orchitis
 - Up to 35% of adolescent mumps cases are complicated by orchitis.
 - Orchitis develops within 4–10 days of the onset of the parotid swelling.
 - Sterility is uncommon.

- Aseptic meningitis
- Pancreatitis
 - Mild inflammation is common.
 - Serious involvement is rare.

DIAGNOSIS

HISTORY

- Prodromal symptoms uncommon but may include the following:
 - Fever
 - Anorexia
 - Myalgia
 - Headache
- Onset usually pain and swelling in front of and below ear
- Swelling
 - Usually starts on one side of the face, then progresses to the other
- Mild fever
 - Usually accompanies parotid swelling
- Dysphagia and dysphonia are common.
- Testicular pain and swelling, along with constitutional symptoms, occurs in postpubertal males usually 1 week after parotid swelling but occasionally simultaneously or alone.
- Epigastric pain and constitutional symptoms with pancreatic involvement
- Fever, headache, and stiff neck with meningitis
- Behavioral changes, seizures, and other neurologic abnormalities are rare.
- Other symptoms are analogous to the particular organ involved.

PHYSICAL EXAM

- Nonerythematous, tender parotid swelling (erythema seen with suppurative parotitis)
- Swelling ultimately obscures the mandibular ramus.
- The ear is displaced upward and outward.
- Importantly, up to 30% of symptomatic cases of mumps are not

associated with parotitis.

- Submaxillary and sublingual glands also may be swollen.
- Inflammation may be noted intraorally at the orifice of Stensen duct.
- Presternal edema is occasionally noted.
- Mumps are infrequently associated with truncal rash.
- Tender, edematous testicle in mumps orchitis (usually unilateral)
- Ask the patient if the pain (at the parotid) intensifies with the tasting of sour liquids:
 - Have the patient suck on a lemon drop or lemon juice, and note any discharge from Stensen duct.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Uncomplicated parotitis
 - Mild leukopenia with lymphocytosis
- Suppurative parotitis and mumps orchitis
 - Leukocytosis
- Pancreatic involvement
 - Hyperamylasemia and elevated serum lipase
- Salivary adenitis without pancreatic involvement
 - Isolated hyperamylasemia
- Gram stain and culture of pus expressed from Stensen duct is diagnostic in suppurative parotitis.
- CDC lab criteria for mumps diagnosis
 - Isolation of mumps virus from clinical specimens: blood, urine, buccal swab (Stensen duct exudates), throat washing, saliva, or CSF
 - Detection of mumps virus nucleic acid by reverse transcriptase PCR
 - Obtain specimens for culture and PCR as soon as possible after onset of symptoms, particularly in vaccinated individuals.
 - Positive serologic test for mumps IgM

ALERT

Mumps IgM may be negative in MMR-vaccinated individuals who develop mumps disease. A negative IgM test in these patients does not rule out mumps.

- Significant rise between acute and convalescent titers in mumps IgG

levels by any standard assay (complement fixation, neutralization, hemagglutination inhibition, or enzyme immunoassays)

ALERT

Paired acute and convalescent serum titers may not show a rise in IgG levels in MMR-vaccinated individuals with mumps disease.

- For detailed information regarding collection and interpretation of laboratory studies and mumps case reporting, see <http://www.cdc.gov/mumps/>.

Imaging

Sialography is useful to evaluate for stones or strictures but is contraindicated in acute infection.

Diagnostic Procedures/Other

Lumbar puncture if meningitis is suspected: CSF pleocytosis (predominately mononuclear)

DIFFERENTIAL DIAGNOSIS

- Mumps parotitis can be distinguished from the other viral causes by clinical presentation along with specialized laboratory studies.
- Cases of tuberculous and nontuberculous (atypical) mycobacterial parotitis are rare but have been reported.
- Salivary calculus can be diagnosed by sialogram.
- Recurrent childhood parotitis, also known as juvenile recurrent parotitis
 - Rare, recurrent swelling of parotids
 - Seen in children 3–6 years old
 - Not associated with suppuration or external inflammatory changes
 - Largely a diagnosis of exclusion
- Cervical or preauricular adenitis
 - May simulate parotitis
 - Close anatomic localization should be diagnostic.
- Infectious mononucleosis and cat-scratch disease are other considerations.
- Drug-induced parotid enlargement occasionally occurs.
- Malignancies of the parotid are extremely rare.

- Sjögren syndrome is rare but reported in children.
- Pneumoparotitis is seen in those with a history of playing a wind instrument, glass blowing, scuba diving, and even general anesthesia.

TREATMENT

GENERAL MEASURES

- Supportive therapy is all that is required in mumps parotitis.
- Antibiotics directed against *S. aureus* should be used in cases of suppurative parotitis.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Most children have resolution of glandular swelling by ~1 week.
- Disappearance of testicular pain and swelling can be expected 4–6 days after onset.
- Testicular atrophy is common, although infertility is rare.
- Markedly elevated pancreatic enzymes should be monitored until they improve.
- Children should not return to school until at least 5 days after the onset of parotid swelling.
- Isolation: standard precautions; droplet precautions for 5 days after onset of parotid swelling

PROGNOSIS

Complete recovery in 1–2 weeks is the rule.

COMPLICATIONS

- Meningitis
 - >50% have a CSF pleocytosis.
 - This “aseptic meningitis” is usually benign.
- Encephalitis: rarely causes permanent sequelae
- Cerebellitis
- Facial nerve palsy

- Oophoritis, nephritis, thyroiditis, myocarditis, mastitis, arthritis, transient ocular involvement, deafness, and sterility (all rare)

FAQ

- Q: Should immunization be deferred in children with intercurrent illness?
- A: No. Children with minor illnesses, even with fever, should be vaccinated.
- Q: Should vaccination be withheld in children living with immunocompromised hosts?
- A: No. Vaccinated children do not transmit mumps vaccine virus.

MUNCHAUSEN SYNDROME BY PROXY (CHILD ABUSE IN THE MEDICAL SETTING)

John Stirling

BASICS

DESCRIPTION

- Symptoms of illness in a child that are exaggerated, fabricated, or induced by a caretaker. There is usually no underlying health disorder in the child.
- Results in harm to the child victim through repeated interactions with the medical care system, including unnecessary tests, medications, and surgeries
- Known by many names, including the following:
 - “Pediatric condition falsification”
 - “Caregiver-fabricated illness”
 - “Medical child abuse”
 - “Factitious disorder by proxy”
- All refer to harm that befalls children through the actions of a caregiver in a medical setting.
- Symptoms decrease when the child is separated from the perpetrator.

EPIDEMIOLOGY

- Rare, with no typical presentation. The most commonly described symptoms include apnea, seizures, factitious fevers, feeding and GI problems, failure to thrive, behavioral problems, bleeding, and sepsis.
- Presenting symptoms may present along a spectrum of severity from mild to fatal.
- Most victims are <4 years of age, but victims may often be older children.
- Males and females are equally represented.
- Symptoms may be present for years before factitious illness is considered and diagnosed.
- Morbidity is significant; cases may be fatal, especially those involving

surreptitious administration of medications, poisoning, or inducing apnea.

ETIOLOGY

- The parent, most commonly the mother, exaggerates, fabricates, or induces the illnesses.
- The term Munchausen syndrome by proxy refers to specific instances where the caregiver is motivated by a desire for self-aggrandizement. As such, it only defines a subset of factitious illnesses.
- Medical providers are advised to concentrate on the specific harm done and the patient's safety rather than on the caregiver's motives.

DIAGNOSIS

HISTORY

Factitious illness should be considered when

- Symptoms and signs described are incongruous with patient's appearance or are seen only when the caregiver is present.
- Diagnostic tests fail to confirm the diagnosis.
- Usual medical treatment is ineffective in alleviating the presenting symptom.
- Caregiver seems unusually knowledgeable or aggressive in suggesting particular medical interventions.
- "Red flags":
 - Frequent moves
 - Siblings who have either died or had unusual medical illnesses
 - Seeking care at a variety of facilities
 - Reluctance to accept less severe diagnoses

PHYSICAL EXAM

- Examinations are usually normal.
- When symptoms have been exaggerated, findings are less than expected (e.g., mild asthma or hyperactive behavior).
- When symptoms have been inflicted, findings are often atypical for the medical condition being considered.
- Failure to thrive or obesity are common.

- Patient may have evidence of additional injuries, including old fractures or scars.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Workup is dictated by the presenting complaint: EEG for seizures, cardiac monitors for syncope, pneumogram for apnea, etc.
- When the workup is consistently normal and symptoms are still described, the differential diagnosis should include factitious disorders.
- If bleeding is the major presentation, identify the blood as the patient's (as opposed to that of the perpetrator or an animal).
- A toxicology screen may be helpful for unusual presentations of poisoning.
- Repeated blood or urine cultures with multiple organisms suggest intentional contamination of the specimen or of the patient.
- Special care must be taken to prevent the caregiver from tampering with diagnostic testing.
- If separating the perpetrator from the patient results in disappearance of symptoms, this "test" may suggest the diagnosis.
- Covert video monitoring of a patient's room may demonstrate the perpetrator harming the child.

DIFFERENTIAL DIAGNOSIS

Factitious disorders often mimic difficult-to-diagnose diseases:

- Apnea/apparent life-threatening event
- Asthma
- Seizures
- Intermittent fevers
- Genitourinary or GI bleeding
- Unexplained abnormalities in electrolytes
- Feeding problems, chronic diarrhea, or vomiting
- Infections with multiple organisms found in blood or urine culture

ALERT

Diagnosis is often delayed and may take months. There are often impediments:

- Physicians and nursing personnel may be reluctant to suspect the

parent because of their own relationship to the family.

- It can be difficult to acknowledge that the child has been harmed by well-intentioned but unnecessary medical procedures or investigations.
- It is often necessary to review records from multiple institutions covering months or years of care. These are often unsuspected and may be difficult to obtain.

TREATMENT

GENERAL MEASURES

- Effective care requires that medical providers work closely with other professionals in the community, both to gather information and to ensure the patient's eventual safety.
- Child protective services, mental health services, and law enforcement agencies each have a role to play. Evaluations must be multidisciplinary.
- A variety of interventions may be appropriate depending on the severity of the presentation, from counseling to foster care to criminal prosecution.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Long-term follow-up is necessary for both victim and caregiver.
- Watch for recurrence of original presentation, or unusual new symptoms, with special attention to the child's self-image.

PROGNOSIS

- If undiagnosed, morbidity and mortality may be significant.
- Victims are essentially taught to be ill, sometimes with lifelong consequences.
- As there are such diverse presentations, reliable, specific data on long-term morbidity are lacking.

- F68.11 Factitious disorder w predom psych signs and symptoms

FAQ

- Q: When should factitious disorders be reported to child abuse authorities?
- A: When there is reasonable suspicion (note: not certainty) that a child is coming to harm due to the actions of a caregiver. When suspicion exists, it is important to involve community agencies in the investigation.
- Q: Is it legal to use video surveillance or to separate the parent from the

patient?

- A: Yes, if done properly. When suspicions of factitious illness are high and other laboratory tests are negative, diagnosis may require these measures. Hospital administration and/or risk management should be consulted on how to proceed. Child abuse pediatricians may also provide assistance.

MUSCULAR DYSTROPHIES

Jessica Rose Nance

BASICS

DESCRIPTION

- Muscular dystrophies (MDs) are a heterogeneous group of disorders characterized by a slow degeneration of muscle with consequent weakness and contracture deformity. Cardiac muscle can be involved in some forms.
- MDs with childhood onset can be divided into 5 groups:
 - Dystrophinopathies (i.e., Duchenne MD [DMD], Becker MD [BMD])
 - Limb girdle MDs (LGMDs)
 - Congenital MD (CMD)
 - Facioscapulohumeral MD (FSH-MD)
 - Emery-Dreifuss MD (EDMD)
- Types of MDs can be differentiated by their clinical features (i.e., pattern of muscle weakness, joint contractures), age of onset, genetic test results, and/or muscle biopsy.

EPIDEMIOLOGY

- Dystrophinopathies
 - DMD: 1 per 3,500 boys (most common)
 - BMD: 1 per 30,000 boys
- LGMD (childhood onset): 5–10 per million
- CMD (all types): 1–10 per 100,000
- FSH-MD: 1 per 20,000
- EDMD: 1 per 300,000

RISK FACTOR

Genetics

Genetic testing is clinically available for most MDs:

- Dystrophinopathies (DMD/BMD): X linked
 - DMD exon duplication/deletion in 70% cases

- DMD point mutation in almost 30% cases
- New mutations of the dystrophin gene are common, and hence, most cases have no affected relatives despite X-linked recessive inheritance. New mutations in the dystrophin gene are found frequently in the mothers of affected boys.
- LGMD: Most childhood-onset LGMDs are autosomal recessive.
 - Sarcoglycanopathies (LGMD2C–F) make up roughly 70% of childhood-onset LGMDs.
 - LGMD2I (FKRP): 5% childhood-onset LGMDs
- CMD: most autosomal recessive (12 genes)
 - Nonsyndromic (LAMA2, COL6A1–COL6A3)
 - Syndromic (e.g., POMT1, POMGT1, FKRP)
- FSH-MD: autosomal dominant (D4Z4 deletion)
- EDMD: X linked (EMD or FHL1 mutations) or autosomal dominant (LMNA mutation)

PATHOPHYSIOLOGY

- Deficient or defective muscle fiber proteins causing fiber dysfunction and/or increased membrane fragility
- Muscle biopsy: Increased variability in muscle fiber size (i.e., degenerating, regenerating, and necrotic fibers), split muscle fibers and increased internal nuclei, fibrosis. Immunohistochemistry may note decreased/absent sarcolemmal proteins (e.g., DMD, LGMDs, CMDs).

DIAGNOSIS

HISTORY

- Neonatal hypotonia, feeding difficulty (CMD)
- Gross motor delay/regression
- Global developmental delay (syndromic CMD) or learning disorders (DMD)
- Exercise intolerance/cramping
- Myalgia (BMD, DMD, FSH-MD)
- Seizures: merosin-negative and syndromic CMD
- DMD

- Onset typically <5 years old with gross motor delays, increasing falls, toe walking, and proximal muscle weakness (e.g., difficulty climbing stairs, rising from floor)
- Dependence on wheelchair for mobility usually between 8 and 12 years of age
- Calf pseudohypertrophy is common.
- Serum creatine kinase (CK) levels are markedly elevated (often >50× normal). Serum transaminases may be elevated (muscle origin).
- Higher incidence of learning difficulties, ADHD, autism, OCD. Loss of ambulation occurs around 13–16 years old. Incidence of cardiomyopathy increases with age, although respiratory muscle weakness (e.g., ineffective cough, hypoventilation, and eventual respiratory failure) is the cause of death in about 75% of DMD boys.
- BMD
 - Milder version of DMD phenotype; onset typically >8 years old
 - Boys remain ambulatory into their 20s.
 - Higher incidence of myalgia, cramps, and myoglobinuria in BMD (vs. DMD)
 - Rarely, cardiomyopathy may be sole or presenting feature.
- LGMD
 - Proximal muscle weakness (neck flexors, hip flexors, shoulder girdle)
 - Onset and progression highly variable
 - Sarcoglycanopathies (LGMD2C–F) can mimic DMD (including calf pseudohypertrophy).
 - Patients are cognitively normal.
- CMD
 - Hypotonia, gross motor delay, weakness, and feeding difficulty typically noted from birth
 - Two main groups of CMDs: (1) nonsyndromic CMD due to defective structural proteins (e.g., merosin-negative CMD, Ullrich/Bethlem MD) and (2) syndromic CMD due to defective glycosylation (e.g., Fukayama MD, muscle-eye-brain disease,

Walker-Warburg syndrome)

- Most children with nonsyndromic CMD are cognitively normal. Seizures may occur in merosin-negative CMD (20–30%). Ullrich MD shows characteristic proximal contractures and distal joint hyperlaxity (fingers, toes). Bethlem MD shows proximal muscle weakness and distal contractures.
- Syndromic CMDs show variable severity, often associated with intellectual disability, eye manifestations, and brain anomalies (e.g., neuronal migration disorders, seizures, hydrocephalus).
- FSH-MD
 - Onset typically <20 years old with facial weakness, scapular winging, and humeral (biceps, triceps) weakness
 - Relative sparing of deltoid strength is seen.
 - Rare infantile-onset cases have been reported.
 - Retinal vasculopathy (Coates disease) and sensorineural hearing loss can occur.
 - Cardiac arrhythmia is occasionally noted (<10%).
- EDMD
 - Onset typically in 1st decade
 - Patients initially present with joint contractures (neck, elbow, and ankles) disproportionate to degree of weakness.
 - Muscle weakness and wasting develop in biceps, triceps, spinatus muscles, and (later) tibialis anterior and peroneal muscles.
 - Cardiac arrhythmias are common by 2nd decade.
 - Pseudohypertrophy is not seen.

PHYSICAL EXAM

- Facial weakness (FSH-MD)
- Pattern of muscle weakness and atrophy
- Scapular winging (FSH-MD)
- Pattern of joint contractures (EDMD) or joint hypermobility (Ullrich MD)
- Pattern of muscle pseudohypertrophy (e.g., calf muscles in DMD, BMD, LGMD)
- Reflexes normal to mildly decreased (except for joints with contractures). Reflexes are not lost until late in disease course.

- Normal sensory exam
- Scoliosis: rapid progression if nonambulatory
- Gower maneuver (when arising from sitting to standing position, patient must put his hand on his knees and “climb up himself”)
- Gait abnormalities (e.g., toe walking, exaggerated lumbar lordosis, Trendelenburg gait)
- Cardiomyopathy (tachycardia, hypotension)
- Respiratory weakness (weak cough)

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serum CK
 - Markedly elevated in DMD, BMD, some LGMD, and CMDs (e.g., Fukuyama MD)
 - CK may be normal late in disease owing to severe muscle atrophy.
 - CK is typically normal in FSH-MD and some CMDs (e.g., Ullrich MD). Normal to mild CK elevation is seen in EDMD.

Diagnostic Procedures/Other

- Nerve conduction study: Merosin-negative CMD may show mild conduction velocity slowing.
- EMG: nonspecific myopathic changes
- MRI muscle: signal change noted reflecting muscle atrophy and fatty infiltration. May guide site of optimal muscle biopsy. Pattern of muscle involvement maybe helpful in diagnosis.
- MRI brain: Merosin-negative CMD shows diffuse white matter signal abnormalities (typically visible by 6 months old).
- Muscle biopsy can be used to confirm dystrophy (see “[Differential Diagnosis](#)”), whereas immunohistochemistry can help in diagnosis of nondystrophic MDs (e.g., LGMD) if DMD genetic testing is normal.

DIFFERENTIAL DIAGNOSIS

- Inflammatory myopathy (e.g., dermatomyositis)
- Metabolic myopathy
- Congenital myopathy
- Anterior horn cell disease (e.g., SMA)
- Polyneuropathy (e.g., CIDP)

- Myotonic dystrophy (different pathology)

TREATMENT

MEDICATION

- Early attention should be directed to prevention of deformity that encumbers function with weakness and prevention of obesity.
- For DMD: Corticosteroids (prednisone [0.75 mg/kg/day] or deflazacort) 0.9 mg/kg/day: Improve muscle strength, prolong independent ambulation (mean = 2.5 years), delay onset of cardiomyopathy and scoliosis, and improve pulmonary function testing. Patients must be monitored for adverse effects of steroid therapy (weight gain, bone demineralization, behavior issues).
- All other MDs: no treatment

ADDITIONAL TREATMENT

General Measures

- Supportive care (e.g., routine immunizations)
- Psychological and/or school support
- Night splinting (DMD, LGMD) to prevent progression of joint contractures
- Physiotherapy: passive stretching
- Orthopedic evaluation: scoliosis surveillance and/or management of joint contractures
- Genetic counseling
- Ophthalmology (retinal) evaluation (FSH-MD), cataract surveillance (DMD patients on steroids)

ADDITIONAL THERAPIES

Several potential therapies for DMD are being studied (e.g., antisense oligonucleotide therapy, DMD nonsense mutation read-through therapy, myostatin inhibitor therapy, stem cell therapy). These therapies remain experimental and are not commercially available in North America or Europe.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Respiratory surveillance
 - Baseline pulmonary evaluation (DMD, CMD) with periodic PFT surveillance, incentive spirometry, and/or cough assist devices
 - Monitor for decline in PFT scores (especially FVC) and/or clinical evidence of nocturnal hypoventilation (e.g., morning headache/nausea, daytime somnolence, orthopnea). If noted, obtain sleep study to evaluate for potential need for nocturnal bilevel positive airway pressure (BiPAP).
 - Monitor kyphoscoliosis.
- Orthopedic surveillance
 - When progressive scoliosis is evident, treatment with spinal fusion is indicated to prevent deteriorating quality of life associated with severe deformity.
 - Following loss of ambulation in DMD, affected boys are at high risk for progressive, collapse-type scoliosis and should be screened at 6–12-month intervals until young adult years.
- Cardiology surveillance
 - Cardiomyopathy is well documented for many MDs, necessitating periodic echocardiogram and ECG surveillance studies for DMD, BMD, LGMD1B, LGMD2C–F (20–30% risk), LGMD2I (30–60% risk), merosin-negative CMD, and EDMD.
 - American Academy of Pediatrics (AAP) guidelines recommend DMD patients receive complete cardiac evaluation every 2 years (until age 10 years) and annually thereafter.
 - Cardiac arrhythmia surveillance is required for EDMD, LGMD1B, and FSH-MD (<10% risk); also consider for any MD patient showing echocardiogram evidence of a cardiomyopathy.
 - Cardiac transplantation should be considered for BMD patients with severe cardiomyopathy, particularly if they have relatively minor skeletal muscle involvement.

PROGNOSIS

- DMD: life expectancy into late 20s, death typically from respiratory failure. Life expectancy is improving with advances in care and realistic hope for specific therapies (fueled by these advances).
- BMD: life expectancy into mid-40s, death typically due to cardiomyopathy
- LGMD: variable. Sarcoglycanopathies may show a DMD-like progression. Autosomal dominant LGMD later onset with slow progression
- FSH-MD: Normal life expectancy

CODES

ICD10

- G71.0 Muscular dystrophy
- G71.2 Congenital myopathies

FAQ

- Q: What test should be ordered first in a boy with suspected DMD?
- A: After confirmation that CK is elevated, 1st-line testing is DMD duplication/deletion analysis (detects 70% cases). If negative, DMD gene should be sequenced. Muscle biopsy is typically reserved for patients with negative genetic testing (i.e., LGMD) or if there is clinical suspicion for inflammatory myopathy (e.g., dermatomyositis). Nerve conduction studies can help differentiate neurogenic disorders (i.e., SMA, polyneuropathy) but show nonspecific myopathic changes in MDs.
- Q: What is the recurrence risk in DMD?
- A: About 2/3 of mothers of males with DMD are carriers. If a female DMD carrier has a son, that boy has a 50% chance of having DMD. If she has a daughter, that girl has a 50% chance of becoming a DMD carrier. Males with DMD or BMD will transmit the mutated gene to all daughters (who become carriers). The sons of DMD males will not be affected (X linked).
- Q: Can female DMD carriers be symptomatic?
- A: Yes. Owing to the random nature of X-chromosome inactivation, roughly 10% of female DMD heterozygotes may develop cardiomyopathy and/or proximal muscle weakness. The AAP recommends female carriers receive a cardiac evaluation in early adulthood and every 5 years after 25–30 years old.

MYASTHENIA GRAVIS

Diana X. Bharucha-Goebel

BASICS

DESCRIPTION

- A neuromuscular (NM) disease presenting with varying weakness that worsens with exercise and improves with rest
- 3 types of myasthenia gravis seen in childhood:
 - Neonatal transient: 10–20% of infants born to mothers with autoimmune myasthenia
 - Congenital myasthenia: rare; <10% of all childhood myasthenia. Weakness usually starts within first 2 years of life; caused by inherited disorder in NM transmission; classified by mutation site (presynaptic, postsynaptic) or by molecular genetics
 - Juvenile myasthenia: autoimmune disorder similar to adult-onset, autoimmune myasthenia gravis; mostly due to production of antibodies against the acetylcholine receptor (AChR). Relatively rare: 1 new diagnosis per million per year; average age of onset 10–13 years, with a female predominance of 2:1 or 4:1

EPIDEMIOLOGY

- Rare: incidence 4–6 per million per year
- Prevalence: 40–80 per million
- Children account for 10–15% of cases of myasthenia gravis annually.

RISK FACTORS

Genetics

- Congenital type: generally autosomal recessive (check consanguinity)
- Occasional family history

PATHOPHYSIOLOGY

- Caused by a disruption in signal transmission from the motor neuron to the muscle. Sensory or cognitive symptoms are absent.
 - The motor nerve terminal lies in close proximity to the end plate, a

region of the muscle cell membrane with a high concentration of AChR.

- Normally, when stimulated, the motor nerve terminal releases acetylcholine that binds receptors, causing muscle contraction. The cleft contains acetylcholinesterase (AChE), an enzyme that breaks down acetylcholine and helps terminate muscle contractions.
- Autoimmune form (juvenile or JMG)
 - Autoantibody blocks AChR activity → increased rate of receptor breakdown → fewer receptors are present → leads to decreased muscle contraction
 - AChR antibody accounts for ~85% of JMG.
 - Thymic pathology is believed to be central to pathogenesis of autoimmune myasthenia; however, thymic pathology (e.g., hyperplasia) is present in less than 1/3 of children who undergo thymectomy.
 - Of JMG patients without elevated AChR antibody, some are positive for antibodies to muscle-specific kinase (MuSK).
 - A small percentage of autoimmune JMG patients do not have an identified antibody.
- Neonatal (transient) myasthenia: Infants are born with weakness and hypotonia.
 - Due to maternal–fetal transmission of antibodies against AChR
 - Severity of maternal symptoms does NOT predict likelihood that infant will be affected. Occasional arthrogryposis (joint contractures) reflects decreased fetal movement in utero.
 - High levels of maternal antibodies against fetal form of AChR pose an increased risk of disease.
 - Previous pregnancy with affected infant places future child at much higher risk.
 - In rare cases, mother is asymptomatic despite placentally transmitted antibody.
- Congenital myasthenic syndromes: group of genetic disorders of NM junction; classified by site of NM transmission defect and more recently by molecular genetics
 - Includes presynaptic defects, synaptic defect (due to end plate

AChE deficiency), postsynaptic defects (primary AChR deficiency, primary AChR kinetic abnormality, or perijunctional skeletal muscle sodium channel mutation)

COMMONLY ASSOCIATED CONDITIONS

- In juvenile myasthenia, other autoimmune disorders may occur:
 - Hyperthyroidism in 3–9% of patients
 - Small increase in incidence of juvenile idiopathic arthritis and diabetes
- Some reports suggest increased incidence of seizures in autoimmune myasthenia
- Screening for thymoma at initial diagnosis by chest CT or MRI scan is appropriate:
 - Children appear to have lower incidence of thymic tumor or pathology than adults with autoimmune myasthenia.

DIAGNOSIS

Most patients present with ptosis and diplopia alone or in combination with swallowing difficulties, dysphonia, and generalized weakness.

HISTORY

- Neonatal transient: mother with known autoimmune myasthenia or history of weakness, ptosis, or dysphagia
- Congenital myasthenia
 - Usually presents in first 1–2 years of life (rarely later) with hypotonia, poor feeding, ptosis, and delayed motor milestones
 - Possible family history of similar weakness
 - No response to thymectomy or immunosuppressant medications
- Juvenile myasthenia
 - Gradual onset of fatigable weakness over weeks, months, or even years
 - Symptoms are worse after prolonged activity or late in the day.
 - Intermittent ptosis, diplopia, dysphagia, and dysphonia are common.
 - Ocular myasthenia gravis: a subset of 10–15% of patients with myasthenia who have isolated ptosis and ophthalmoplegia

(weakness in extraocular muscles) in absence of systemic or bulbar symptoms

PHYSICAL EXAM

- Neonatal transient: from birth, hypotonic infant with weak suck, weak cry, and ptosis
- Congenital and juvenile myasthenia
 - Weakness of neck flexion
 - Reflexes often preserved
 - Ptosis, ophthalmoplegia, and variable feeding problems often are earliest findings.
 - Generalized weakness in limbs may be asymmetric. Weakness is more pronounced with endurance tasks.
 - Shallow, rapid respirations and/or vital capacity <50% predicted (in older children) suggest impending respiratory failure.
 - Check for scoliosis.

DIAGNOSTIC TESTS & INTERPRETATION

- Juvenile myasthenia
 - Nerve conduction and electromyography studies: Repetitive stimulation of nerve shows diagnostic decremental response due to decreased AChR. May be normal in some patients; normal study doesn't exclude diagnosis.
 - Single-fiber electromyography measures variability in firing rates of 2 muscle fibers innervated by different branches of the same motor neuron. Large variability suggests higher threshold for activation. This test is more sensitive than repetitive nerve stimulation but is technically more challenging and often requires sedation.
 - Edrophonium chloride (Tensilon) is a fast-acting AChE-blocking agent (no longer widely available in the United States).
 - Patients with myasthenia often show immediate, transient improvement in muscle strength after IV infusion.
 - Measurable weakness should be present prior to testing, and a placebo dose of saline should be given initially.
 - Although risk of hyperreactive cholinergic response with muscle weakness and bradycardia is low, atropine should always be

available, and vital signs should be closely monitored during test; contraindicated in patients with heart disease

- Measurable cranial nerve dysfunction, such as ptosis, is often responsive to edrophonium.
- Children receive 20% of 0.2 mg/kg dose (0.04 mg/kg) of Tensilon over 1 minute; if no response after 45 seconds, the rest of the dose (0.16 mg/kg) is given, up to a maximum of 10 mg. Have atropine and epinephrine readily available.

Lab

- AChR antibody levels (most specific): elevated in ~80% of patients with generalized myasthenia and ~50% of patients with isolated ocular myasthenia
- Second most common antibody is to muscle-specific receptor tyrosine kinase (MuSK-Ab). Antibodies to striated muscle protein and low-density lipoprotein receptor-related protein are also described but are rare.

DIFFERENTIAL DIAGNOSIS

- Generalized botulism
 - In endemic areas, may cause generalized weakness in infants; caused by Clostridium toxin that blocks release of acetylcholine from nerve terminal
- Guillain-Barré syndrome or acute inflammatory demyelinating polyneuropathy
 - Frequent cause of rapidly progressive generalized weakness
 - Unlike myasthenia, patients often have sensory symptoms, and areflexia occurs even with minimal weakness.
- Acute spinal cord compression
 - Can present as generalized (but not variable) weakness of extremities
 - Look for sparing of facial and extraocular muscles, a sensory level, bowel or bladder dysfunction, and hyperactive reflexes.
- Organophosphate ingestion: pyridostigmine bromide (Mestinon)
 - Can cause profound weakness
 - Symptoms of parasympathetic hyperactivity are usually present:

hypersalivation, miosis, diarrhea, and bradycardia.

- Penicillamine used to treat autoimmune disorders can induce autoantibodies that bind AChR, causing myasthenia gravis.

TREATMENT

INITIAL STABILIZATION

Treat respiratory failure, a rare but serious complication of juvenile myasthenia gravis.

GENERAL MEASURES

- Neonatal myasthenia
 - Severity of disability should be used to guide aggressiveness of therapy.
 - Respiratory or swallowing impairment: Pyridostigmine syrup, 60 mg/5 mL, 1 mg/kg/dose q4h up to a daily maximum of 7 mg/kg/24 h divided 5–6 doses; 1 mg IM = 30 mg PO dose
- Juvenile myasthenia
 - Most patients benefit from pyridostigmine bromide (Mestinon) given 3–4 times/day. A long-acting formulation prior to bedtime may alleviate obstructive hypoventilation during sleep.
 - Pyridostigmine blocks AChE activity and results in increased acetylcholine.
 - Usual starting dosage is ~1 mg/kg/24 h. Dosage is slowly titrated upward, following symptoms, at several-day intervals to a maximum dose of ~7–8 mg/kg/24 h. Absolute maximum daily dose is 300 mg/day for older children. Common side effects: hypersalivation, blurry vision, and diarrhea.
 - Glycopyrrolate (1 mg PO) may decrease diarrhea.
 - Prednisone
 - ▢ Consider in patients with disabling symptoms and inadequate response to pyridostigmine
 - ▢ Watch for transient worsening within weeks in up to 50% of patients.
 - ▢ Start daily dose at 2 mg/kg, watch for improvement in 3–6

- weeks, and taper toward 1.5 mg/kg/24 h on alternate-day schedule for 4 months. Taper slowly thereafter by 5 mg/week.
 - ▣ Monitor for side effects, including growth stunting.
 - ▣ Calcium every-other-day dosing may limit bone loss from chronic steroids.
- Rituximab
 - ▣ MuSK Ab–positive patients are often refractory to other treatments (Mestinon, steroids, IVIG) with incomplete or short-lived benefit.
 - ▣ Rituximab has induced sustained benefit in patients with refractory disease via B-cell depletion in MuSK Ab–positive patients; however, large controlled studies in this population have not been performed.
- Azathioprine
 - ▣ Induces remission in 30%; significant improvement in another 25–60%
 - ▣ Useful adjunct to steroids and thymectomy; however, requires 3–12 months for benefits to occur
- Juvenile myasthenics with profound weakness and respiratory failure (myasthenic crisis) should undergo immediate therapy to decrease the number of circulating antibodies:
 - Plasmapheresis or IV immunoglobulin can help within days by decreasing AChR antibodies
 - Steroids diminish antibody production over weeks to months.

SURGERY/OTHER PROCEDURES

Thymectomy

- In adults, 20–60% remission; another 15–30% show marked improvement (somewhat less in pediatric patients)
- Thymectomy earlier in the course of illness appears to produce a higher rate of remission.

ONGOING CARE

- The following medications can exacerbate myasthenia gravis:

- Corticosteroids may worsen symptoms.
- Aminoglycosides
- Ciprofloxacin
- β -Adrenergic blocking agents, including eye drops
- Lithium
- Procainamide
- Quinidine
- Phenytoin
- Prolonged recovery after exposure to nondepolarizing NM blocking agents
- Always start new medications cautiously.

PROGNOSIS

- Neonatal transient
 - Self-limited disorder that resolves spontaneously over weeks or months of life as maternal antibodies disappear
 - Infant may require ventilator and nutritional support during first few months of life.
 - Infants with arthrogryposis multiplex congenita (born to mothers with antibodies against the fetal form of AChR) may gain some mobility over time and with passive range-of-motion therapy.
- Congenital myasthenia
 - Prognosis depends on specific defect.
 - Autosomal recessive disorders tend to be more severe than dominant disorders. Weakness shows variable response to cholinesterase inhibitors.
 - Immunosuppressants are not helpful. In general, these are indolent disorders.
 - Ptosis and fatigability resemble the juvenile type but are more stable over time.
- Juvenile myasthenia
 - Most patients do extremely well with treatment; patient selection for early surgery requires experience and may improve outcome.
 - Longitudinal studies suggest rate of spontaneous remission ~2% per year.
 - Patients with generalized weakness slightly less likely to experience

remission.

- Mortality rate from myasthenia is near that of the general population in patients <50 years old.

Patient Monitoring

- Watch for transient worsening of symptoms.
- Monitor for side effects of corticosteroids, including growth stunting.
- Medication effects: GI upset due to AChE inhibitors

COMPLICATIONS

Respiratory failure, nocturnal hypoventilation, visual disturbance, thymic cancer (more common in adults, rare in pediatrics), other autoimmune disorders

MYOCARDITIS

Bradley S. Marino • John L. Jefferies

BASICS

DESCRIPTION

Myocarditis is defined as inflammation of the myocardium on histologic examination. Cardiovascular complications may be significant and include myocardial dysfunction, arrhythmias, conduction abnormalities, and cardiac arrest.

EPIDEMIOLOGY

- True incidence of acute myocarditis is difficult to estimate because of the wide range in clinical severity, various etiologies, and underdiagnosis.
- More than 50% of pediatric cases seen are in infants <1 year of age.
- Viral myocarditis has a seasonal distribution, which varies according to the viral species.

RISK FACTORS

- Exposure to infectious agents, drugs, toxins, and systemic diseases
- Drug exposure
- Autoimmune disease
- Systemic disease

PATHOPHYSIOLOGY

- Pathophysiology of myocarditis may vary based on cause (see “[Etiology](#)”).
- Viral myocarditis is best characterized and involves a complex interaction among the virus, host immune response, and environmental factors. Three stages include (1) viral injury and innate immune response, (2) acquired host immune response, and (3) recovery or chronic cardiomyopathy.
- Inflammatory response from innate and acquired immune response may result in significant damage to the myocardium and conduction

system.

- Development of autoantibodies may also play a key role in acute and chronic myocardial damage.
- Virus may cause direct damage to the myocardium independent of inflammation, secondary to cleavage of structural proteins.
- Pathogenesis of nonviral myocarditis is poorly understood.
- Regardless of the cause, symptom severity increases with worsening ventricular function and/or with worsening arrhythmias.
- Fulminant myocarditis may be characterized by both severe systolic and diastolic dysfunction.
- Progressive left ventricular systolic dysfunction may lead to hypotension, acidosis, and end-organ dysfunction.
- Left ventricular diastolic dysfunction may result in elevated left ventricular end diastolic pressures, leading to pulmonary venous and arterial hypertension, with concomitant pulmonary edema and right-sided heart failure.

ETIOLOGY

- Causes include infection, toxins, drugs, autoimmune disease, and systemic disease.
- Infectious causes include viral, bacterial, rickettsial, fungal, helminthic, spirochetal, and protozoal infections.
- Viral infection is the most common in developed countries including enteroviruses, erythroviruses, adenoviruses, and herpes viruses. Both RNA and DNA viruses have been implicated. Previously, the enteroviruses, specifically coxsackie B, were commonly seen. However, there has been a shift in the spectrum. Currently, parvovirus B19 is most commonly seen. There are growing reports of certain herpes viruses, specifically HHV6, becoming more prevalent.
- Nonviral infectious causes are far less common but must be considered especially in endemic areas, such as Central and South America where Chagas disease is prevalent.
- Nonviral myocarditis may be secondary to exposure to chemicals (arsenic and hydrocarbons), alcohol, radiation, drugs (chemotherapeutics), drug hypersensitivity, autoimmune disease such as systemic lupus erythematosus, or systemic disease such as Churg-

Strauss or sarcoidosis.

- Giant cell myocarditis is a very rare form of myocarditis in children that is associated with autoimmune disease and drug hypersensitivity. These patients respond poorly to typical care and frequently require cardiac transplantation.

DIAGNOSIS

SIGNS AND SYMPTOMS

- Prodromal
 - Antecedent flulike illness
 - Gastroenteritis
 - Rheumatologic symptoms
 - Fever
- Left-sided heart failure
 - Exercise intolerance
 - Easy fatigability
 - Dyspnea
 - Orthopnea
 - Anorexia, loss of appetite/poor feeding, early satiety
 - Emesis (especially in children)
- Right-sided heart failure
 - Abdominal pain/cramping
 - Swelling of abdomen/lower extremities
 - Loose stools

HISTORY

- Duration of symptoms
- Travel history
- Family history

PHYSICAL EXAM

Any of the following may be present:

- Pulmonary
 - Rales
 - Tachypnea

- Retractions
- Cardiovascular
 - Jugular venous distention
 - Normal to hyperdynamic precordium with or without right ventricular heave
 - Lateral displacement of the point of maximal impulse (PMI)
 - Tachycardia: arrhythmia (atrial and/or ventricular ectopy may be present)
 - Heart sounds: accentuation of second heart sound (secondary to pulmonary artery hypertension), murmur (mitral and/or tricuspid insufficiency), gallop, and/or rub
- Abdomen: hepatomegaly, splenomegaly, ascites
- Extremities
 - Weak pulses
 - Poor capillary refill
 - Cool extremities

DIAGNOSTIC TESTS & INTERPRETATION

- Despite limited sensitivity and specificity, endomyocardial biopsy (EMB), using the Dallas criteria for histopathologic classification, remains the gold standard for confirming the diagnosis of acute myocarditis.
 - These criteria are limited in that they provide information with regard to inflammation but do not assess for the presence of viral pathogens.
 - Current approaches indicate benefit in analyzing the tissue for viral DNA by polymerase chain reaction (PCR).
 - EMB has inherent problems, including sample selection bias, as tissue is only obtained from the right ventricular endocardium and the possible morbidity and mortality associated with an invasive procedure.
- Electrocardiogram findings may be supportive of the diagnosis:
 - Highly variable findings may include sinus tachycardia, low voltage QRS, ST segment depression/elevation, flattening or inversion of the T wave, conduction system disease including complete heart block, prolongation of the QT interval, and arrhythmias (premature

atrial contractions/supraventricular tachycardia, or premature ventricular contractions/ventricular tachycardia).

Lab

- Erythrocyte sedimentation rate and C-reactive protein level may be elevated.
- Creatinine kinase MB fraction and troponin T and I levels may be elevated.
- Cultures (bacterial, viral, fungal) of blood, urine, stool, and nasopharyngeal swabs may be considered.
- Viral PCR analysis of tissue including myocardium, blood, or sputum may be considered.
- Acute and convalescent serologic studies may be considered for selected antibody studies.

Imaging

- Chest radiograph
 - Cardiomegaly and varying degrees of pulmonary edema
 - Possible pleural effusions
- Echocardiography
 - Depressed systolic function (may be biventricular with normal to mildly dilated chamber sizes)
 - Depressed diastolic function
 - Focal wall motion abnormalities
 - Valvular insufficiency
 - Pericardial effusion
- Cardiac MRI
 - Assessment of chamber size and systolic function
 - Fibrosis by delayed enhancement
 - Abnormal delayed enhancement and edema as seen by T2 weighting

DIFFERENTIAL DIAGNOSIS

- Severe left-sided obstructive heart lesions
 - Mitral stenosis
 - Valvular aortic stenosis
 - Coarctation of the aorta

- Congenital coronary artery anomalies
 - Anomalous left coronary artery from the pulmonary artery and other coronary variants
- Incessant arrhythmias
 - Incessant supraventricular tachycardia
 - Ventricular tachycardia
- Metabolic disorders including mitochondrial disease
- Drug use
 - Cocaine or other stimulants
- Acquired disease
 - Kawasaki disease
 - Coronary artery disease
- Genetic syndromes
 - Neuromuscular disease
 - Genetically triggered cardiomyopathies

TREATMENT

- Initial management should be based on the clinical presentation. These include the following: bed rest and limited activity (during acute phase).
- Standard medical regimens for acute care should be based on appropriate heart failure therapies and may include the following:
 - Inotropic support should be considered for patients with evidence of low cardiac output. Medication infusions may include milrinone, dopamine, and dobutamine. If epinephrine is required, mechanical support should be considered.
 - Diuretics
 - Afterload reduction may be considered if volume overload exists with preserved cardiac output (e.g., nitroglycerin and nitroprusside).
 - Antiarrhythmics may be used in cases of hemodynamically significant arrhythmias.
 - Mechanical ventilation in patients with respiratory failure secondary to myocardial failure
 - Mechanical support (in patients with rapidly progressing, severe

heart failure; used as a bridge to transplantation): left ventricular or biventricular assist devices, extracorporeal membrane oxygenation (ECMO)

- Rescue therapy: cardiac transplantation
- Standard medical regimens for chronic care should be based on appropriate heart failure therapies and may include the following:
 - Angiotensin-converting enzyme inhibitors (ACEi)
 - β -blockers
 - Angiotensin receptor blockers
 - Diuretics (e.g., spironolactone for ventricular remodeling)
 - Anticoagulation with unfractionated or low-molecular-weight heparin acutely and aspirin and/or Coumadin chronically for patients with severe myocardial depression and ventricular dilation
 - Implantable devices may be considered for patients with conduction system disease (pacemaker) or those at risk for sudden cardiac death (implantable cardioverter-defibrillator).

MEDICATION

- Immunosuppression: High-dose gamma globulin (2 g/kg IV immunoglobulin [Ig] over 24 hours) during the acute phase has been associated with improved recovery of left ventricular function and with a tendency for better survival during the first year after presentation.
- Steroids, azathioprine, calcineurin inhibitors, cyclosporine, cyclophosphamide, and other immunosuppressive medications have all been proposed as effective agents, although insufficient evidence of therapeutic benefit is currently available to recommend routine use.
- Antiviral therapy does not currently have an accepted role in myocarditis management.
- Use of interferon therapy is being widely studied but there continues to be a lack of demonstrable benefit.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Clinical changes in systolic and diastolic function
- Monitoring for life-threatening arrhythmias
- Effects of the illness on other systems
 - Nutritional status
 - Growth
 - Development
 - Comorbid illnesses

PROGNOSIS

- Prognostic data are limited by the lack of complete ascertainment of all cases of acute myocarditis, with many patients likely exhibiting mild symptoms, which spontaneously resolve.
- Prognosis is often dictated by clinical presentation and underlying etiology. However, if treated appropriately early in the course, outcome can be quite favorable.
- Prognosis is poor in patients with fulminant lymphocytic myocarditis with significant hemodynamic compromise with a mortality of >40% in adults and ~75% in children, without aggressive management strategies.
- Mortality is higher in children presenting in the neonatal period.
- Giant cell myocarditis represents a unique subgroup with a particularly poor prognosis, unless transplanted.

COMPLICATIONS

- Acidosis
- End-organ hypoperfusion and resultant dysfunction
- Pulmonary venous and arterial hypertension
- Pulmonary edema
- Unfavorable ventricular remodeling
- Conduction system disease including heart block
- Arrhythmias

- I40.9 Acute myocarditis, unspecified

NARCOLEPSY

Jennifer A. Accardo

BASICS

DESCRIPTION

- Lifelong neurologic disorder that often initially manifests in childhood or adolescence and can cause significant functional impairment and disability
- Excessive daytime sleepiness and inappropriate transitions from wakefulness into rapid eye movement (REM) sleep
- Narcolepsy may occur with or without cataplexy.
- Other associated features include hypnagogic hallucinations, sleep paralysis, and nighttime sleep fragmentation.

GENERAL PREVENTION

- Narcolepsy is not preventable.
- Narcolepsy is underrecognized, especially in children.
- Physicians should screen for sleep dysfunction and excessive sleepiness as part of anticipatory guidance.

EPIDEMIOLOGY

- Prevalence in the United States is reported to range from 25 to 50 per 100,000; prevalence may be higher in the Japanese population.
- An estimated 200,000 Americans have narcolepsy, but fewer than 50,000 of these individuals have been diagnosed with the disorder.
- Approximately half of patients with narcolepsy have symptoms before age 15 years and <10% with symptoms <age 5 years, but often, diagnosis may lag 10–15 years after onset of symptoms.
- Cataplexy is present in 50–70% of adult patients and perhaps at least as many pediatric patients but may be initially sporadic or difficult to identify.

RISK FACTORS

- 1st-degree relatives of patients with narcolepsy with cataplexy have a

1–2% risk (which is 10- to 40-fold more than the general population) of developing narcolepsy.

- Both genetic and environmental factors may be involved in the development of narcolepsy.
- There is an association between narcolepsy with cataplexy and histocompatibility leukocyte antigens (HLA) subtypes, specifically DQB1*0602 in 85–95% and DR2 antigens. About 40% of cases of narcolepsy without cataplexy are also DQB1*0602 positive.
- Increased risk of narcolepsy after H1N1 vaccination has been a topic of interest.

PATHOPHYSIOLOGY

- Hypocretin (also known as orexin) is a neuropeptide produced by neurons in the perifornical area of the lateral hypothalamus that is supplied to several areas of the brain that promote wakefulness. It may also inhibit REM sleep. It mediates appetite.
- To better reflect pathophysiology, the American Academy of Sleep Medicine has categorized narcolepsy into type 1 and type 2. Type 1 involves hypocretin deficiency, such as would be detected in cerebrospinal fluid (CSF) via lumbar puncture, or manifested clinically by the presence of cataplexy. Type 2 does not involve hypocretin deficiency, and in the absence of CSF testing would be the presumptive diagnosis for a patient who had not manifested cataplexy. Onset of cataplexy would herald a change in diagnosis from type 1 to type 2.
- Narcolepsy type 1 is caused by selective loss of the hypocretin-producing neurons in the hypothalamic region.
- The association between narcolepsy and specific HLA antigens has suggested autoimmune pathogenesis; however, this has yet to be definitively established.

COMMONLY ASSOCIATED CONDITIONS

- Secondary narcolepsy may be seen with CNS trauma, strokes, brain tumors, and demyelinating diseases, particularly involving the lateral and posterior hypothalamus, midbrain, and the pons.
- Genetic syndromes such as Prader-Willi syndrome, myotonic

dystrophy, and Niemann-Pick type C syndrome may be associated with secondary narcolepsy.

DIAGNOSIS

HISTORY

- Excess daytime sleepiness starting with recurrence of naps may be early signs of disease.
- In adults, naps tend to be restorative but are more likely to be described as “unrefreshing” in children.
- Cataplexy, the abrupt loss of muscle tone provoked by laughter or strong emotions such as surprise, sadness, or anger, is almost pathognomonic for narcolepsy. Loss of muscle tone can range from sagging of face, eyelids, or jaw; blurred vision; and knee buckling to complete collapse but with preserved consciousness.
- Hypnagogic (on sleep onset) and hypnopompic (on awakening) hallucinations involve vivid auditory or visual hallucinations during transitions between sleep and wakefulness. Such hallucinations can also be experienced infrequently by normal individuals.
- Sleep paralysis is the inability to move or speak for a few seconds or minutes at sleep onset or offset. Normal individuals can also experience sleep paralysis, often in the context of sleep deprivation.

PHYSICAL EXAM

- Normal in most idiopathic cases; children with narcolepsy are often overweight/obese.
- Vertical gaze palsy, confusion, poor memory, developmental regression, impaired thermoregulation, and signs of endocrine dysfunction may be present in cases of secondary narcolepsy.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Levels of CSF hypocretin ≤ 110 pg/mL (30% of mean control value) are strongly indicative of narcolepsy with cataplexy. CSF testing is usually reserved for complicated or ambiguous cases.
- HLA antigen typing with HLA DQB*0602 and DR2 are strongly

associated with narcolepsy with cataplexy but also present in 12–38% of the normal population. A negative result can be helpful in ruling out the condition, and HLA testing should be considered supportive rather than diagnostic.

Imaging

Brain MRI is indicated with sudden onset of sleepiness, recent head injury, or an abnormal neurologic exam.

Diagnostic Procedures/Other

- Overnight polysomnography (PSG) and multiple sleep latency test (MSLT) are considered standard of care for diagnosis.
- MSLT is a protocol consisting of four or five 20-minute nap opportunities 2 hours apart after an overnight PSG to determine mean sleep latency (MSL) and sleep-onset REM periods (SOREMPs) within 15 minutes of falling asleep. PSG is performed to ensure adequate nighttime sleep and exclude other sleep disorders that could cause daytime sleepiness. On MSLT, MSL <8 minutes and ≥ 2 SOREMPs are diagnostic of narcolepsy. SOREMP at the beginning of the preceding night's PSG can now be substituted for a SOREMP on the MSLT. Two or more SOREMPs tend to be specific for narcolepsy, whereas up to 30% of the general population may have MSL <8 minutes. Other factors influencing sleepiness such as chronic sleep deprivation or sedating medications must provide context for test interpretation.

DIFFERENTIAL DIAGNOSIS

- Chronic insufficient sleep
- Poor sleep hygiene (particularly nighttime electronics use)
- Delayed sleep phase disorder (manifesting as daytime sleepiness)
- Idiopathic CNS hypersomnia (without cataplexy, SOREMPs, or other REM intrusion phenomena in wakefulness or sleep)
- Primary sleep disorders such as obstructive sleep apnea, restless legs syndrome, periodic limb movement disorder
- Kleine-Levin syndrome (cyclical episodes of hypersomnolence, classically also with overeating and hypersexuality lasting days to weeks with normal intervals in between)
- Psychiatric disorders/depression

- Medication side effects, drug/alcohol abuse
- Atonic drop attacks associated with childhood epilepsy syndromes such as Lennox-Gastaut syndrome
- Cataplexy can be associated with Coffin-Lowry syndrome or Norrie syndrome, both rare and involving other deficits including intellectual disability.

TREATMENT

MEDICATION

- Daytime sleepiness
 - Methylphenidate, 5–30 mg/24 h (max 60 mg/24 h). Consider other long-acting formulations such as Concerta, Ritalin LA, Metadate CD, Focalin XR, etc.
 - Dextroamphetamine (Dexedrine) 5–40 mg/24 h (max 60 mg/24 h)
 - Mixed amphetamine salts (Adderall XR) 10–30 mg/24 h
 - Modafinil (Provigil), 100–400 mg/24 h. FDA Pediatric Advisory Committee warning; recommends use only if 1st- and 2nd-line treatments have failed and the benefits outweigh the risks of serious dermatologic and psychiatric side effects
- Cataplexy
 - Sodium oxybate (Xyrem): treats both hypersomnia and cataplexy. Dose is given at bedtime while in bed and again 2½–4 hours later due to profound sedating effects.
 - Venlafaxine (Effexor) starting at 12.5–25 mg
 - Selective serotonin reuptake inhibitors: fluoxetine (Prozac) 5–30 mg/24 h or sertraline (Zoloft) 25–100 mg/24 h
 - Clomipramine (Anafranil) 25–100 mg /24 h
 - Imipramine (Tofranil) 25–75 mg /24 h

ADDITIONAL TREATMENT

- Regular sleep schedule
- Short scheduled naps
- Regular physical exercise

ONGOING CARE

PROGNOSIS

Children with narcolepsy can be expected to have normal life expectancy and normal intellectual functioning. Lifestyle and medication treatments to reduce sleepiness and cataplexy improve academic performance, quality of life, and ability to participate.

FAQ

- Q: What is the chance that a sibling of the patient may develop narcolepsy?
- A: There is a 1% possibility that siblings and offspring could be affected.
- Q: Will a patient with narcolepsy be able to drive a car?

- A: Patients with narcolepsy can legally drive, provided they are on the appropriate medications to keep them from falling asleep at the wheel.
- Q: Is there a cure for narcolepsy?
- A: No. Treatment is symptomatic.

NECK MASSES

Nicholas Tsarouhas

BASICS

DESCRIPTION

A mass in the tissues of the neck; cervical adenopathy is defined as a neck node >1 cm.

ETIOLOGY

Varies depending on underlying condition

DIAGNOSIS

To diagnose and appropriately manage neck masses, one must combine the history with a careful examination of the mass. The major task of the differential diagnosis is to distinguish infections from congenital and malignant causes.

HISTORY

- Fever: infection, Kawasaki disease, malignancy, “PFAPA” (periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis) syndrome
- Intercurrent infection: reactive hyperplasia, mononucleosis, abscess, congenital cyst
- Subacute or chronic cervical lymphadenitis: cat-scratch disease, toxoplasmosis, Epstein-Barr virus (EBV), and mycobacterial infection
- Increasing size: infection, newly infected congenital lesion, malignancy (less common)
- Sore throat: mononucleosis, peritonsillar or retropharyngeal abscess
- Swallowing problems: retropharyngeal or peritonsillar abscess, thyroglossal duct cyst
- Cat contact: cat-scratch disease, toxoplasmosis
- Recurrently infected mass: infected congenital cyst (thyroglossal duct, branchial cleft)
- Mass noticed neonatally: cystic hygroma, hemangioma,

sternocleidomastoid tumor of infancy

- Weight loss, cough, chronic constitutional symptoms: malignancy, tuberculosis
- Hypothyroid or hyperthyroid symptoms: thyroglossal duct cyst, thyroidal diseases

PHYSICAL EXAM

- Tender, erythematous, indurated mass may indicate cervical adenitis, infected congenital lesion, or cat-scratch disease
- Nontender, enlarged lymph nodes(s) suggest reactive hyperplasia or malignancy.
- Fluctuant mass may indicate adenitis with abscess or cystic hygroma.
- Drainage suggests adenitis with abscess, atypical mycobacterial disease, infected thyroglossal duct, or branchial cleft cyst.
- Regional adenopathy: reactive hyperplasia, cat-scratch disease, or malignancy
- Exudative pharyngitis: mononucleosis
- Asymmetric soft palate with uvular deviation suggests peritonsillar abscess.
- Pulmonary findings: tuberculosis, malignancy
- Midline mass suggests thyroglossal duct or dermoid cyst or thyroidal disease.
- If mass moves with tongue protrusion, thyroglossal duct cyst may be present.
- Sinus opening may indicate thyroglossal duct, branchial cleft, or dermoid cyst.
- Multiloculated mass that transilluminates suggests cystic hygroma.
- Matted-down mass may indicate malignancy.
- Mass posterior to sternocleidomastoid muscle may be malignancy or infection.
- Inferior deep cervical nodes (scalene and supraclavicular) suggest malignancy.
- Generalized adenopathy suggests malignancy.
- Hepatosplenomegaly may indicate malignancy or infectious mononucleosis.
- Skin discoloration suggests trauma, abscess, or atypical mycobacterial

disease.

- A skin papule is a clue to cat-scratch disease.
- Conjunctivitis, oral involvement, extremity changes, rash, and adenopathy, in the context of fever: Suspect Kawasaki disease.
- Torticollis in a neonate suggests sternocleidomastoid (pseudo) tumor of infancy.

DIAGNOSTIC TESTS & INTERPRETATION

- CBC
 - Infections: leukocytosis
 - Mononucleosis: atypical lymphocytosis
 - Kawasaki: thrombocytosis after 1st week
 - Neck malignancies: usually normal initially
- Complete metabolic panel with lactate dehydrogenase (LDH) and uric acid when malignancy is suspected
- “Mono spot” (mononucleosis) test: less reliable in children <4 years old; EBV titers more useful
- Indirect fluorescent antibody titers for Bartonella: confirms cat-scratch disease
- Purified protein derivative: negative or weakly positive in atypical mycobacterial infections
- Chest radiograph: important in all evaluations when malignancy is a possibility; adenopathy seen in malignancies and tuberculosis; cavitary lesions and infiltrates in tuberculosis
- Lateral neck radiograph: prevertebral soft tissue space at C2–C3 abnormally wide ($>1/2$ adjacent vertebral body diameter) in cases of retropharyngeal abscess
- Ultrasound
 - 1st-line imaging modality in neck masses
 - provides immediate, noninvasive information on location, size, and composition of mass (cystic vs. solid)
 - Doppler adds information about vascularity.
- CT or MRI scan: useful in evaluating deep neck infections and complex neck masses
 - CT advantages: more readily available; shorter study; less need for sedation

- MRI advantages: no ionizing radiation; better soft tissue resolution
- Thyroid scintigraphy: useful when malignancy is a concern
- Gram stain and culture of specimen after needle aspiration or incision and drainage: diagnostic and therapeutic with infections
- Histologic evaluation after fine-needle aspiration or biopsy: diagnostic for malignant versus congenital versus infectious causes

DIFFERENTIAL DIAGNOSIS

- Infectious
 - Reactive hyperplasia: self-limited, enlargement of bilateral minimally tender nodes; usually viral
 - Bacterial lymphadenitis
 - Usually staphylococcal or streptococcal infection of unilateral, tender, swollen, warm, erythematous node
 - Cellulitis–adenitis syndrome in neonates caused by group B *Streptococcus*
 - Cat-scratch disease
 - A usually self-limited, although sometimes protracted, illness (2–4 months)
 - Caused by the gram-negative bacillus *Bartonella henselae*
 - Starts as a papule at a cat-scratch site; progresses to regional adenopathy, 5–50 days later (median, 12 days)
 - Axillary adenopathy is most common; cervical nodes 2nd most common.
 - Adenopathy for weeks to months
 - Tuberculosis: acute or insidious onset of fever and firm, nontender adenopathy in children exposed to adult infected with acid-fast bacillus *Mycobacterium tuberculosis*
 - Atypical mycobacterial disease
 - Infection usually caused by *Mycobacterium avium* complex or *Mycobacterium scrofulaceum* (ubiquitous agents found in the soil)
 - Rapidly enlarging mass of firm, nontender nodes in young children with no known exposure to tuberculosis
 - Nodes often occur with overlying skin discoloration and thinning; some spontaneously drain.

- Infectious mononucleosis: EBV infection most commonly seen in older children who present with fever, exudative pharyngitis, adenopathy, and hepatosplenomegaly.
- Toxoplasmosis
 - Parasitic disease caused by *Toxoplasma gondii* which presents with cervical adenopathy, rash, fever, malaise, and hepatosplenomegaly
 - Acquired from contact with cat feces or inadequately cooked meat
- Retropharyngeal abscess
 - Suppurative adenitis of the retropharyngeal nodes that presents in children <5 years of age
 - These children often have fever, neck stiffness, dysphagia, respiratory distress, drooling, and stridor.
- Peritonsillar abscess: suppurative sequela of a severe tonsillopharyngitis, usually caused by group A β -hemolytic *Streptococcus* (GABHS); commonly presents in older children and adolescents with trismus, “hot potato” voice, and uvular deviation from a bulging palatal abscess
- Ludwig angina
 - Rapidly expanding, diffuse inflammation of the submandibular/sublingual spaces
 - May compromise the airway
 - Often occurs with dental infections
- Congenital
 - Branchial cleft cyst: common congenital neck lesion (usually a remnant of the 2nd branchial cleft) which presents as a nontender (unless infected) cyst at the anterior border of the sternocleidomastoid
 - Thyroglossal duct cyst: common congenital neck mass which is a remnant of the embryonic thyroglossal sinus and presents as a nontender (unless infected), mobile, anterior midline mass near the hyoid bone
 - Cystic hygroma (lymphangioma): complex, multiloculated mass of lymphatic tissue, which presents in the 1st year of life as a large,

soft, compressible mass in the posterior triangle of the neck; may cause airway obstruction

- Dermoid cyst: small, firm, nontender mass, usually high in the midline
- Hemangioma: bluish purple, blanching mass characterized by rapid growth in the 1st year of life, then slow regression
- Sternocleidomastoid (pseudo) tumor of infancy (congenital muscular torticollis): benign perinatal fibromatosis, often associated with difficult deliveries or abnormal uterine positioning, that results in a hard, immobile, fusiform mass in the sternocleidomastoid
- Laryngocele: cystic dilation of the laryngeal saccule; presents as an air-filled cyst or as a foreign body sensation with coughing
- Cervical wattle: benign pedunculated congenital anomaly on lateral neck with a core of elastic cartilage
- Cervical bronchogenic cyst: cervical neck mass in the anteromedial neck (superior to the sternal notch), resulting from abnormal development of the tracheobronchial tree
- Thymic cyst: ectopic thymic mass resulting from abnormal development of pharyngeal pouches and branchial clefts
- Teratoma: malformation of all three germ layers that can cause significant airway obstruction as well as feeding dysfunction
- Ranula: a mucocele created by obstruction of the sublingual salivary glands; usually a painless, slowly accumulating mass
- Malignant
 - Hodgkin lymphoma: slowly enlarging, unilateral, firm, nontender neck malignancy; usually presents in previously well adolescents
 - Non-Hodgkin lymphoma: presents in young adolescents as a painless, rapidly growing, firm collection of lymph nodes
 - Leukemia: most common tumor associated with cervical adenitis in first 6 years of life
 - Neuroblastoma: commonly presents in infants/young children as a large, nontender abdominal mass; associated with a myriad of signs and symptoms due to its propensity for metastasis
 - Rhabdomyosarcoma: head and neck malignancy that usually presents as a rapidly enlarging mass

- Melanoma: an increasingly identified cause of neck malignancy in pediatrics
- Thyroid
 - Chronic lymphocytic thyroiditis (Hashimoto thyroiditis): autoimmune childhood goiter that may be eu-, hypo-, or hyperthyroid
 - Thyrotoxicosis (Graves disease): clinically hyperfunctioning thyroid caused by circulating thyroid cell–stimulating antibodies
 - Thyroiditis: painful bacterial infection of the thyroid caused by Staphylococcus or Streptococcus
- Miscellaneous
 - Kawasaki disease
 - Idiopathic vasculitis distinguished by prolonged fever, conjunctivitis, oral involvement, extremity changes, rash, and unilateral cervical node >1.5 cm
 - Cervical node: least common feature
 - PFAPA syndrome
 - Periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis
 - Idiopathic, periodic, febrile syndrome most commonly seen in young children
 - Sinus histiocytosis with massive lymphadenopathy (Rosai–Dorfman disease); benign form of histiocytosis that presents as massive, painless enlargement of cervical nodes
 - Hematoma: secondary to trauma
 - Hypersensitivity reaction: secondary to bites, stings, or other allergens
 - Drugs: Notably, phenytoin and isoniazid may be associated with lymphadenopathy.
 - Immunization: Adenopathy may follow DPT or polio immunization.

TREATMENT

GENERAL MEASURES

- Infectious

- Antibiotics
- Incision and drainage (I&D) of abscesses
- Congenital
 - Antibiotics if infected
 - ENT referral for surgical excision
- Malignancy: oncology referral for chemotherapy/radiation/excision

ALERT

Corticosteroids should not be given to neck mass patients until malignancy has been excluded, except in dire conditions of airway compromise.

- Thyroidal: endocrine referral for pharmacotherapy
- Miscellaneous
 - Kawasaki disease: IVIG and aspirin therapy to prevent coronary artery aneurysms; cardiology referral for echocardiography
 - PFAPA syndrome: Steroids (a single dose) are efficacious in aborting fever attacks.
 - Sternocleidomastoid tumor of infancy: massage, range of motion, and stretching

ONGOING CARE

Close follow-up is essential for all neck masses; consider referral for biopsy in the following cases:

- Nodes not responding to antibiotics
- Toxic illness/systemic symptoms
- Clinical signs of malignancy (weight loss, peripheral adenopathy, hepatosplenomegaly)
- Firm, nontender nodes fixed to deep tissues
- Nodes posterior to the sternocleidomastoid or in the lower cervical/supraclavicular regions
- Bilateral nodes >2 cm

CODES

ICD10

- R22.1 Localized swelling, mass and lump, neck
- R59.0 Localized enlarged lymph nodes
- L02.11 Cutaneous abscess of neck

FAQ

- Q: How should nodes respond to therapy?
- A: Consider referral for biopsy if increasing size after 2 weeks, no decrease in size >2–4 weeks, or not back to normal >8–12 weeks.
- Q: Do all external neck abscesses need antibiotic therapy after drainage?
- A: Many experts believe that antibiotics are not always necessary if I&D is done appropriately.
- Q: Is antibiotic coverage for community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) necessary?
- A: As CA-MRSA is increasingly common, an antibiotic agent with MRSA coverage is indicated; clindamycin is a common choice.

NECROTIZING ENTEROCOLITIS

Susan W. Aucott • Fizan Abdullah

BASICS

DESCRIPTION

Necrotizing enterocolitis (NEC) is a severe acquired GI disorder that occurs in the newborn period and consists of diffuse necrotic injury to the bowel, which can result in perforation or subserosal collections of gas. The entire GI tract is susceptible, but the most frequently involved areas are the distal small bowel and proximal colon. Lesions vary from being diffuse areas of patchy necrosis to more isolated focal disease. Systemic signs and symptoms related to the inflammatory GI injury are accompanied by characteristic radiographic findings of pneumatosis.

EPIDEMIOLOGY

- NEC typically has an onset at 1–3 weeks of life (3–20 days) after the initiation of enteral feedings. The more premature the infant, the longer the child is at risk for developing NEC, with cases reported as late as 3 months of age.
- NEC affects mostly premature infants, but up to 10% of cases occur in term infants.
- The incidence of NEC is variable and ranges from 1 to 7% of all neonatal intensive care unit admissions or 1–3 per 1,000 live births.
- Preterm infants account for the vast majority of total NEC cases; the risk increases with decreasing gestational age and birth weight.
- Prevalence in very-low-birth-weight (VLBW) infants (birth weight <1,500 g) is 7%.
- Highest risk is in infants with birth weights between 500 and 750 g (15%).

RISK FACTORS

- The greatest risk factor for NEC is prematurity. Additional risk factors for both preterm and full-term infants include the following:
 - Cardiovascular instability

- Respiratory compromise resulting in recurrent or prolonged hypoxia
- Cyanotic heart disease
- Polycythemia
- Exchange transfusions
- Bowel malformations
- Perinatal asphyxia
- Small size for gestational age
- Maternal preeclampsia
- Antenatal cocaine abuse
- Prolonged use of IV antibiotics

GENERAL PREVENTION

- The use of maternal breast milk exclusively has been advocated. Donor breast milk, when maternal breast milk is unavailable, has been shown to decrease the incidence of NEC.
- A rapid rate of feeding advancement (>20 mL/kg/day) may increase the risk of NEC in infants less than 1,500 g. Early initiation of trophic feeds (<10 mg/kg/day) for several days prior to advancing feeding volumes may stimulate maturation of the GI tract with resultant improvement in feeding tolerance.
- The use of probiotics has not been shown consistently to effectively decrease the incidence for VLBW infants. Concern has been raised of an increased risk of sepsis when using probiotics.
- Immunonutrient supplementation with agents such as arginine, glutamine, lactoferrin, and omega-3 polyunsaturated fatty acids is being investigated, but there is currently insufficient evidence to make any recommendations for their use.

PATHOPHYSIOLOGY

- Varying degrees of inflammation early in the course cause superficial mucosal ulcerations and submucosal edema and hemorrhage, leading to transmural coagulation necrosis and perforation in the most severe cases.
- The most common sites for NEC include the terminal ileum, ileocecal region, and ascending colon.
- 50% of infants have both colonic and small intestine disease, with the

other 50% divided between isolated ileal and colonic involvement.

ETIOLOGY

- The etiology of NEC is unknown but thought to be a multifactorial process.
- Various factors causing direct and indirect mucosal disruption, which in turn may lead to an increased permeability in the gut of agents that lead to injury, include the following:
 - Hypoxia/ischemia leading to mucosal injury
 - GI tract immaturity
 - Immature host defense
 - Enteral feedings
 - Decreased diversity of bacteria within the GI lumen
- Enteral alimentation
 - Because 95% of infants who develop NEC have been enterally fed, initiation of feedings has been implicated as an important contributor to the etiology of NEC.
 - The composition of the formula (osmolarity), the rate of volume increase, and the immaturity of the mucosa have all been implicated as factors.
- Because of the frequent report of epidemic, cluster-type episodes, a variety of microorganisms has been implicated in the development of NEC, although there is no single causative organism.
 - Blood cultures may be positive in 20–30% of cases, often gram-negative organisms.
- Immaturity of the GI mucosal defense system against invading organisms has been noted in NEC.
- Medications may have a direct mucosal injury.

DIAGNOSIS

ALERT

Delay in making the correct diagnosis of NEC and instituting appropriate therapy may lead to a rapid progression of symptoms and often a worse outcome.

PHYSICAL EXAM

- The triad of abdominal distention, bloody stools, and feeding intolerance is frequently seen 8–10 days after initiating enteral feedings.
- The clinical spectrum varies dramatically from nonspecific symptoms of feeding intolerance to severe abdominal distention, sepsis, and shock. A staging system ranks the disease into 3 categories based on severity of the clinical signs and symptoms, aiding formulation of individual treatment plans.
 - Stage I (suspected NEC)
 - Temperature instability
 - Apnea
 - Bradycardia
 - Lethargy
 - Cyanosis
 - Glucose instability
 - Increased gastric residuals
 - Emesis (may be bilious)
 - Abdominal distention
 - Heme-positive stools
 - Stage II (definitive NEC): stage I plus
 - Mild metabolic acidosis
 - Mild thrombocytopenia
 - Poor perfusion
 - Severe abdominal distention
 - Absent bowel sounds
 - Abdominal tenderness
 - Grossly bloody stools
 - Possible abdominal wall cellulitis, fullness/mass
 - Ascites
 - Stage III (advanced NEC): stage I and II plus
 - Shock/deterioration of vital signs
 - Metabolic acidosis
 - Thrombocytopenia
 - Disseminated intravascular coagulation (DIC)

- Significant abdominal tenderness/peritonitis
- Respiratory compromise
- Neutropenia

DIAGNOSTIC TESTS & INTERPRETATION

Lab

No single laboratory feature is diagnostic of NEC. Obtaining a blood culture and monitoring serial complete blood counts (CBCs) and blood gases are essential for monitoring patients with NEC to assess for the following:

- Thrombocytopenia
- Acidosis, metabolic
- Anemia
- Neutropenia
- DIC

Imaging

Abdominal radiographs are essential for the diagnosis and staging of NEC:

- Stage I: mild dilatation of bowel loops
- Stage II
 - Dilated loops, which may be fixed
 - Pneumatosis intestinalis (presence of submucosal or subserosal air in the intestinal wall)
 - Possible portal venous gas
- Stage III: likely pneumoperitoneum, free air

DIFFERENTIAL DIAGNOSIS

- Systemic
 - Sepsis with ileus
 - Pneumothorax causing a pneumoperitoneum
 - Hemorrhagic disease of the newborn
 - Swallowed maternal blood
- GI tract
 - Volvulus
 - Malrotation
 - Hirschsprung colitis
 - Intussusception

- Spontaneous bowel perforation
- Stress gastritis
- Meconium ileus
- Milk protein allergy

TREATMENT

The best therapy for NEC is prevention. When present, early recognition and rapid medical management of infants with NEC are critical to minimize the progression of this aggressive disease.

ADDITIONAL TREATMENT

General Measures

- Length of therapy and reinstitution of feedings are based on the severity of the episode and on clinical, laboratory, and radiologic abnormalities.
- If there are no laboratory or radiographic abnormalities, feedings may be started 24–72 hours after the episode.
- If mild abnormalities are present and the infant is only mildly ill, a 7-day course of therapy is considered.
- When laboratory and radiologic abnormalities include pneumatosis intestinalis, acidosis, and/or thrombocytopenia, a 10- to 14-day course is indicated.

SURGERY/OTHER PROCEDURES

- First-line therapy for NEC is medical management and is successful in 50–75% of infants.
- Surgical intervention is required in 25–50% of all cases.
- Indications include the following:
 - Pneumoperitoneum
 - Cellulitis of the anterior abdominal wall, abdominal mass
 - Suspicion of intestinal infarction with a fixed loop of dilated bowel on radiography
 - Metabolic acidosis secondary to bowel necrosis unresponsive to medical therapy
- The goal of surgery is to remove all necrotic bowel and to preserve as

much bowel length as possible. The most widely accepted procedure is laparotomy with resection of gangrenous intestine and exteriorization of all viable ends as stomas.

- Peritoneal drains placed at the bedside were developed as a palliative procedure to decrease surgical morbidity and mortality in infants weighing <1,000 g, decompressing the peritoneal cavity of gas, necrotic debris, and stool. This approach has a higher mortality rate and increased adverse neurodevelopmental outcome than initial laparotomy. However, the majority of pediatric surgeons in the United States believe there is role for peritoneal drainage as a bridge to the more definitive operation.

INPATIENT CONSIDERATIONS

Initial Stabilization

- Therapy is based on the severity and progression of the symptoms.
- Initial management of all patients with suspected or proven NEC
 - NPO status
 - IV fluids
 - Nasogastric (NG) tube placement for decompression
 - IV antibiotics: broad spectrum
 - Total parenteral nutrition (TPN) to ensure adequate nutrition and growth
 - Severely ill patients may require hemodynamic support, acid–base regulation, and respiratory support as clinically appropriate.
- Evaluate every 6 hours to once a day, depending on the severity of the episode:
 - Blood cultures
 - CBC, electrolytes, and blood gas
 - Fluid status
 - Abdominal radiograph

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Despite early recognition and intervention, NEC is associated with a

significant morbidity and mortality.

DIET

- During acute illness, NPO and TPN
- On resolution of illness, slow reintroduction of feeds is necessary, as the infant is at risk for recurrent NEC.

PROGNOSIS

- Overall mortality for infants with NEC is between 20% and 40% but can be as high as 60% in patients with stage III NEC.
- Infants who survive the acute stage of NEC have a good long-term survival with 80–95% survival to discharge. However, hospitalization is 20 days longer on average than similar infants without NEC.
- Infants recovering from NEC have a 25% risk of microcephaly and serious neurodevelopmental delays.

COMPLICATIONS

- Acute complications that may occur with NEC include GI perforation, DIC, sepsis, shock, fluid and electrolyte imbalance, and respiratory failure.
- Long-term complications occur in 10–30% of infants and include the following:
 - Intestinal strictures
 - Acquired short bowel syndrome if the patient undergoes lengthy surgical resection of bowel
 - Enterocolic fistulas or anastomotic leaks
 - Malabsorption
 - Cholestasis
 - Failure to thrive
- Most common complication (10–35%) is intestinal stricture: occurs mainly in the left colon

CODES

ICD10

- P77.9 Necrotizing enterocolitis in newborn, unspecified
- P77.1 Stage 1 necrotizing enterocolitis in newborn
- P77.2 Stage 2 necrotizing enterocolitis in newborn

FAQ

- Q: What are the most common complications of NEC?
- A: Mortality, poor growth, prolonged hospitalization, and the development of intestinal strictures
- Q: Is NEC preventable?
- A: The development of NEC is not clearly preventable, but cautious feedings in extremely premature infants with gradual advancement and use of breast milk decrease the risk of NEC.
- Q: Is NEC exclusively a process that occurs in the premature infant?
- A: Approximately 10% of cases occur in full-term infants with underlying risk factors.
- Q: How is spontaneous intestinal perforation (SIP) different from NEC?
- A: SIP represents a perforation not associated with pneumatosis, inflammation, or ischemia (all hallmarks of NEC) and occurs in infants that often have not yet been fed. Risk factors include extreme

prematurity and early steroid use, particularly in combination with indomethacin in the first week of life.

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

Anne M. Marsh • Alison T. Matsunaga

BASICS

DESCRIPTION

Neonatal alloimmune thrombocytopenia (NAIT) is one of the major causes of severe thrombocytopenia in the newborn.

- Analogous to ABO/Rh incompatibility but involves platelets instead of RBCs
- Presents with bleeding complications including petechiae, bruising, mucosal bleeding, and/or intracranial hemorrhage (ICH) that can occur in utero

EPIDEMIOLOGY

Incidence is ~1:1,000 to 1:2,000 live births.

GENERAL PREVENTION

The disease cannot be prevented.

PATHOPHYSIOLOGY

Antibody-mediated platelet destruction

ETIOLOGY

Maternal IgG antibodies (Ab), directed against paternally inherited platelet-specific antigens in the fetus, cross the placenta, enter the fetal circulation, and attack fetal platelets.

- HPA-1a (formerly PLA-1) incompatibility is by far the most common cause of NAIT in those of Caucasian ancestry, accounting for ~75% of cases. The disease happens when the mother is HPA-1a negative (HPA 1b/1b) and father is HPA-1a positive (HPA 1a/1a or 1a/1b). If the fetus inherits HPA-1a from father, maternal exposure to HPA-1a-positive fetal platelets during pregnancy causes mother to generate anti-HPA-1a IgG Ab. Anti-HPA-1a Ab crosses the placenta and causes platelet destruction.

- Other common antigens implicated in NAIT include HPA-2, HPA-3, HPA-5, HPA-9, and HPA-15.
- HPA-4 incompatibility accounts for the majority of cases in Asian populations.
- At least 23 other low-frequency antigens have been reported in a small fraction of cases.
- HPA-1a–negative mothers who are HLA-DRB3*0101 positive are far more likely to develop Ab than those who are DRB3 negative.
- The role of HLA platelet antigens in NAIT is unclear.

DIAGNOSIS

HISTORY

- NAIT is suspected in a non–ill-appearing neonate who presents shortly after birth with clinical signs of bleeding and documented thrombocytopenia.
- Maternal history of previous births with thrombocytopenia, NAIT, ICH, or fetal losses?
- Maternal history of thrombocytopenia or ITP?
- Is current maternal platelet count normal?
- Family history of thrombocytopenia or bleeding disorders?
- Symptoms suggestive of an infection in the mother or infant?
- Medications used during pregnancy or in the newborn period

ALERT

Maternal platelet count in NAIT should be normal. Thrombocytopenia in the mother, and/or a history of maternal ITP should prompt you to consider alternative diagnoses such as autoimmune thrombocytopenia (i.e., antibodies directed toward maternal platelets, passively transfer into the fetal circulation, and destroy fetal platelets).

PHYSICAL EXAM

- Most neonates with NAIT are well and nonseptic appearing.
- May have mild easy bruising and bleeding symptoms
- If severely affected, may develop ICH
- Document the following exam findings:

- General: Evaluate for evidence of a congenital disorder (e.g., dysmorphic features).
- Head/neck: Exclude presence of full fontanelle and cephalohematoma.
- Abdomen: Exclude presence of organomegaly and mass.
- Extremities: Exclude presence of radial-thumb defects.
- Neurologic exam: Evaluate for irritability, lethargy, seizure, and focal neurologic deficits.
- Skin: Evaluate for pallor, petechiae, ecchymoses, hemangiomas, and vascular lesions. Evaluate for bleeding from phlebotomy sites, heel sticks, circumcision, and the umbilical cord.
- If congenital anomalies, hepatosplenomegaly, abdominal mass, or skeletal defects are present, consider alternative diagnoses.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
- Isolated thrombocytopenia: Platelets are often $<50,000/\mu\text{L}$ at birth.
- May see anemia if the infant has suffered severe bleeding complications
- Screening coagulation studies
- PT, PTT, thrombin time, and fibrinogen should be normal.
- Maternal platelet count: should be normal
- NAIT testing: HPA incompatibility between mother and child needs to be identified. Testing can be performed on mother and father to avoid collecting blood samples on the infant.
 - Serologic testing: Maternal serum containing platelet-reactive antibodies is tested against a panel of platelet glycoproteins, including HPA-1a, to look for incompatibility.
 - Platelet cross-matching: Maternal serum containing platelet-reactive antibodies is tested against washed paternal platelets to look for incompatibility.
 - Testing also against washed maternal platelets can exclude “autoantibodies” as seen in ITP.
 - Platelet antigen genotyping: DNA-based testing of the platelet glycoprotein genotype of both parents can be performed in only a

few laboratories but can reveal potential incompatibilities (i.e., specifically HPA-1 through HPA-6, HPA-9, and HPA-15).

Imaging

Head ultrasound to rule out ICH

DIFFERENTIAL DIAGNOSIS

- Infection
 - Bacterial or viral (e.g., rubella, cytomegalovirus)
- Congenital
 - Thrombocytopenia absent radius
 - Amegakaryocytic thrombocytopenia
 - Wiskott-Aldrich syndrome: X-linked condition with triad of immunodeficiency, eczema, and thrombocytopenia (small platelet size)
 - May-Heglin anomaly: Döhle bodies in WBCs (large platelet size)
- Immunologic
 - Autoimmune thrombocytopenia (i.e., maternal ITP): The degree of thrombocytopenia in autoimmune thrombocytopenia tends to be much less severe than in NAIT.
- Hematologic
 - DIC: increased platelet consumption (e.g., sepsis, NEC)
 - Thrombosis: for example, renal vein thrombosis, catheter-associated thrombosis
 - Hemangioma with Kasabach-Merritt syndrome
- Oncologic
 - Leukemia
 - Neuroblastoma
 - Down syndrome—TMD
- Metabolic
 - Methylmalonic acidemia
 - Isovaleric acidemia

TREATMENT

GENERAL MEASURES

- Daily platelet counts should be obtained until there is documentation of improvement without treatment/intervention.
- Close monitoring for any evidence of bleeding complications, especially ICH
- Avoidance of any invasive procedures (e.g., arterial or lumbar punctures) until platelet count is in a more stable range.
- Platelet count $<30,000/\mu\text{L}$ is generally accepted as a threshold for therapeutic intervention. Much higher thresholds are used if ICH is present.
- Treatment is platelet transfusion (10 mL/kg).

ALERT

All blood products administered should be treated appropriately for a neonate, that is, irradiated, CMV negative, ABO compatible, volume reduced, or washed if indicated.

- Potential sources of platelets for transfusion
 - HPA-1b/1b (i.e., HPA-1a neg) platelets
 - An excellent 1st choice but not always readily available
 - It is not appropriate to await HPA-matched platelets for transfusion, especially if the infant has clinically significant bleeding.
 - Random donor platelets
 - Most readily available but not ideal, given that 98% of the population is HPA-1a positive.
 - Will usually elevate the platelet count transiently until a more suitable blood product can be obtained
 - Maternal apheresis platelets
 - Ideal source for platelets but can take days to obtain
 - Do not wait for maternal platelets if the infant has clinically significant bleeding.
 - Important: Maternal platelets must be washed or volume reduced to remove antibody-containing maternal plasma.
 - Failure to wash or volume reduce maternal platelets may result in prolongation of the fetal thrombocytopenia.
 - HPA-specific platelets

- If an incompatibility other than HPA-1a is identified, consult your blood bank to see if HPA-specific platelets are available.
- IVIG is another potential therapeutic agent.
- May be used concurrently with platelet transfusions when the platelet count is $<30,000/\mu\text{L}$, especially when clinical signs of bleeding are present.
- Consider use as monotherapy when the platelet count is 30,000–50,000/ μL . Dose of IVIG is 1 g/kg. Multiple doses may be required.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Given the implications for future pregnancies, NAIT testing should be considered in all infants with thrombocytopenia ($<50,000/\mu\text{L}$), even if there is another likely etiology.
- If diagnosis of NAIT is confirmed, family counseling regarding management of future pregnancies is strongly recommended. Consultation with a high-risk obstetrician and perinatologist should be made for any future pregnancy at risk for NAIT.

PROGNOSIS

- Overall prognosis is fair to good. Most patients will experience little morbidity or mortality. ICH may lead to very significant morbidity and/or mortality.
- Most cases will resolve in 1–4 weeks.

COMPLICATIONS

- ICH: incidence ~20%, most occur antenatal
- Bleeding from umbilical stump, phlebotomy sites, and/or circumcision
- Petechiae and ecchymoses
- Cephalohematoma
- GI or GU bleeding

CODES

ICD10

- P61.0 Transient neonatal thrombocytopenia
- D69.42 Congenital and hereditary thrombocytopenia purpura

FAQ

- Q: Can an infant with NAIT safely receive maternal breast milk?
- A: Colostrum and maternal breast milk (MBM) contain immunoglobulins that are passively transferred to an infant. In a pregnancy affected by NAIT, this may include antiplatelet antibodies. The amount of antiplatelet antibodies transferred in MBM is probably minor and there are no reports of adverse consequences in infants with NAIT who have received MBM. The use of MBM in infants with NAIT therefore appears to be safe and should not be discouraged.
- Q: What is the HPA-1a–negative (homozygous HPA-1b/1b) mother’s risk of having other affected newborns?
- A: It depends on the genotype of the father.
 - If the father is homozygous for HPA-1a (HPA 1a/1a), all offspring will be heterozygous HPA 1a/1b positive and at great risk for developing NAIT.
 - If the father is heterozygous for HPA-1a (HPA 1a/1b), 50% of offspring will be at risk for developing NAIT.
- Q: Can NAIT happen in a 1st pregnancy?
- A: Unlike hemolytic disease of the newborn due to Rh incompatibility, NAIT can occur even in 1st born offspring. It is important to know that

NAIT tends to become more severe with each subsequently affected pregnancy.

NEONATAL APNEA

Kalpashri Kesavan • Zankhana Master • Estelle B. Gauda

BASICS

DESCRIPTION

- Apnea of infancy is an unexplained episode of cessation of breathing for 20 seconds or longer or a shorter respiratory pause associated with bradycardia, cyanosis, pallor, and/or marked hypotonia in infants with gestational age (GA) of 37 weeks or more at the onset of apnea.
- Apnea of prematurity (AOP) is a pause of breathing for >15–20 seconds or accompanied by oxygen desaturation ($\text{SpO}_2 \leq 80\%$ for ≥ 4 seconds) and bradycardia (heart rate $< 2/3$ of baseline for ≥ 4 seconds) in infants born < 37 weeks GA.
- Mechanisms of apnea
 - Central apnea
 - Caused by decreased central nervous system (CNS) stimuli to respiratory muscles
 - No evidence of obstruction to airflow but absent chest wall motion
 - Obstructive apnea
 - Can be due to factors such as pharyngeal instability, neck flexion, nasopharyngeal occlusion
 - Characterized by absent airflow but persistent chest wall motion
 - Mixed apnea
 - Mixed etiology, with obstructive apnea preceding (usually) or following central apnea
- Periodic breathing is a normal neonatal breathing pattern, defined by ≥ 3 pauses, each ≥ 3 seconds, with < 20 seconds of regular respiration between pauses.

EPIDEMIOLOGY

- Apnea and bradycardia occur in $\sim 2\%$ of all healthy term infants.
- AOP is inversely correlated to GA. It occurs in $< 10\%$ of neonates 34–

35 weeks GA and in almost all neonates <28 weeks GA at birth.

RISK FACTORS

- Prematurity is the most common cause of apnea.
- Risk factors common to both AOP and apnea of infancy are as follows:
 - Age (infant <30 days old at higher risk)
 - Upper respiratory tract infections
 - Gastroesophageal reflux (GER)
 - Anemia
 - Cardiac arrhythmias
 - CNS insult (hemorrhage, seizure, tumors)
 - Immunizations (after DTaP injection)
 - Maternal medications, such as magnesium sulfate, prostaglandins, or narcotics

PATHOPHYSIOLOGY

- Immature respiratory control in neonates
 - Immature chemoreceptors in brainstem and in the periphery (carotid body) may lead to decrease in respiratory drive and apnea.
- Hypoxic ventilatory depression
 - Newborn infants have enhanced sensitivity of respiratory control system to inhibitory neurotransmitters (such as gamma aminobutyric acid [GABA], adenosine, serotonin, and prostaglandin) that can lead to apnea.
- Impaired hypercapnic ventilatory response
 - Prolonging expiratory time (but not increasing frequency or overall tidal volume) may lead to less minute volume as well as uncoordinated movements of respiratory muscles in response to hypercapnia, resulting in apnea.
- Laryngeal chemoreflex
 - Activation of laryngeal chemoreceptors (via superior laryngeal nerve afferents) as seen in GER can result in apnea, bradycardia, and hypotension.
- Sleep state
 - Neonates spend majority of their time in active sleep. Apneas are more common during active sleep when respirations are irregular.

- Changes in neuromodulatory inputs and generalized inhibition of skeletal muscle activity during sleep are also contributory.
- Congenital central hypoventilation syndrome (CCHS)
 - Alveolar hypoventilation due to abnormality in the central integration of chemoreceptor information as a result of PHOX2B mutation

DIAGNOSIS

HISTORY

- Most important part of the evaluation is a thorough and appropriately tailored history.
- Detailed review of the event including time, duration, surrounding circumstances, relation to feeds, appearance of the infant, need for stimulation or resuscitation efforts, and extent
- Thorough details of past medical history including prenatal, birth, and neonatal course; history of prematurity, lung disease, previous apparent life-threatening events (ALTEs)
- Evaluate for recent illness, exposure to infection, feeding difficulties, medications, or vaccines
- Significant family history includes smoke exposure, previous infant deaths, genetic disorders, and cardiac/respiratory disorders.
- Probe for evidence or suspicion of child maltreatment.

PHYSICAL EXAM

- Detailed physical examination, including vital signs, with particular attention to cardiorespiratory and neurologic system is very crucial in determining any underlying condition.
- Examine for signs of child abuse.

DIAGNOSTIC TESTS & INTERPRETATION

ALERT

Initial diagnostic panel for ALTE patients should include CBC with differential, CRP, serum glucose and electrolytes, ABG, urine culture, urine toxicology screen, EKG, respiratory viral panel (RSV, flu,

rhinovirus), and pertussis culture.

- Routine screening tests for various etiologies without historical risk factors or suggestive physical exam findings is a very low-yield process.
- Further testing should be based on clinician judgment depending on history and physical exam findings.

Lab

Ammonia, lactate, pyruvate if there are concerns of a metabolic syndrome

Imaging

- Chest x-ray to evaluate for infection or cardiac disease
- Skeletal survey if child abuse is suspected
- Head CT or head ultrasound (if <6 months old) in suspected trauma or elevated intracranial pressure
- Head MRI, if indicated, to evaluate for congenital malformations

Diagnostic Procedures/Other

- EKG/Holter monitoring to evaluate for arrhythmias or conduction problems
- Lumbar puncture if sepsis/meningitis is in the differential diagnosis
- EEG to rule out seizures, especially in case of recurrent ALTE
- A pH probe or modified barium swallow if concerning ALTE is associated with feeding
- Sleep study for evaluation of different types of apnea
- Ophthalmologic exam to identify retinal hemorrhages if child abuse is suspected

DIFFERENTIAL DIAGNOSIS

Immaturity of respiratory control is the primary cause for AOP, but many coexisting factors can potentiate or worsen apnea. Apnea of infancy is uncommon and should warrant a thorough evaluation.

- Infections
 - Respiratory illness: respiratory syncytial virus, pertussis, or pneumonia
 - Sepsis, urinary tract infection, necrotizing enterocolitis, or CNS infection

- Environmental
 - Suffocation, head injury
 - Child abuse
 - Hypothermia or hyperthermia
- Neurologic
 - Seizure
 - Intracranial hemorrhages, CNS malformations
 - Hydrocephalus
 - Neuromuscular disorders
 - CNS tumors
 - Post general anesthesia
- Respiratory
 - Obstructive sleep apnea
 - Nasal obstruction
 - Airway obstruction
 - Foreign body aspiration
 - Breath-holding spells
 - Vocal cord abnormality: laryngotracheomalacia
 - Chest masses/malformations
 - Pneumonia
 - Upper respiratory tract infection
- Metabolic
 - Inborn errors of metabolism
 - Hypoglycemia or electrolyte disturbances
- Cardiovascular
 - Congenital heart disease, patent ductus arteriosus (PDA)
 - Arrhythmias: long QT syndrome, Wolff-Parkinson-White syndrome
 - Cardiomyopathy
 - Myocarditis
- Gastrointestinal
 - GER, feeding hypoxemia
 - Dysphagia or swallowing disorder, intussusception
- Toxin/drugs
- Overdose
 - Sedatives, seizure medications, pain medications

- Hematologic
 - Anemia
- Genetic
 - CCHS
 - Craniofacial anomalies (Pierre Robin sequence)
 - Down syndrome
 - Prader-Willi syndrome

ALERT

Preterm infants with a high frequency of apnea associated with chronic intermittent hypoxia need prolonged respiratory support, take longer to achieve oral feeds, have a greater incidence of retinopathy of prematurity, and have greater risk of adverse neurodevelopmental outcomes.

TREATMENT

MEDICATION

- AOP: Methylxanthines (theophylline and caffeine citrate) are used in hospital settings. Caffeine is preferred due to better absorption, less toxicity, and a wider therapeutic window and half-life that allows once-daily dosing.
- Caffeine citrate (IV or PO) dosing: Loading dose of 20 mg/kg and maintenance dose of 5–8 mg/kg/day. Common side effects include tachycardia, arrhythmia, feeding intolerance, seizures, and diuresis.
- Usually, AOP resolves by 36–40 postmenstrual weeks; however, in more immature infants, born at less than 28 weeks' gestation, apnea may continue until 40–43 weeks postmenstrual age. Once caffeine is discontinued, it is recommended to watch for 5–7 days.

ADDITIONAL TREATMENT

General Measures

- Continuous positive airway pressure (CPAP) splints open the upper airway and improve oxygenation by increasing functional residual capacity. CPAP may be used to treat mixed and obstructive apnea. Positive pressure ventilation may be needed for severe or persistent apnea.

- Patients with a major ALTE should be observed with continuous cardiorespiratory monitoring for a minimum of 23 hours in a hospital setting.
- In case of ALTE where a specific cause was identified, medical or surgical treatment of underlying disorder is indicated.
- Follow-up of the infant with a health care practitioner is recommended within 48 hours after discharge.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Infants born before 37 weeks should pass a car seat test prior to discharge after birth.
- Caregivers should be instructed on back-to-sleep, crib safety measure, and avoidance of tobacco smoke exposure and trained in cardiopulmonary resuscitation.
- Home cardiorespiratory monitoring may be considered for infants with chronic lung disease (especially those requiring oxygen supplementation, CPAP, or ventilator). Home monitoring should be used in infants with a tracheostomy or with neurologic, genetic, or metabolic conditions affecting respiratory control. Parents should be appropriately counseled about the purpose, stresses, end point, and proper usage. Parents should be made aware that use of home monitoring does not reduce the risk for sudden infant death.

PROGNOSIS

- Premature infants have 3–5% increased risk for sudden infant death syndrome (SIDS).
- AOP has not been found to be precursor or predictor of SIDS; however, there may be increased risk of SIDS in patients with ALTE.

CODES

ICD10

- P28.4 Other apnea of newborn
- P28.3 Primary sleep apnea of newborn
- G47.31 Primary central sleep apnea

FAQ

- Q: Should infants on caffeine for AOP be discharged home?
- A: It is not universal practice that infants with AOP are discharged home on caffeine and home monitoring. It is more common to discharge the infant home 5–7 days after caffeine has been discontinued.
- Q: What should be the end point of home monitoring?
- A: For AOP, if no true events are detected for several weeks and the infant is older than 43 weeks post menstrual age (PMA) and off of all respiratory stimulants for 7 days. For infants who are born at 23–25 weeks, apnea could persist beyond 43 weeks PMA. For monitoring in other cases, it would depend on the frequency and severity of the events.
- Q: What is the role of antireflux medication in the treatment of apnea?
- A: Controversy exists regarding the role of GER in causing apnea in premature infants. Reflux is most likely to trigger apneic events in term infants. Nevertheless, if there is a clear relationship between the apneic event and reflux, then a trial of antireflux medication is recommended.

However, if there is no clinical improvement, it should be discontinued.

NEONATAL CHOLESTASIS

Stefany B. Honigbaum • Kathleen B. Schwarz

BASICS

DESCRIPTION

- Neonatal cholestasis is defined as elevated conjugated bilirubin levels that occur in the newborn period. It typically indicates hepatobiliary dysfunction.
- Further studies are needed on any infant who is jaundiced beyond 2 weeks old (or 3 weeks if breastfed).
- Biochemical definition: serum conjugated bilirubin >20% of the total bilirubin concentration or direct bilirubin >2 mg/dL

EPIDEMIOLOGY

- Full-term infants: Most common causes in the 1st month are extrahepatic biliary atresia (EHBA), idiopathic neonatal hepatitis, alpha-1 antitrypsin deficiency, and progressive familial intrahepatic cholestasis (PFIC).
- Premature infants: must consider sepsis and TPN-associated cholestasis
- Incidence of neonatal cholestasis is 1 in 2,500 live births (excluding infants with history of parenteral nutrition).

RISK FACTORS

Genetics

Causes of biliary atresia, neonatal hepatitis, and most other etiologies of neonatal cholestasis remain unknown.

Known genetic causes include the following:

- Alpha-1 antitrypsin deficiency
 - Autosomal codominant expression
 - Mutations in SERPINA1 gene
 - 10–15% of individuals develop hepatic disease.
 - 2 alleles most commonly associated with liver disease: Z and M
- Alagille syndrome
 - Autosomal dominant, variable expressivity

- Mutations in JAG1 and NOTCH2 gene
- PFIC
 - Group of familial cholestatic disorders: PFIC-1, 2, and 3. Note PFIC 1 and 2 have low GGT values.
 - Autosomal recessive
 - Caused by mutations in FIC1, ATP8B1, ABCB11, and ABCB4 genes

PATHOPHYSIOLOGY

- Neonatal cholestasis is jaundice secondary to elevated conjugated bilirubin levels in the newborn period.
- Typically, infants are not jaundiced at birth but develop cholestasis within days to weeks of life. In utero, the placenta and maternal liver perform the necessary hepatic functions for the infant. The liver slowly matures throughout the 1st year of life to reach full hepatic metabolism potential.
- Neonatal cholestasis can be caused by a variety of mechanisms of hepatobiliary dysfunction that results in poor bile flow or excretion. In addition, there is inefficient enterohepatic circulation in the newborn period, which contributes to bilirubin accumulation.

ETIOLOGY

Most likely etiologies in <2-month-old infant:

- Obstructive: biliary atresia, gallstones/sludge, inspissated bile, choledochal cyst, neonatal sclerosing cholangitis, congenital hepatic fibrosis/Caroli disease, Alagille syndrome
- Idiopathic: idiopathic neonatal hepatitis
- Infection: UTI, sepsis, cytomegalovirus (CMV), herpes simplex virus (HSV), syphilis, parvovirus B19, adenovirus, enterovirus
- Metabolic/genetic: alpha-1 antitrypsin deficiency, tyrosinemia, PFIC, cystic fibrosis (CF), galactosemia, lipid storage disease, bile acid synthesis defects, mitochondrial hepatopathy, peroxisomal disorders
- Endocrine: hypothyroidism, panhypopituitarism
- Toxic: parenteral nutrition–associated cholestasis, drug-induced
- Miscellaneous: hypoperfusion/shock

COMMONLY ASSOCIATED CONDITIONS

- 10% of infants with biliary atresia also have another major congenital defect (other than laterality defects, see below).
- Biliary atresia splenic malformation (BASM): syndromic form of BA with laterality defects
 - Situs invertus
 - Polysplenia or asplenia
 - Malrotation
 - Congenital heart disease
- Alagille syndrome
 - Syndromic appearance (triangular face, deep set eyes, broad nose)
 - Cardiac anomalies, typically peripheral pulmonary stenosis (PPS)
 - Butterfly vertebrae
 - Ophthalmologic findings: posterior embryotoxon

DIAGNOSIS

HISTORY

- Pregnancy and birth history
- History of consanguinity
- Family history/racial background
- Infectious exposure
- TPN exposure, prolonged history of NPO status
- Presence/absence of extrahepatic manifestations
- Signs and symptoms:
 - Jaundice
 - Hepatomegaly
 - Pale-colored stools
 - Dark-colored urine
 - For specific diagnoses:
 - Alagille syndrome: typical facies, heart murmur
 - Congenital infections: low birth weight, microcephaly, rash, chorioretinitis
 - Metabolic disorders: irritability, hypoglycemia, poor feeding, lethargy

PHYSICAL EXAM

- Jaundice/scleral icterus
- Hepatomegaly
- Splenomegaly
- Cardiac murmurs
- Dysmorphic facial features
- Neurologic abnormalities
- Stool color

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Clinical scenario must be taken into consideration to determine which of the following are appropriate:

- Fractionated serum bilirubin (total and direct)
- ALT, AST, alkaline phosphatase
- Gamma glutamyl transpeptidase (GGT)
- Serum albumin
- Prothrombin time/INR
- Glucose
- CBC
- Urine culture +/- blood culture
- Urine-reducing substances
- Serum alpha-1 antitrypsin level and phenotype
- Serologies: CMV, HSV, enterovirus, hepatitis A and B
- Fat-soluble vitamin levels: A, D, and E
- Cortisol, TSH, T₄
- Infant metabolic screen
- Plasma amino acids, urine organic acids, lactate/pyruvate
- Urine succinylacetone (tyrosinemia)
- Genetic testing for Alagille syndrome, PFIC (1–3), alpha-1 antitrypsin deficiency
- Serum and urine bile acids

Imaging

- Abdominal ultrasound (choledochal cyst, presence of gallbladder)
- Chest x-ray (for butterfly vertebrae with Alagille syndrome)

- Hepatobiliary scintigraphy (HIDA scan) after phenobarbital administrations for 5 days
- X-rays of skull and long bones (for congenital infections and peroxisomal disorders)

Diagnostic Procedures/Other

- Liver biopsy for histology, routine viral culture, immunohistochemistry, and electron microscopy as indicated
- Sweat chloride analysis
- MRCP
- Ophthalmologic exam (for posterior embryotoxin in Alagille syndrome, chorioretinitis)
- Intraoperative cholangiogram
- Echocardiogram (PPS in Alagille syndrome)

DIFFERENTIAL DIAGNOSIS

See “[Etiology](#).” The provider must be able to distinguish neonatal cholestasis from physiologic or breast milk jaundice in infancy.

ALERT

Most causes of neonatal cholestasis require expedited diagnosis and intervention:

- Biliary atresia
- Choledochal cyst
- Infection
- Metabolic disorders (e.g., galactosemia)
- Endocrine disorders (e.g., hypothyroidism, hypopituitarism)

TREATMENT

MEDICATION

- Ursodeoxycholic acid (improvement in hepatic function and absorption of fat-soluble vitamins)
- Antihistamines and rifampin (for pruritus associated with cholestasis)
- Antibiotics and antivirals (when appropriate)
- ADEK vitamins (if fat-soluble vitamin deficiencies)

ISSUES FOR REFERRAL

All neonates with cholestasis as defined earlier should have referrals to a pediatric gastroenterologist for further evaluation and management. If the provider suspects biliary atresia or metabolic disease, referral to the appropriate subspecialist should be prompt.

ADDITIONAL THERAPIES

- Consider the need for speech therapy, occupational therapy, or physical therapy when appropriate.
- Nutritional support

SURGERY/OTHER PROCEDURES

- Intraoperative cholangiogram if suspect biliary atresia
- Kasai procedure (hepatoportoenterostomy) for biliary atresia
- Surgical referral for removal of choledochal cyst
- Biliary diversion for severe pruritus associated with Alagille syndrome and PFIC
- Liver transplantation

INPATIENT CONSIDERATIONS

Initial Stabilization

- Sepsis must be identified and treated.
- Coagulopathy (prolonged INR) should be treated with vitamin K.

ONGOING CARE

DIET

- Nutritional support needed. Typically, an elemental formula with high content medium-chain triglycerides is better absorbed in cholestasis.
- Consider need for nasogastric tube feeds.
- Special diets
 - Supplementation with pancreatic enzymes (CF)
 - Galactose-free (galactosemia)

PROGNOSIS

Varies based on underlying diagnosis. Biliary atresia remains the most common indication for pediatric liver transplantation.

COMPLICATIONS

- End-stage liver disease (ascites, coagulopathy) and portal hypertension requiring liver transplantation
- Infection
- Failure to thrive
- Poor bone health
- Developmental delay

CODES

ICD10

- K83.1 Obstruction of bile duct
- Q44.2 Atresia of bile ducts
- P59.20 Neonatal jaundice from unspecified hepatocellular damage

FAQ

- Q: If my patient has an abnormal HIDA scan, does that mean he/she has biliary atresia?
- A: A HIDA scan can be abnormal in obstructive causes of cholestasis other than biliary atresia. A surgical evaluation via an intraoperative cholangiogram is the gold standard to diagnose biliary atresia.

- Q: What vitamin deficiencies are most common in infants with cholestasis?
- A: Infants with cholestasis often have malabsorption of fat-soluble vitamins (A, D, E, and K) and require supplementation.

NEONATAL ENCEPHALOPATHY

Jennifer C. Burnsed • Frances J. Northington

BASICS

DESCRIPTION

A neonatal neurologic diagnosis notable for depressed level of consciousness with or without seizures. This is a nonspecific term with many etiologies, most commonly hypoxic ischemic encephalopathy (HIE).

EPIDEMIOLOGY

- Most commonly term infants
- Incidence in developed countries 2.5 per 1,000 live births
- 50–80% of cases secondary to HIE

RISK FACTORS

- Variable depending on etiology
- HIE
 - Sentinel event (placental abruption, uterine rupture, cord accident, etc.)
 - Maternal factors: advanced age, obesity, diabetes, severe preeclampsia, infertility treatments, maternal thyroid disease, and placental abnormalities

PATHOPHYSIOLOGY

- Hypoxic ischemic event leading to brain injury with energy failure and ongoing secondary injury, leading to encephalopathy and possibly seizures
- Ongoing injury involves excitotoxic glutamate accumulation in synapses, alterations in cellular calcium management, free radical production and nitrosative/oxidative damage, mitochondrial failure, activation of proteases, and other death cascades, cellular death, with both acute and delayed cytokine production and inflammation.
- Other etiologies include various metabolic disorders, hypoglycemia, kernicterus, nonketotic hyperglycinemia, intracranial infection,

perinatal arterial ischemic stroke (PAIS), and sinovenous thrombosis.

DIAGNOSIS

HISTORY

- Sentinel event (uterine rupture, placental abruption, cord accident, cardiorespiratory arrest in delivery room)
- Low Apgar scores
- Advanced resuscitation required in delivery room (intubation, chest compressions, medications)

PHYSICAL EXAM

- Altered level of consciousness (hyperalert or lethargic/obtunded)
- Initial hypotonia
- Weak or absent reflexes
- Decerebrate posturing
- Distal flexion, complete extension
- Abnormal autonomic nervous system:
 - Constricted or unreactive pupils
 - Deviated/dilated pupils
 - Bradycardia
 - Periodic breathing/apnea
- Possible seizure activity: Importantly, seizures may continue but be subclinical (electrical only) after loading dose of an antiepileptic drug (AED).

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Umbilical cord gas (HIE)
- Glucose (hypoglycemia)
- Electrolytes (metabolic abnormalities)
- Bilirubin (kernicterus)
- Lactate and ammonia (HIE and metabolic abnormalities)
- Plasma amino acids and urine organic acids (metabolic abnormalities)

Imaging

- Head ultrasound (cerebral edema associated with HIE, intracranial hemorrhage)
- MRI with DWI (structural anomalies, stigmata of various encephalopathies, stroke, intracranial hemorrhage)

Diagnostic Procedures/Other

- EEG (seizures, electrographic background—specifically discontinuity, burst suppression patterns)
- Amplitude-integrated EEG (if available)
- Lumbar puncture (cell count for infection, metabolic workup including neurotransmitters)

DIFFERENTIAL DIAGNOSIS

- HIE
- Metabolic disorder
- Intracranial hemorrhage or PAIS
- Hypoglycemia
- Kernicterus
- Nonketotic hyperglycinemia
- Epileptic syndromes/seizure disorder
- Infection (meningitis, encephalitis)

TREATMENT

MEDICATION

- Antiepileptic medications for seizures
 - Phenobarbital or levetiracetam, depending on clinical preference. Multiple other AED are used based on clinical experience and preference.
 - No conclusive data available to guide choice of AED currently. Developing a consensus on treatment with neonatal and neurology consultants is recommended.

ADDITIONAL THERAPIES

- Hypothermia therapy (HT) for moderate to severe HIE (significantly decreased risk of death or moderate to severe disability when treated)

- Criteria for initiation of HT in newborns:
 - <6 hours of age, ≥ 35 weeks' gestation, and $\geq 1,800$ g
 - Umbilical cord or infant pH ≤ 7.0 or base deficit ≥ 16 mmol/L at <1 hour of life AND moderate to severe encephalopathy
 - Umbilical cord or infant pH between 7.01 and 7.15 or base deficit between 10 and 15.9 mmol/L at <1 hour of life AND
 - 10 minute Apgar score <5 OR
 - Need for assisted ventilation at birth with continuation AND moderate to severe encephalopathy
 - Moderate to severe encephalopathy (1–3 of the following present in the newborn)
 - Lethargy
 - Stupor/coma
 - Decreased or no activity
 - Distal flexion, complete extension
 - Decerebrate posture
 - Hypotonia or flaccidity
 - Abnormal primitive reflexes: weak/absent/incomplete moro
 - Abnormal autonomic nervous system (constricted or unreactive pupils, deviated/dilated pupils, bradycardia, periodic breathing/apnea)
- Specific management of metabolic disorder or electrolyte/glucose abnormality
 - Time of appearance of symptoms in relationship to birth and presence or absence of a perinatal sentinel event often provides important clues to presence of a metabolic disorder.
 - Immediate recognition and treatment of hypoglycemia, hyponatremia, and hypocalcemia with further investigation into causality and prevention of recurrence
 - Recognition of hyperammonemia is emergent.
 - Lactate/pyruvate ratios, plasma amino acids, urine organic acids, and possibly CSF neurotransmitter levels are often helpful and diagnostic.
 - EEG combined with pyridoxine supplementation can be diagnostic as well.

- DW-MRI may reveal important diagnostic clues for metabolic encephalopathies.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Developmental pediatrician
- Pediatric neurologist
- Geneticist (if applicable)

PROGNOSIS

- Widely variable depending on etiology, severity (if HIE), and treatment
- Of patients with moderate to severe HIE treated with hypothermia: at 6–7 years of age, death or an IQ score below 70, 47%; death, 28%; death or severe disability, 41%; moderate or severe disability, 35%; attention–executive dysfunction, 4%; visuospatial dysfunction, 4%
- Perinatal arterial stroke: cerebral palsy (58%), epilepsy (39%), language delay (25%), and behavioral abnormalities (22%)

CODES

ICD10

- P91.60 Hypoxic ischemic encephalopathy [HIE], unspecified
- P91.61 Mild hypoxic ischemic encephalopathy [HIE]
- P91.62 Moderate hypoxic ischemic encephalopathy [HIE]

FAQ

- Q: Is neonatal encephalopathy secondary to HIE always associated with an acute perinatal event?
- A: No. Neonatal encephalopathy may be secondary to an ongoing process in utero and not associated with an acute event. There may be signs prenatally such as decreased fetal movement or abnormalities in fetal heart tracings.
- Q: Does the infant have to be less than 6 hours old to be a candidate for hypothermia therapy?
- A: Yes. Current research has shown that in order to prevent the secondary energy failure and further brain injury, hypothermia should be initiated as soon as possible and within 6 hours of birth. If there is concern for encephalopathy in the delivery room, according to the Neonatal Resuscitation Program, the radiant warmer may be turned off and the infant may be passively cooled until further evaluation can be performed. If applicable, consultation with a referral center that

provides hypothermia therapy should be performed as soon as possible. Research trials will determine if there is any value in a more delayed application of the therapy.

NEPHROTIC SYNDROME

Stephanie Clark • Rebecca Ruebner

BASICS

DESCRIPTION

Nephrotic syndrome (NS) is defined by nephrotic-range proteinuria, hypoalbuminemia, edema, and hypercholesterolemia. Nephrotic-range proteinuria is typically found when there is 3–4+ protein on the urine dipstick and is defined as $>40 \text{ mg/m}^2/\text{h}$ or a spot protein-to-creatinine ratio $>2 \text{ mg protein/mg creatinine}$.

EPIDEMIOLOGY

- Minimal change nephrotic syndrome (MCNS) is the most frequent cause of NS in younger children:
 - Occurs mainly between 2 and 8 years of age, with a peak at 3 years
 - Boys are more commonly affected than girls (3:2).
 - Atopy and MCNS have an association.
- Focal segmental glomerulosclerosis (FSGS) is the 2nd most frequent cause of NS in childhood:
 - Children with FSGS are more likely than children with MCNS to have steroid-resistant nephrotic syndrome (SRNS).
- Less common than MCNS and FSGS are congenital NS (<3 months) and infantile NS (<1 year).
- Black and Hispanic children have a higher incidence of FSGS than do white and Asian children.
- Prevalence of 16 cases per 100,000 in children <16 years

PATHOPHYSIOLOGY

- Disruption of podocyte architecture composing the glomerular filtration barrier leads to proteinuria, hypoalbuminemia, and subsequently edema.
- Hypercholesterolemia occurs due to increased liver production of cholesterol in response to hypoalbuminemia as well as to loss of lipoprotein lipase in urine.

- MCNS Pathology
 - The glomerular tuft and size are normal.
 - Mesangial expansion is absent or minimal.
 - Immunofluorescence is usually negative, although mild staining for C3, IgM, and IgA may occasionally be found.
 - Electron microscopy reveals effacement of the visceral (podocyte) epithelial foot processes, which is reversible.

ETIOLOGY

- Most pediatric cases are primary; 5–10% are secondary to other diseases.
- The most common primary cause of NS in childhood is MCNS. It is characterized by minimal histologic changes on light microscopy and is usually steroid-sensitive nephrotic syndrome (SSNS).
- Other causes of primary NS include FSGS, membranous, and membranoproliferative glomerulonephritis (GN).
- Secondary causes of NS include infections, vasculitis, diabetes, drugs (e.g., NSAIDs), and hereditary disorders.
- Examples of congenital NS include Finnish type, diffuse mesangial sclerosis (DMS), and syphilitic nephrosis.
- NS can also be caused by inherited mutations in proteins involved in the podocyte cytoskeleton, which often results in SRNS and FSGS.

DIAGNOSIS

HISTORY

- Inquire about known atopy or food intolerance.
- Inquire about drug exposure (especially NSAID agents).
- Inquire about any recent infections.
- Signs and symptoms:
 - Fatigue and general malaise
 - Reduced appetite
 - Weight gain and facial swelling
 - Puffy eyes
 - Abdominal swelling or pain

- Foamy urine
- Atopy
- Pitting, dependent edema
- Fluid accumulation in body spaces (ascites, pleural effusions, scrotal swelling)
- Mild hypertension (10–20% of patients)

PHYSICAL EXAM

Look for edema in the most dependent area of the child:

- Legs
- Lumbar spine
- Scalp
- Soft ear cartilage
- Scrotum/labia

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Initial lab tests

- The urine dipstick usually shows 2,000 mg/dL (4+) of protein:
 - In small children with NS, the urine dipstick may show <4+.
- Timed or spot urine protein collection
 - 24-hour urine shows >40 mg/kg/day.
 - Spot urine protein-to-creatinine ratio >2 mg/mg.
- Microscopic hematuria is present in 10–20% of cases: The presence of RBC casts is more suggestive of glomerulonephritis.
- Serum creatinine usually normal
- Serum albumin usually <2.5 g/dL
- Total cholesterol elevated, usually >200 mg/dL but can be as high as 500 mg/dL
- Home testing
 - The 1st morning urine is tested for protein with urine dipsticks daily.

Imaging

In complicated cases, renal ultrasound to evaluate for kidney size, parenchymal architecture, and renal venous thrombosis.

DIFFERENTIAL DIAGNOSIS

- Edema
 - CHF
 - Liver failure
 - Protein-losing enteropathy
 - Protein-energy malnutrition (Kwashiorkor)
- NS:
 - MCNS
 - FSGS
 - Membranous GN
 - Membranoproliferative GN
 - Diffuse mesangioproliferative GN

TREATMENT

MEDICATION

First Line

- Corticosteroids are used as 1st-line therapy in suspected MCNS.
 - On presentation: prednisone 2 mg/kg/day for 4–6 weeks (maximum: 60 mg); then prednisone 1.5 mg/kg on alternate days (maximum: 40 mg) and continued for 2–5 months with tapering of the dose.
 - On relapse: prednisone 2 mg/kg/day until urine protein test results are negative or trace for 3 consecutive days; then prednisone 1.5 mg/kg on alternate days for at least 4 weeks.
 - Inadequate duration of corticosteroid therapy is associated with increased risk of relapse

Second Line

- Alkylating agents (cyclophosphamide, chlorambucil)
- Mycophenolate mofetil (MMF)
- Calcineurin inhibitors (cyclosporine A, tacrolimus)
- Rituximab

Supportive Medications

- Diuretics
- ACE inhibitors or angiotensin receptor blockers

- Statins for hypercholesterolemia in persistent NS

ALERT

- Live vaccines are contraindicated while daily corticosteroids or alkylating agents are being given.
- Children in relapse, on corticosteroids, or on alkylating agents and who are nonimmune and exposed to varicella should receive VZIG.
- Albumin and/or furosemide must be used cautiously to prevent pulmonary edema from rapid fluid shifts or intravascular dehydration.

ADDITIONAL TREATMENT

General Measures

- Influenza vaccination yearly
- Full pneumococcal vaccination with PCV13 when needed and 23-valent pneumococcal vaccine
- PPD and chest x-ray at initial presentation prior to starting corticosteroids if risk factors for tuberculosis present

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- When to expect improvement:
 - Remission occurs 2–4 weeks after starting corticosteroids in MCNS.
- Signs to watch for:
 - Fever, abdominal pain, oliguria, respiratory distress
- Pitfalls:
 - Recognize situations in which hypovolemia may occur and trigger thrombosis and/or acute kidney injury.
- Monitor for complications of glucocorticoid therapy:
 - Growth failure
 - Cataracts
 - Hypertension
 - Osteopenia
 - Steroid-induced gastritis

DIET

Restrict salt intake while in relapse or on daily corticosteroids.

PATIENT EDUCATION

Educate the family about urine testing, complications, diet, and prognosis.

PROGNOSIS

- The prognosis for MCNS is excellent, with a mortality rate of <1%:
 - 80–90% of MCNS are steroid-sensitive.
 - 20–30% of MCNS will never relapse.
 - 40% of MCNS become steroid-dependent or frequent relapsers.
 - Remaining 30–40% MCNS have infrequent relapses.
- Patients with FSGS, genetic forms of NS, or other secondary causes are more likely to be steroid-resistant and may progress to develop chronic kidney disease.

COMPLICATIONS

- Risk factors for hypovolemia in NS:
 - Severe relapse, GI illness, diuretic use, or sepsis
- Risk factors for thrombosis in patients with NS:
 - Hypovolemia, immobilization, thrombocytosis; urinary losses of protein C, protein S, and antithrombin III
- Risk factors for acute kidney injury in patients with NS:
 - Hypovolemia, bilateral renal vein thrombosis, diuretics, or ACE inhibitors
- Most complications are secondary to steroid therapy and include growth retardation, glaucoma, posterior lens cataracts, obesity, mood changes, hirsutism, osteoporosis, and infection.
- Spontaneous bacterial peritonitis (SBP) is an important and potentially life-threatening complication of NS.
 - Symptoms include fever, abdominal pain, vomiting, and diarrhea.
 - Diagnosis is confirmed by ascitic fluid polymorphonuclear cell count of ≥ 250 cells/mm³ and positive bacterial culture.
 - Rapid institution of antibiotic therapy is crucial in any patient with NS and suspected SBP.
- Diarrhea and vomiting may result in rapid, severe hypovolemia.
- Vascular thromboses are found with NS in relapse, especially if hypovolemia is present.

- Sites of thrombosis include lower extremities, IVC, renal veins, cerebral sinuses, and pulmonary emboli.
- Viral infections (measles, varicella) may be life threatening in immunocompromised patients.
- Acute reversible renal failure is an uncommon complication of NS of childhood.

CODES

ICD10

- N04.9 Nephrotic syndrome with unspecified morphologic changes
- N04.0 Nephrotic syndrome with minor glomerular abnormality

- N05.1 Unsp neph syndrome w focal and segmental glomerular lesions

FAQ

- Q: Will the MCNS recur?
- A: The clinical course tends to be one of multiple remissions and relapses. Relapses usually improve around the time of puberty.
- Q: Can the NS return in adult life?
- A: Yes. This does occur.
- Q: Is macroscopic hematuria ever found with MCNS?
- A: Gross hematuria suggests a renovascular event or a diagnosis other than MCNS. Microscopic hematuria occurs in ~10–20% of cases.
- Q: What other agents are used to treat NS?
- A: Cyclosporin A, tacrolimus, MMF, cyclophosphamide, and ACE inhibitors/angiotensin receptor blockers are used in children with steroid-dependent or steroid-resistant NS.

NEURAL TUBE DEFECTS

Eric B. Levey

BASICS

DESCRIPTION

Neural tube defects (NTDs): CNS malformations due to abnormalities of neural tube closure during early embryonic development and include anencephaly, encephalocele, and spina bifida (SB)

- Open NTDs: Exposed neural tissue and membranes protrude through a bony defect and lack a skin covering.
 - Due to failure of primary neural tube closure during the 3rd and 4th weeks after fertilization
 - Include anencephaly, craniorachischisis, myelomeningocele, and myeloschisis
- Closed NTDs: theorized to be due to defects of secondary neurulation. Less common than open NTDs and are skin covered.
 - Include some encephaloceles and various types of occult spinal dysraphism (OSD)
- Anencephaly: due to failed closure of rostral neural tube with total or partial absence of cranial vault and cerebral hemispheres
- Encephalocele: partial failure of rostral neural tube closure
 - Abnormal brain tissue protrudes through a skull defect usually covered by skin.
 - 70–80% are occipital, 20% are frontal.
 - 10–20% of occipital defects are meningoceles and contain no brain tissue.
- SB: means “spine split in two” and includes open and closed types
 - Myelomeningocele (MMC): open NTD of the spine, most common type of SB, and characterized by herniation of dysplastic spinal cord and meninges through a posterior vertebral column defect
 - Closed SB: often not diagnosed at birth and often referred to as occult spinal dysraphism.
 - Intact skin over the defect

- Wide spectrum of defects including lipomyelomeningocele, dermal sinus tracts, diastematomyelia (split cord malformations), myelocystocele, other tumors and cysts of the cord, and congenital spinal cord tethering

EPIDEMIOLOGY

Prevalence

- NTDs affect ~1 in 1,000 established pregnancies worldwide, with significant geographic variation.
- In the United States, birth prevalence has been decreasing due to periconceptional supplementation with folic acid as well as prenatal diagnosis and termination of pregnancy.
- CDC data from 2004 to 2006 showed 0.64 NTDs per 1,000 births (~2,660 cases per year), with 54% classified as SB, 32% anencephaly, and 13% encephalocele.

RISK FACTORS

Most NTDs are due to the interaction of genetic, environmental, and dietary risk factors.

- Variants of multiple genes probably confer some increased genetic susceptibility.
- Maternal nutrition and dietary factors
 - Inadequate maternal folic acid intake
- Maternal diabetes mellitus
- Maternal obesity
- Maternal use of valproic acid (10× risk), carbamazepine, or alcohol during pregnancy
- Maternal exposure to hyperthermia during early pregnancy (e.g., sauna, hot tub, fever)

Genetics

- In most NTD cases, a specific genetic cause is not found.
- Positive family history in ~5% NTD cases
- After 1 child with an NTD, the recurrence rate is 2–5% for subsequent pregnancies.
- A chromosomal or cytogenetic abnormality in ~10% of isolated NTDs, higher percentage in those with multiple congenital anomalies

- NTDs common in trisomy 13 and 18 and can be seen with duplications and deletions.
- Also seen as in single gene disorders or syndromes (e.g., Meckel, Waardenburg, 22q11 deletion syndromes)
- A number of candidate risk factor genes have been studied; the most implicated are those in the folate one-carbon metabolic pathway.
 - A homozygous 677C>T mutation of the methylenetetrahydrofolate reductase (MTHFR) gene in mother or child is associated with ~1.8 times increased risk.

GENERAL PREVENTION

- Periconceptual folic acid supplementation has the potential to reduce NTDs by 50–70%.
- Because many pregnancies are not identified until after neural tube closure occurs, and because more than 50% of pregnancies are unplanned, the CDC recommends that all women of childbearing age receive a minimum of 0.4 mg (400 mcg) of folic acid daily.
- Women at high risk (prior pregnancy with NTD, on valproic acid, etc.) should take high-dose folic acid (4 mg daily), starting 1 month before and through the first 3 months of pregnancy.
- If taking valproic acid, consider switching to alternative medication during pregnancy.

COMMONLY ASSOCIATED CONDITIONS

- Open SB is virtually always associated with some malformation of the brain.
- Most children with MMC have a Chiari II (Arnold-Chiari) malformation, small posterior fossa with elongation of the cerebellum, and herniation through the foramen magnum.
 - Chiari II malformation often causes obstructive hydrocephalus.
 - Historically, about 80% of children with MMC required a CSF shunt.
- Callosal dysgenesis, cortical dysplasia, and subependymal heterotopias are also common.
- MMC is commonly associated with nonverbal learning disabilities and executive dysfunction.

- Open and closed SB: impairments directly due to spinal cord dysfunction:
 - Paraparesis and sensory loss usually correlating with the level of the lesion
 - Neurogenic bladder dysfunction
 - Neurogenic bowel dysfunction
- Congenital foot deformities (club foot) and hip dysplasia are common with NTDs.

DIAGNOSIS

HISTORY

- Anencephaly, occipital encephaloceles, and open forms of SB are usually diagnosed prenatally and are obvious at birth.
- Occult frontal encephaloceles may come to attention because of developmental delays, seizures, or focal neurologic signs.
- OSD can present with progressive neurogenic bowel and bladder dysfunction, lower extremity weakness and/or sensory loss, gait abnormalities, foot deformities, and (rarely) recurrent meningitis.

PHYSICAL EXAM

- Serial head circumferences are (HC) used to monitor infants for progressive hydrocephalus.
 - Macrocephaly strongly suggests increased intracranial pressure (ICP).
 - Normal HC but with increasing percentiles over time may indicate hydrocephalus.
- Dysmorphic features may indicate a syndrome.
- Cranial nerve palsies (strabismus, vocal cord paresis, facial asymmetry), upper extremity (UE) weakness, and abnormal muscle tone can be seen with Chiari II malformation.
- OSD often signaled by a dimple, sinus tract, lipoma, hemangioma, or tuft of hair in the lumbosacral area.
- Functional motor level correlates with ambulatory potential in patients with SB.

- Flaccid paralysis is usually seen below the SB lesion; however, spasticity can be seen.
 - Sensory level may not correspond to motor level.
- Signs of tethered cord syndrome include worsening lower extremity (LE) weakness and spasticity.
- Limb growth may be asymmetric with shorter limb on more affected side (especially in OSD).
- Orthopedic exam should focus on hips, feet/ankles, and spine.
- Skin exam is important for identifying pressure ulcers in areas of impaired sensation.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Maternal serum alpha fetoprotein (MSAFP) testing, routinely done at 16–18 weeks gestation, is usually elevated with open NTDs.
- Elevated MSAFP should prompt referral for high-resolution ultrasound.
- Genetic testing including chromosomal microarray often done to look for cause

Imaging

- Prenatal ultrasound
 - Identifies >99% of cases of anencephaly and 90% of cases of MMC
- Postnatal neuroimaging
 - CT: often used to evaluate hydrocephalus: for initial newborn scan and older children when acute shunt malfunction suspected
 - Ultrasound: useful before anterior fontanel closes, especially to monitor hydrocephalus
 - MRI: gold standard for evaluating congenital anomalies of the spine and brain
 - For most patients with MMC, MRI is not necessary in the newborn period.
 - Better for defining the Chiari II malformation and other brain anomalies
 - Spine MRI is used to evaluate tethered cord or syringomyelia.
- Evaluation for suspected OSD

- Spine ultrasound may be useful for ruling out OSD or tethered cord in newborn or early infant.
- MRI is used to diagnose and define OSD in infants >6 months of age.
 - Lumbosacral MRI will identify most lesions.
 - However, consider MRI of brain and entire spine to evaluate for higher associated CNS anomalies (e.g., syringomyelia, diastematomyelia, Chiari malformation)
- OSD is common incidental finding on imaging that includes spine (e.g., KUB, upper GI, pelvis x-rays).
 - Isolated SB occulta (a defect of posterior vertebrae) without spinal cord involvement can be found in ~10% of the general population at autopsy.
 - Usually asymptomatic but should be vigilant for signs/symptoms of neurologic involvement
 - Further imaging is usually not necessary.
- Renal imaging is commonly done in children with MMC or other types of SB.
 - Ultrasound of kidneys and bladder is used to evaluate urinary tract in newborns and on regular basis in older children to monitor for hydronephrosis, hydroureter, and stones.
 - Voiding cystourethrogram (VCUG) is used to evaluate bladder emptying and vesicoureteral reflux in newborns and later as needed.
 - Nuclear medicine studies can be useful for evaluating kidney function and scarring from previous pyelonephritis.

Diagnostic Procedures/Other

- Urodynamic studies (cystometrogram) are used to evaluate bladder function and identify those at high risk for hydronephrosis.
- EEG for suspected seizures

TREATMENT

MEDICATION

- Anticholinergic medications (e.g., oxybutynin, tolterodine) are used to

relax the spastic bladder and increase capacity.

- Prophylactic antibiotics used when significant vesicoureteral reflux or recurrent urinary tract infections (UTIs)

GENERAL MEASURES

- Route of delivery
 - For most NTDs with vertex presentation, no clear benefit of cesarean delivery
 - Infants who undergo fetal surgery are delivered by cesarean section.
- Clean intermittent bladder catheterization (CIC): commonly used for neurogenic bladder dysfunction
 - For newborns with hydronephrosis, high-grade reflux, or high postvoid residuals
 - Older children for continence
- Latex precautions: avoidance of natural rubber latex to prevent development of latex allergy

ADDITIONAL THERAPIES

- Infants with SB are generally referred to their state's early intervention program.
- Older children typically receive therapy in school but may benefit from additional therapy through the health care system.

SURGERY/OTHER PROCEDURES

- Open encephalocele and SB: neurosurgical closure usually done within first few days of life to prevent infection and protect brain/spinal cord from injury. A moist, sterile dressing is applied to the defect until it is closed.
- Hydrocephalus often develops after an open NTD is closed (stopping leakage of CSF).
- CSF shunts (usually ventriculoperitoneal [VP]) are placed to treat progressive hydrocephalus.
- Fetal closure of MMC has been associated with reduced risk of hydrocephalus and improved developmental and motor outcomes in one prospective randomized trial.
- Fetal surgery for MMC should be considered in select patients prior to 26 weeks' gestation.

- OSD: Neurosurgical exploration and untethering of the spinal cord is usually done after diagnosis.
- Multiple urologic and orthopedic procedures are used to treat the complications of SB. Extensive discussion is beyond the scope of this chapter.

ONGOING CARE

Children with symptomatic SB ideally should be followed in a multidisciplinary SB clinic that includes neurosurgery, urology, and orthopedics as well as a medical generalist (pediatrics, physiatry or neurology) with experience evaluating and treating children with SB.

- Other specialties that are often important:
 - Physical therapy (mobility, LE function)
 - Occupational therapy (ADLs, UE function)
 - Neuropsychology (cognitive function)
 - Social work (coping, adjustment to chronic illness, linkage to resources)
 - Ophthalmology (can identify increased ICP when imaging is equivocal)

PROGNOSIS

- Anencephaly: 75% are stillborn; the remainder do not survive beyond the neonatal period.
- Encephalocele: Prognosis depends on the size of the defect, the amount of brain tissue involved, development of hydrocephalus, and the extent of associated brain malformation.
- MMC
 - Most survive into adulthood.
 - Most have IQ in normal range and almost all of remainder have mild intellectual disability. However, nonverbal learning disabilities and executive dysfunction are very common.
 - Risk of epilepsy ~15%; corresponds to degree of intellectual disability.
- SB (open and closed types)

- Prognosis for ambulation depends on the level of the lesion:
 - Sacral level: Most are community ambulators without assistive devices.
 - Low lumbar (L4–L5): Most will walk but many require bracing and some require crutches or other assistive devices.
 - Midlumbar (L3): often require bracing of the knee (and sometimes hip) to walk with crutches or a walker.
 - High lumbar (L1–L2) and thoracic: usually walk in therapy only and use wheelchair as primary means of mobility

COMPLICATIONS

- Encephalocele: Hydrocephalus, intellectual disability, motor deficits, and epilepsy are common.
- MMC
 - VP shunt infection or malfunction
 - Symptomatic Chiari II malformation
 - Infants: feeding difficulties/aspiration, hoarse cry or stridor (due to vocal cord paralysis), and central apnea
 - Older children: cranial nerve palsies, occipital headaches, UE weakness, sleep-disordered breathing
 - Syringomyelia
 - Strabismus
- SB (open and closed types)
 - Neurogenic bladder: UTI, hydronephrosis, stones, incontinence, risk of CKD
 - Neurogenic bowel: constipation, impaction, incontinence
 - Orthopedic deformities: scoliosis, hip dysplasia, ankle/foot deformities
 - Tethered spinal cord syndrome
 - Latex allergy
 - Pressure ulcers
 - Osteoporosis and pathologic fractures
 - Deep venous thrombosis
 - Obesity (especially nonambulatory patients)
 - Sexual dysfunction in males

CODES

ICD10

- Q00.0 Anencephaly
- Q01.9 Encephalocele, unspecified
- Q76.0 Spina bifida occulta

FAQ

- Q: Are neural defects genetic?
- A: Genetic factors are definitely involved, but in most cases, a single genetic cause is not found.
- Q: What is the chance of having another child with a neural tube defect?
- A: Recurrence risk with each subsequent pregnancy is about 2–5%.
- Q: How can someone reduce their risk of having a child with an NTD?
- A: Take 400 mcg of folic acid daily (preferably starting prior to conception) and avoid alcohol and drugs that can increase risk (especially valproic acid).

NEUROBLASTOMA

Lars M. Wagner

BASICS

DESCRIPTION

- Neuroblastoma is a “small round blue cell tumor” of childhood which arises from developing neural crest cells in the sympathetic nervous system.
- The clinical behavior of neuroblastoma is amazingly diverse. Some tumors undergo maturation into benign ganglioneuroma or even spontaneously regress without therapy, whereas others inexorably progress despite intensive treatment.
- Behavior of neuroblastoma tumors can often be predicted by combining clinical features (age, stage) with pathologic/molecular features (histologic characteristics, tumor ploidy, MYCN amplification, 1p, and 11q23 status).
- Integrating clinical and molecular features allows for appropriate risk stratification so that treatment can be tailored to the risk of recurrence. Current risk stratification identifies three separate groups of patients with different prognoses and treatment strategies:
 - Low-risk patients: localized tumors and/or favorable clinical and molecular features
 - Intermediate-risk patients: more extensive primary tumor or regional disease or unfavorable clinical and molecular features
 - High-risk patients: patients >18 months with metastatic disease or unfavorable molecular features

EPIDEMIOLOGY

- The median age at diagnosis is 19 months, with 89% of cases diagnosed younger than 5 years of age. Fewer than 5% of patients are diagnosed older than 10 years of age.
- The male:female ratio is 1.1:1.
- The majority of tumors arise in the retroperitoneum, with the adrenal gland being the single most common location.

Incidence

About 800 new cases per year in the United States (10 per million children per year)

Prevalence

- Accounts for 8–10% of all childhood cancer, making it the most common extracranial solid tumor and the most common cancer overall during the first 2 years of life
- Accounts for 15% of all pediatric cancer deaths
- Occurs in 1 per 7,000 live births

RISK FACTORS

Genetics

- Most cases arise spontaneously. One percent are familial (autosomal dominant) and are usually associated with ALK mutations.
- Patients with associated congenital central hypoventilation syndrome often have PHOX2B mutations.

PATHOPHYSIOLOGY

Tumor growth can cause symptoms in multiple ways:

- Neurologic: nerve or cord compression from paraspinal tumors
- Hypertension: from renal artery distortion or occasionally from excessive catecholamine release
- Pain: from metastatic bone disease
- Pancytopenia: from marrow disease

ETIOLOGY

No known etiology or causative environmental exposures

COMMONLY ASSOCIATED CONDITIONS

May occur along with other disease that have dysregulation of the peripheral nervous system, such as neurofibromatosis type I, Hirschsprung disease, or central congenital hypoventilation syndrome

DIAGNOSIS

HISTORY

- Patients with low-risk disease often appear well and the tumor is discovered incidentally on exam or imaging studies for other reasons.
- High-risk patients often are ill-appearing with obvious symptoms related to tumor location:
 - Abdominal pain or distension
 - Painful bone metastases causing limp
 - Orbital bone metastases causing swelling or discoloration (raccoon eyes)
 - Paraspinal tumors causing weakness, pain, or bowel/bladder symptoms
- Marrow involvement causing pallor and fatigue, petechiae
- Some patients may have paraneoplastic syndromes causing opsoclonus/myoclonus/ataxia related to antineuronal antibodies or excessive diarrhea related to vasoactive intestinal peptide (VIP) secretion.

PHYSICAL EXAM

- Exam findings depend on primary tumor site and extent of dissemination.
- Patients with disseminated disease often have fever and/or worsening nutritional status.
- Patients with abdominal disease may have bulky firm abdominal mass, and hypertension may occur from renal artery distortion or rarely catecholamine release. The liver may be massively enlarged, particularly in patients with stage 4S disease in the 1st year of life.
- Patients with thoracic tumors may have Horner syndrome, and occasionally, respiratory symptoms from airway compression.
- Patients with paraspinal tumors with invasion into the spinal canal may have weakness and/or radicular pain.
- Bone metastases may have associated proptosis, soft tissue swelling, or discoloration from venous stasis.
- Regional or distant nodes may be enlarged, particularly in the supraclavicular region.
- Bluish firm skin nodules may be seen in infants.
- Pallor or petechiae from marrow metastases

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
 - Decreased hemoglobin, platelets, and/or WBC may indicate marrow involvement.
- Lactic dehydrogenase (LDH)
 - Often elevated with large or metastatic tumors
- Urine catecholamines (homovanillic acid [HVA], vanillylmandelic acid [VMA])
 - Can be done on spot urine samples
 - Elevated in 90% of patients

Imaging

- CT or MRI
 - To evaluate primary tumor site
 - Calcification quite common in neuroblastoma
- Metaiodobenzylguanidine (MIBG)
 - Most specific test for neuroblastoma
 - Uptake seen in primary tumor and metastases in 90% of patients
- Bone scan done if tumor is not avid on MIBG.
- Alternatively, fluorodeoxyglucose-18 positron emission tomography (FDG-PET) scan may also identify tumor in MIBG-negative patients.

Diagnostic Procedures/Other

- Tumor biopsy is usually required, unless there is metastatic tumor in bone marrow coupled with elevated urine HVA/VMA.
 - Tumor tissue usually expresses neuroendocrine markers (synaptophysin, neuron-specific enolase [NSE]) and often contains neuropil.
 - The determination of favorable vs. unfavorable histology is made based on degree of differentiation, presence of stroma, mitotic/karyorrhectic index, and age of patient.
- Neuroblastomas are immature; ganglioneuroblastomas have some maturity but are still malignant, whereas ganglioneuromas are fully mature and benign.
- Bilateral bone marrow aspirates and biopsies help complete staging.
- The International Neuroblastoma Staging System (INSS) is the current

staging system:

- Stage 1: completely resected localized tumor
- Stage 2: incompletely resected localized tumor (2A) or with regional node involvement (2B)
- Stage 3: unresectable tumor crossing midline or contralateral regional lymph node involvement
- Stage 4: dissemination to nodes, bone marrow, liver, skin (except 4S)
- Stage 4S: <1 year old, with stage 1–2 primary tumor and metastases limited to liver, skin, or bone marrow

DIFFERENTIAL DIAGNOSIS

- Abdominal masses: Wilms tumor, germ cell tumor, hepatoblastoma, abdominal sarcoma, or lymphoma
- Thoracic masses: lymphoma, leukemia, germ cell tumor
- “Small round blue cell tumors of childhood”: non-Hodgkin lymphoma, rhabdomyosarcoma, Ewing sarcoma/peripheral neuroectodermal tumor (PNET)

TREATMENT

- Treatment is based on risk stratification using age 18 months, stage, DNA ploidy, favorable vs. unfavorable histology, MYCN amplification, and loss of heterozygosity (LOH) 1p/11q.
- Low-risk tumors
 - Treatment is surgery alone, generally without adjuvant chemotherapy.
 - Selected patients with stage 4S disease may never even require surgery and may be closely observed without therapy.
- Intermediate-risk tumors
 - Treatment generally uses 2–8 cycles of outpatient chemotherapy, performing surgical resection when appropriate.
 - Chemotherapy includes carboplatin, etoposide, doxorubicin, and cyclophosphamide.
 - Selected patients may also receive topotecan or cis-retinoic acid.

- High-risk tumors
 - Treatment involves multiple cycles of intense induction chemotherapy, with surgical resection of primary tumor done when appropriate.
 - Treatment is then consolidated with high-dose chemotherapy and autologous peripheral blood stem cell transplant.
 - Following recovery, they receive irradiation to the primary tumor site, as well as any metastatic sites that were slow to respond to induction therapy. Finally, patients receive multiple cycles of cis-retinoic acid coupled with anti-GD2 antibody, which targets the GD2 protein that is ubiquitously expressed on neuroblastoma cells.
 - Chemotherapy used during induction consists of vincristine, doxorubicin, cyclophosphamide, cisplatin, and etoposide. High-dose chemotherapy often involves carboplatin, etoposide, and melphalan. Newer regimens are testing the use of busulfan and melphalan.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Referral to a pediatric oncologist is essential before any diagnostic procedures or therapeutic interventions.

Patient Monitoring

- On therapy
 - Laboratory monitoring for myelosuppression and organ function
 - Disease reevaluation with imaging and bone marrow testing prior to surgery and stem cell transplant
- Off therapy
 - Close follow-up for disease recurrence up to 5 years after completion of therapy, using imaging and urine catecholamine measurement
 - Monitoring for late effects of cancer therapy, especially in young growing children

PROGNOSIS

- Adverse prognostic factors

- Age >18 months
- Advanced stage
- MYCN gene amplification
- Unfavorable histology
- Diploid tumor genome (primarily infants)
- LOH at chromosome arms 1p or 11q
- Expected outcomes with current therapy
 - Low-risk disease: >90% 3-year event-free survival
 - Intermediate risk: approximately 85% 3-year event-free survival
 - High-risk: approximately 30–50% 3-year event-free survival

COMPLICATIONS

Treatment-related complications (see “[Cancer Therapy Late Effects](#)” chapter)

- Growth delays
- Renal insufficiency
- Hearing loss
- Hypothyroidism
- Second malignancy
- Cardiac dysfunction
- Infertility

ICD10

- C74.90 Malignant neoplasm of unsp part of unspecified adrenal gland
- C48.0 Malignant neoplasm of retroperitoneum
- C38.3 Malignant neoplasm of mediastinum, part unspecified

FAQ

- Q: Are siblings of children with neuroblastoma at increased risk for neuroblastoma compared with the general population?
- A: No, except in rare families with a known history of neuroblastoma (<1%).
- Q: Can neuroblastoma spontaneously regress?
- A: Yes, but this is usually seen only in children <1 year of age with lower stage disease or in infants with stage 4S disease.
- Q: What are the biggest risks during therapy?
- A: As with all intensive chemotherapy regimens, the risk of infection is high. This is especially true during the autologous stem cell transplant phase.
- Q: What therapy is available to patients who either fail to go into remission or relapse following aggressive therapy?
- A: There is no curative therapy after disease recurrence in high-risk neuroblastoma. However, some patients can have meaningful stabilization of disease with therapeutic MIBG administration or other experimental therapies.

NEUROFIBROMATOSIS-1

Robert Listernick

BASICS

DESCRIPTION

- Neurofibromatosis type 1 (NF-1) is an autosomal dominant tumor suppressor gene disorder.
- NF-1 is diagnosed based on the presence of any 2 of the following National Institutes of Health (NIH) Consensus Conference diagnostic criteria:
 - 6 or more café au lait spots, at least 1.5 cm in diameter in postpubertal individuals or 0.5 cm in diameter in prepubertal individuals
 - Inguinal or axillary freckling
 - 2 or more cutaneous neurofibromas or 1 plexiform neurofibroma
 - 2 or more iris Lisch nodules
 - Optic nerve glioma
 - Osseous lesions, including sphenoid wing dysplasia, dysplasia of a long bone (most commonly tibia)
 - A 1st-degree relative (parent, sibling, or offspring) with NF-1

ALERT

Note: Neurofibromatosis type 2 (NF-2) is a rare distinct autosomal dominant tumor suppressor gene disorder characterized by bilateral vestibular schwannomas as well as schwannomas of cranial and peripheral nerves, meningiomas, and ependymomas. It is caused by mutations in the NF2 gene, which codes for a protein known as merlin. This chapter focuses on NF-1.

EPIDEMIOLOGY

Incidence

- NF-1: 1 in 3,000 live births
- NF-2: 1 in 33,000 live births

Prevalence

- NF-1: 1 in 4,000–5,000
- NF-2: 1 in 60,000

RISK FACTORS

Genetics

- Autosomal dominant
 - 50% of the cases are inherited; others occur as sporadic mutations.
 - Penetrance is complete; however, expression is variable even between family members who have same mutation.
 - NF1 gene, which codes for neurofibromin, is located on chromosome 17q11.2
- No known ethnic predisposition
- Course impossible to predict except in two circumstances
 - Deletion of whole NF1 gene leads to early appearance and large numbers of cutaneous neurofibromas, severe cognitive impairment, and dysmorphic features.
 - 3 base pair in-frame deletion of exon 17 leads to multiple café au lait spots and intertriginous freckling but no other NF-1 manifestations.

DIAGNOSIS

HISTORY

- Growth
 - Accelerated linear growth may be first sign of precocious puberty and presence of optic pathway tumor.
- Vision
 - Optic pathway tumors (OPTs) generally occur before 7 years of age; young children rarely complain of visual loss.
- Development
 - Speech delay, motor incoordination, learning problems, and attention-deficit/hyperactivity disorder (ADHD)
- Headache
 - Common; hydrocephalus due to obstructing tumor may occur.
- Family history

- 1st-degree relative may have unrecognized NF-1.

PHYSICAL EXAM

- Growth
 - Assess growth chart with attention to accelerated linear growth as early sign of precocious puberty, rarely growth hormone excess.
 - Assess head circumference for macrocephaly.
- Café au lait spots
 - Collections of heavily pigmented melanocytes of neural crest origin in the epidermis
 - 53% of children with NF-1 will have 6 or more by 3 years; 97% by 6 years
- Axillary and inguinal freckling
 - Present in 80% of children by 6 years
- Discrete neurofibromas
 - Benign nerve sheath tumors that appear as discrete masses arising from peripheral nerve
 - Cutaneous neurofibromas protrude just above the skin surface or lie just under the skin often with an overlying violaceous hue.
 - Subcutaneous neurofibromas are generally much harder.
- Plexiform neurofibromas
 - Benign peripheral nerve sheath tumors which involve single or multiple nerve fascicles, often arising from branches of major nerves
 - “Wormy” sensation on palpation often with overlying hyperpigmentation or hypertrichosis
 - Most external plexiform neurofibromas are present at birth or become apparent during the first several years of life.
 - May lead to disfigurement, blindness (secondary to amblyopia, glaucoma, or proptosis), or loss of limb function
 - Thoracic or abdominal plexiform neurofibromas may have no external manifestations but may lead to invasion or compression of vital structures (e.g., ureters, bowel, spinal cord).
- Lisch nodules
 - Best assessed with slit lamp
 - Slightly raised, well-circumscribed melanocytic hamartomas of the

iris thought to be virtually pathognomonic of NF-1

- Increase with age; present in only 30% of children <6 years but >95% of adults
- OPTs
 - Are present in 15% of children with NF-1, although only half are symptomatic and 40% of those will require treatment
 - Complete yearly eye exams mandatory for NF-1 patients <10 years
 - Ophthalmologic signs include afferent papillary defect, optic nerve atrophy, papilledema, strabismus, or defects in color vision.
 - 40% of children who have chiasmal tumors develop precocious puberty.
- Bony dysplasias
 - Sphenoid wing dysplasia may lead to enophthalmos or pulsating exophthalmos.
 - Tibial dysplasia, congenital thinning and bowing; failure of primary union following fracture results in pseudarthrosis.
- Hypertension
 - In children, most commonly due to fibromuscular dysplasia of renal artery
 - Pheochromocytoma rare in children
- Complete neurologic exam
 - Assess for signs of intracranial or intraspinal tumors.
- Scoliosis
 - Assess for idiopathic juvenile scoliosis, short-segment dystrophic scoliosis.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- NF1 gene mutation
 - Can be identified in >98% of individuals with clinical diagnosis of NF-1
 - However, gene testing is not necessary in vast majority of cases.
 - Gene testing may be useful for:
 - Very young children who don't meet diagnostic criteria
 - Prenatal testing in familial cases
 - Children with unusual or very mild manifestations of NF-1

Imaging

- “Screening neuroimaging” of asymptomatic children not recommended
- MRI of brain recommended for signs of increased intracranial pressure or focal neurologic deficits, abnormal visual exam, or accelerated growth suggestive of precocious puberty
- Unidentified bright objects (“UBOs”)
 - Regions of increased signal intensity on T2-weighted images found in the internal capsule, basal ganglia, cortex, cerebellar hemispheres, optic tract, or brainstem
 - Disappear with age
 - UBOs don’t enhance or cause mass effect.
 - Significance unknown; may be associated with cognitive impairment or learning disabilities

Diagnostic Procedures/Other

A biopsy of plexiform neurofibroma looking for malignancy (malignant peripheral nerve sheath tumor) is necessary if there are signs of rapid growth, new onset pain, or neurologic dysfunction.

DIFFERENTIAL DIAGNOSIS

McCune-Albright syndrome has large café au lait spots with irregular margins, polyostotic fibrous dysplasia, and autonomous endocrine hyperfunction (Cushing syndrome, hyperthyroidism, precocious puberty).

TREATMENT

GENERAL MEASURES

- Treatment of neurofibromatosis (NF) is multidisciplinary and should be performed in a multidisciplinary setting.
- All 1st-degree relatives should be examined for the cutaneous manifestations of NF-1 and should undergo slit-lamp examination to ascertain presence of Lisch nodules.
- Available consultants should include experts in orthopedics, oncology, ophthalmology, genetics, endocrinology, surgery, neurosurgery, plastic surgery, and psychiatry.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Yearly visits allow the physician to identify early NF-1 complications while providing counseling and dissemination of information regarding NF-1.
- All children with NF-1 who are 10 years old and younger should have complete yearly ophthalmologic examinations looking for signs of an optic pathway tumor.
- Blood pressure taken at each visit
- Vigilance/anticipatory care regarding common psychological and developmental issues, such as speech delay, incoordination, ADHD, and learning disabilities
- Early educational assessment and interventions may improve developmental outcome.

COMPLICATIONS

- Cognitive impairment
 - Mean IQ ~95
 - 60% incidence of learning disabilities/ADHD; visual/perceptual disabilities common
- Malignancies
 - Malignant peripheral nerve sheath tumor (5–10% lifetime incidence)
 - Acute myelogenous leukemia
 - Juvenile myelomonocytic leukemia
 - Rhabdomyosarcoma
 - Gastrointestinal stromal tumors
 - Pheochromocytoma
- Skeletal
 - Pseudarthrosis
 - Scoliosis
 - Osteoporosis
- Vasculopathy
 - May involve any arterial vessel

- Renal artery stenosis, hypertension
- Moyamoya disease, poststenotic capillary proliferation in cerebral vasculature may lead to cerebral infarct; treatment by encephaloduroarteriomyosynangiosis (EDAMS) procedure.
- Intermittent claudication of an extremity
- Endocrine
 - Precocious puberty due to chiasmal glioma
 - Pheochromocytoma (rare in children)
 - Growth hormone excess (also rare)

- L81.3 Cafe au lait spots

FAQ

- Q: My child has NF-1. What specialists must he see?
- A: Your child should have yearly check-ups with a physician familiar with the issues of NF, ideally in a NF-1 multidisciplinary clinic.
- Q: Does my child with NF-1 need any x-rays?
- A: X-rays or MRI scans need only be done if your child has signs or symptoms suggestive of a particular complication of NF-1.
- Q: Is my child going to die because of NF-1?
- A: Although a very small minority of children with NF-1 has life-threatening complications, almost all individuals with NF-1 live long, productive lives.

NEUTROPENIA

Kristin A. Shimano

BASICS

DESCRIPTION

A decrease in the number of circulating neutrophils (both segmented and band forms), strictly defined as an absolute total neutrophil count (ANC) of $<1,500/\mu\text{L}$ in children older than 1 year of age, $<1,000/\mu\text{L}$ in children younger than 1 year of age, and $<5,000/\mu\text{L}$ in the 1st week of life

- To calculate ANC, multiply the total WBC count by the percentage of segmented neutrophils and band forms.
- For example: WBC count $5,200/\mu\text{L}$ with 15% segs/polys, 4% bands, 76% lymphocytes, 5% monocytes: $\text{ANC} = 5,200 \times (0.15 + 0.04) = 988$
- Severe neutropenia is defined as an ANC $<500/\mu\text{L}$.

EPIDEMIOLOGY

- Normal values for total WBC counts and ANC vary with age and race.
- Children of some ethnic groups, including African and Middle-Eastern groups, have lower total WBC counts and lower ANCs than do white children.
 - Lower end of normal range for ANC may be $800/\mu\text{L}$ in 30% of African Americans and does not represent an increased risk for infection.
- Infants have a higher total WBC count and a higher percentage of lymphocytes in their differential counts.
- Prevalence of congenital and idiopathic neutropenia: 2.1 cases per million in the United States
- Incidence of neonatal alloimmune neutropenia: 2 per 1,000 live births

RISK FACTORS

Genetics

- A number of mutations causing severe congenital neutropenia have been identified.
 - Autosomal recessive: Kostmann syndrome (HAX1)

- Autosomal dominant: ELA2, GFL1, GATA2, others
- X-linked: WASP
- Cyclic neutropenia: autosomal dominant or sporadic (ELA2)

ETIOLOGY

- Decreased production of neutrophils
 - Viral suppression
 - Marrow suppression by drugs, chemotherapy, or radiation
 - Nutritional deficiencies
 - Primary disorders of myelopoiesis
- Increased destruction of neutrophils
 - Immune-mediated destruction
 - Increased use (usually with overwhelming infection)
 - Sequestration in the spleen

DIAGNOSIS

HISTORY

- Recent or current viral infection
- Current or recurrent fever, skin abscesses, infections, or oral ulceration
- Temporal pattern of symptoms
- Symptoms of malabsorption, such as diarrhea or failure to thrive
- Delayed cord separation
- Medication use or toxin exposure
- Diet: evidence of nutritional deficiency
- Developmental history
- Ethnicity
- Family history of neutropenia, recurrent infection, or early death; consanguinity
- Results of prior CBC with differential: Prior normal WBC count and ANC essentially rule out severe congenital neutropenia.

PHYSICAL EXAM

- Growth curve
- Oral ulceration or gingival irritation
- Phenotypic abnormalities (thumb anomalies, dwarfism, partial

albinism)

- Hepatosplenomegaly or lymphadenopathy
- Bruises, petechiae, pallor
- Birthmarks (café au lait spots)
- Neurologic exam
- Signs of infection
 - Fever (temperature should not be taken rectally)
 - Tachycardia or hypotension
 - Pharyngitis or thrush
 - Cellulitis, perirectal or labial abscesses
 - Signs of local infection (such as inflammation, pus) may be diminished due to lack of neutrophils.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Repeat CBC with differential
 - Neutropenia due to viral suppression is extremely common and counts may normalize on repeat exam.
 - Hemoglobin and platelets are important as well; can help determine if this is an isolated neutropenia or pancytopenia
- Serial CBCs, twice weekly for 6 weeks, to rule out cyclic neutropenia
- Evaluation of exocrine pancreatic function if Shwachman-Diamond syndrome is a consideration
- Immunologic evaluation (immunoglobulins, lymphocyte subsets) to rule out immunodeficiency
- Antineutrophil antibodies: can often be detected in autoimmune neutropenia if multiple methods of testing are used; use unclear, however, given imperfect sensitivity and specificity
- Cross-typing maternal serum and paternal neutrophils in evaluation of neonatal alloimmune neutropenia
- Genetic testing for certain disorders

Diagnostic Procedures/Other

- Bone marrow aspirate and biopsy indicated in severe chronic neutropenia, pancytopenia, or when there is other concern for a marrow disorder

- Biopsy may be normal, or may reveal a decrease in the number of myeloid precursors or a maturational arrest of the myeloid line (usually in the later stages), depending on the cause of neutropenia.

DIFFERENTIAL DIAGNOSIS

- Neutropenia associated with infection
 - Viral suppression is a very common cause of transient neutropenia.
 - Viral: hepatitis A and B, parvovirus B19, respiratory syncytial virus (RSV), influenza A and B, rubeola, rubella, varicella, cytomegalovirus (CMV), Epstein-Barr virus (EBV), HIV
 - Bacterial: group B streptococcal disease, tuberculosis, brucellosis, tularemia, typhoid, paratyphoid
 - Other: malaria, visceral leishmaniasis, scrub typhus, sandfly fever
- Drug induced
 - Antibiotics: sulfonamides (trimethoprim/sulfamethoxazole is a common offender), penicillin, chloramphenicol (may be irreversible)
 - Chemotherapy agents: alkylating agents, antimetabolites, anthracyclines
 - Antipyretics: aspirin, acetaminophen (uncommon)
 - Sedatives: barbiturates, benzodiazepines
 - Phenothiazines: chlorpromazine, promethazine
 - Antirheumatic agents: gold, penicillamine, phenylbutazone
- Immunologic
 - Benign neutropenia of childhood: very common cause of chronic neutropenia; immune-mediated; onset usually <2 years of age; typically a benign course with resolution within several years
 - Isoimmune neonatal neutropenia: due to transplacental transfer of maternal antibodies against paternal antigens
 - Manifestation of an autoimmune disease: systemic lupus erythematosus, autoimmune lymphoproliferative syndrome (ALPS), Felty syndrome (neutropenia, splenomegaly, and rheumatoid arthritis), others
- Congenital
 - Severe congenital neutropenia
 - Cyclic neutropenia: regular oscillations in the number of circulating

neutrophils (periodicity every 7–36 days; duration of neutropenia, 3–10 days)

- Marrow failure syndromes
 - Shwachman-Diamond Syndrome: neutropenia and exocrine pancreatic insufficiency
 - Part of evolving aplastic anemia: acquired (idiopathic), Fanconi anemia, dyskeratosis congenital, Diamond-Blackfan anemia
- Primary immunodeficiencies
 - Cartilage/hair hypoplasia: neutropenia, dwarfism, abnormal cellular immunity
 - Reticular dysgenesis
 - Chédiak-Higashi syndrome: oculocutaneous albinism, platelet dysfunction, leukocyte inclusions
 - Other abnormalities in T and B lymphocytes
- Bone marrow infiltration
 - Malignancy: leukemia or solid tumors metastatic to bone marrow
 - Osteopetrosis
 - Gaucher disease (lysosomal storage disorder)
- Metabolic
 - Nutritional: malnutrition, copper deficiency, zinc deficiency, megaloblastic anemia secondary to folate or vitamin B₁₂ deficiency
 - Inborn errors of metabolism: Barth syndrome (skeletal myopathy, dilated cardiomyopathy, neutropenia), glycogen storage disease I, others
- Miscellaneous
 - Hypersplenism
 - Radiation injury

TREATMENT

MEDICATION

- Granulocyte colony-stimulating factor (G-CSF)
 - Indicated for severe congenital neutropenia and cyclic neutropenia (decreases infections and mortality)
 - May be used in some patients with neutropenia due to other causes

ADDITIONAL TREATMENT

General Measures

- Isolation of hospitalized patient: prudent until the cause of the neutropenia is identified
- “Neutropenic precautions”: Standard hand hygiene is sufficient (no need for masks/gowns/gloves).
- Correction of underlying cause of neutropenia (discontinue drug, treat infection, correct nutritional deficiency)
- Treatment of fever and suspected infection when neutropenic: Initially, broad-spectrum antibiotics are indicated; after the diagnosis has been established, this may not always be necessary (i.e., individuals with chronic benign neutropenia).
- Prophylactic antibiotics are not usually beneficial and may predispose to systemic fungal infection.
- Stool softeners may be helpful in the profoundly neutropenic patient at risk for constipation to prevent development of a perirectal abscess.
- No therapy may be required if neutropenia is not severe and there are no serious or recurrent infections (often the case in chronic benign neutropenia).

ADDITIONAL THERAPIES

- Withdrawal of offending drug in drug-induced neutropenia
- Treatment of underlying disorder in many cases of acquired neutropenia
- Stem cell transplant may be indicated in some patients with severe congenital neutropenia or neutropenia due to other causes (such as bone marrow failure syndromes).

ISSUES FOR REFERRAL

- Chronic or profound neutropenia
- History of recurrent unusual or severe infections
- When bone marrow examination is indicated

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Management of febrile episodes (depends on etiology of neutropenia)

- Prompt evaluation by a physician
- Obtain CBC with differential and blood culture.
- Treat with IV antibiotics.
- Hospitalize if ill-appearing or high-risk for infection.
- Monitor daily CBC with differential.

Patient Monitoring

- CBCs and physical exams at regular intervals while the patient is neutropenic
- Depending on the etiology of the neutropenia, annual bone marrow biopsy surveillance for leukemia or MDS

PROGNOSIS

- Duration of neutropenia depends on diagnosis.
 - Neutropenia resulting from infection or drug-related marrow suppression is usually short lived.
 - Autoimmune neutropenia (benign neutropenia of childhood) typically resolves within 2 years.
 - Congenital neutropenia syndromes may result in chronic lifelong neutropenia.
- Likelihood of infection depends on severity of neutropenia (higher risk if $<500/\mu\text{L}$) and cause of neutropenia (higher risk in disorders of neutrophil production).

COMPLICATIONS

- Systemic infections, including pneumonia and sepsis
- Localized infections such as cellulitis, labial abscesses, perirectal abscesses, oral mucosal ulceration, thrush, otitis media, stomatitis, or gingivitis
- Typical pathogens:
 - Bacterial: staphylococci, streptococci, enterococci, *Pseudomonas*, gram-negative bacilli
 - Fungal: *Candida* or *Aspergillus*
- Transformation to leukemia or MDS

ADDITIONAL READING

CODES

ICD10

- D70.9 Neutropenia, unspecified
- D70.0 Congenital agranulocytosis
- D70.4 Cyclic neutropenia

FAQ

- Q: Do all patients with neutropenia require G-CSF?
- A: No. Patients with severe congenital neutropenia have fewer infections when treated with G-CSF. Patients with benign neutropenia generally do not need G-CSF.
- Q: Can a neutropenic patient receive vaccinations?
- A: Yes, if neutropenia is the only immunologic abnormality
- Q: Should a child with neutropenia be kept in isolation?
- A: No. Neutropenic patients may go to school and do not need to wear masks.

NON-HODGKIN LYMPHOMA

Michelle L. Hermiston

BASICS

DESCRIPTION

- Non-Hodgkin lymphoma (NHL) arises from the malignant proliferation of developing or mature B or T lymphocytes.
- Extent of disease is determined using the Murphy's staging system:
 - Stage I: single tumor (extranodal) or single nodal area, excluding mediastinum or abdomen
 - Stage II: single tumor with regional nodal involvement, 2 or more tumors or nodal areas on the same side of the diaphragm, or a primary GI tract tumor (resected) with or without regional node involvement
 - Stage III: tumors or lymph node areas on both sides of the diaphragm, any primary intrathoracic or extensive intra-abdominal disease (unresectable), or any paraspinal or epidural tumors
 - Stage IV: bone marrow or CNS disease regardless of other sites; marrow involvement defined as 0.5–25% malignant cells

EPIDEMIOLOGY

- 3rd most common childhood malignancy (~12% cancers in individuals <20 years of age in developed countries)
- Number of cases is increasing in adolescents and young adults.
- Male-to-female ratio: 3:1

Incidence

- 10–20 cases per 1 million children/year
- Higher frequency of endemic Burkitt-type in equatorial African countries (10–15 per 100,000 children younger than age 5–10 years)
- Incidence increases steadily with age; in children, usually seen in 2nd decade of life (unusual in those <3 years of age)

RISK FACTORS

Environmental factors

- Drugs: immunosuppressive therapy and diphenylhydantoin
- Radiation: atomic bomb survivors and ionizing radiation
- Viruses: Epstein-Barr virus (EBV) present in >95% of cases of endemic Burkitt versus <20% cases of sporadic; HIV

Genetics

Genetic predisposition: increased risk in patients with immunologic defects (e.g., Bruton agammaglobulinemia, ataxia telangiectasia, Wiskott-Aldrich, severe combined immunodeficiency, X-linked lymphoproliferative syndrome [XLP])

PATHOPHYSIOLOGY

- Unlike adults, low- and intermediate-grade NHL is uncommon in children (~7% of cases).
- NHL in children and adolescent can be divided into 3 major categories according to the National Cancer Institute (NCI):
 - Mature B-cell NHL (Burkitt and Burkitt-like lymphoma, diffuse large B-cell lymphoma [DLBC], primary mediastinal B-cell lymphoma)
 - 50% of childhood NHL
 - Express mature B-cell markers (CD20, surface immunoglobulin [Ig])
 - Terminal deoxynucleotidyl transferase (TdT) negative
 - Burkitt lymphoma has characteristic t(8;14), rarely t(8;22) or t(2;8); all chromosomal translocations involve the c-myc proto-oncogene.
 - DLBC usually of the germinal center B-cell phenotype. Unlike adults, the t(14;18) translocation is rare.
 - Lymphoblastic lymphomas (LL)
 - 30% of childhood NHL
 - In children, 90% T-cell and 10% B-cell origin
 - Morphologically identical to acute lymphoblastic leukemia. TdT positive; express early T (CD5, CD7, cytoplasmic CD3) or B (CD19, CD10) cell markers. Bone marrow involvement of >25% blasts is considered leukemia.
 - Early thymic progenitor (ETP) subtype arises earlier in T-cell

ontogeny and has a worse prognosis in some studies.

- Anaplastic large cell lymphoma (ALCL) (mature T-cell or null-cell lymphomas):
 - 10% of childhood NHL
 - Express CD30 (Ki-1)
 - Contain chromosomal rearrangement involving the ALK gene (85% t2;5)
- Immunodeficiency-associated NHL usually of B cell origin

DIAGNOSIS

HISTORY

- Mature B cell lymphomas
 - Systemic manifestation (e.g., fever, weight loss, anorexia, fatigue) if disseminated; less likely if tumor localized
 - Abdominal mass with pain, swelling, change in bowel habits, nausea, or vomiting
 - Lump in neck unresponsive to antibiotics
- T-cell LL
 - Mediastinal mass symptoms include cough, hoarseness, dyspnea, orthopnea and chest pain, anxiety, confusion, lethargy, headache, distorted vision, syncope, and/or a sense of fullness in the ears.
 - Marrow involvement: bleeding and/or bruising, bone pain, pallor, fatigue
- B-cell LL
 - Tender or painless swelling in neck, axilla, groin or extremities
 - Symptoms of marrow involvement
- ALCL
 - Painless swelling in neck, axilla, groin
 - B type symptoms: fever, night sweats, weight loss

PHYSICAL EXAM

- Mature B-cell NHL
 - Intra-abdominal mass (90%)
 - Involving ileocecal region, appendix, ascending colon, or a

combination

- Lymphadenopathy may be present in inguinal or iliac region.
- Hepatosplenomegaly may be present.
- Acute abdomen with intussusception, peritonitis, ascites, and acute GI bleeding
- Lymphoma is the most frequent cause of intussusception in children >6 years of age.
- Other sites: testis, unilateral tonsil hypertrophy, peripheral lymph nodes, parotid gland, skin, bone, CNS, and marrow
- In endemic Burkitt lymphoma, jaw tumors are the most frequent. Infants often have orbital involvement.
- Lymphoblastic lymphoma
 - T-LL: mediastinal mass (50–70%), possibly pleural effusion present with decreased breath sounds, rales, and cough with or without superior vena cava (SVC) syndrome or superior mediastinum syndrome (SMS):
 - Signs include swelling, plethora, and cyanosis of the face, neck, and upper extremities; diaphoresis; stridor; and wheezing.
 - Lymphadenopathy (50–80%); primarily above diaphragm
 - Abdominal involvement uncommon: likely to involve only liver, spleen, or kidneys
 - Cranial nerve involvement: rare
 - B-LL: firm mass in extremity, enlarged LN
- ALCL
 - Sites: mediastinum, bone, inguinal nodes, skin
 - Bone marrow and CNS involvement: rare at diagnosis

DIAGNOSTIC TESTS & INTERPRETATION

A diagnosis needs to be made expeditiously, as pediatric lymphomas generally have a rapid growth rate.

- Bone marrow aspirate and biopsy may establish the diagnosis without further testing.
- Fluid from ascites in patients with abdominal disease or pleural fluid should be obtained for cytology, immunophenotyping, and cytogenetics.
- Fine-needle aspirate or biopsy of an enlarged lymph node

Lab

- CBC with differential
- Liver and renal function studies
- Tumor lysis labs: serum lactate dehydrogenase (LDH), potassium, calcium, phosphate, uric acid
- Ascitic, CSF, or pleural fluid
 - Cytology
 - Immunophenotyping
 - Cytogenetics

Imaging

- Abdominal ultrasound
- Chest radiographs: posteroanterior and lateral
- CT scan of chest, abdomen, and pelvis
- PET/CT scan
- MRI (especially for bone involvement)

Diagnostic Procedures/Other

- Adequate surgical biopsy
- Bone marrow aspirate and biopsy
- Lumbar puncture with CSF cytology

ALERT

Recumbent positioning, sedation, or positive pressure ventilation may lead to catastrophic respiratory or cardiovascular collapse in patients with partial compromise due to a mediastinal mass. Imaging of airway and consultation with anesthesia, surgeons, and critical care specialists should be obtained prior to any sedation. Procedures may need to be done with local anesthesia only.

DIFFERENTIAL DIAGNOSIS

- **Abdominal mass** (see chapter)
 - Newborn: hydronephrosis, renal cysts, Wilms tumor, or neuroblastoma
 - Older children: constipation, full bladder, hamartoma, hemangioma, cysts, leukemic or lymphomatous involvement of the liver and/or spleen, Wilms tumor, or neuroblastoma

- **Mediastinal mass** (see chapter)
 - Anterior: masses of thymic origin, teratomas, angiomas, lipomas, or thyroid tumors
 - Middle: metastatic or infectious lesions involving the lymph nodes, pericardial or bronchogenic cysts, esophageal lesions, or hernias
 - Posterior: neurogenic tumors (e.g., neuroblastoma, ganglioneuroma, neurofibroma), enterogenous cysts, thoracic meningocele, or hernias

TREATMENT

MEDICATION

- **Chemotherapy**
 - Histology and stage determine therapy
 - Because of a high conversion rate of lymphomas to leukemias, prophylactic CNS treatment is given (except in patients with totally excised intra-abdominal tumor).
 - Duration: mature B cell lymphomas and ALCL, 1–8 months; lymphoblastic lymphomas, 24 months
 - Drugs: cyclophosphamide, vincristine, methotrexate (IV and intrathecal [IT]), prednisone, dexamethasone, daunorubicin, asparaginase, cytarabine, thioguanine, hydrocortisone, doxorubicin, mercaptopurine, etoposide, vinblastine
 - ALCL: crizotinib (a kinase inhibitor that blocks NPM-ALK fusion protein activity)
 - Common side effects: hair loss, myelosuppression with transfusions required, nausea/vomiting
- **Immunotherapy**
 - Rituximab
 - A chimeric monoclonal antibody to the CD20 antigen, which is almost universally expressed in B-cell NHL
 - Few overlapping side effects with the combination of rituximab and conventional chemotherapeutic agents
 - Whether it improves outcome in children is not known.
 - Brentuximab vedotin
 - Antibody drug conjugate to CD30 that is expressed on all ALCL;

currently in clinical trials in children

ADDITIONAL TREATMENT

General Measures

A multidisciplinary approach is imperative to ensure the best therapy.

- Prechemotherapy management
 - Tumor lysis can be present even before initiation of chemotherapy.
 - Allopurinol, hydration, and alkalinization of urine to promote uric acid excretion; may use rasburicase for uric acid >8 mg/dL
 - Monitor uric acid, BUN, calcium, creatinine, potassium, and phosphate levels closely.
- Management of relapse
 - Relapse indicates extremely poor prognosis.
 - No uniform approach to rescue therapy; different chemotherapy combinations may induce a new response.
 - For patients with chemosensitive relapse, salvage therapy followed by high-dose therapy with stem cell support

ADDITIONAL THERAPIES

Radiotherapy

- Adds no therapeutic benefit in children with limited disease; may be indicated in mediastinal DLBCL
- Used occasionally as emergent treatment for SVC obstruction or CNS or testicular involvement
- Cranial radiotherapy given for CNS-positive children with lymphoblastic lymphoma
- Increases short- and long-term toxicity

SURGERY/OTHER PROCEDURES

- Avoid extensive surgery in patients with NHL.
- Performed in mature B-cell NHL if total resection can be achieved
- Additional indications: intussusception, intestinal perforation, suspected appendicitis, or serious GI bleeding

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Patient monitoring weekly to monthly with CBC and physical examination
- Radiologic imaging at intervals during and off therapy

Patient Monitoring

Late effects from therapy:

- Cardiomyopathy from anthracyclines
- Impaired reproductive function or infertility from alkylating agents or radiation
- Second malignant neoplasms from etoposide and alkylators
- Psychological consequences of severe illness

PROGNOSIS

- Important prognostic factors for outcome include tumor burden at presentation.
- Favorable
 - Stages I and II with primary site head and neck (nonparameningeal), peripheral nodes, or abdomen ($\geq 90\%$ 2-year survival)
 - Burkitt: $>90\%$ 2-year survival
- Less favorable
 - Stage III or IV disease; ALCL, LL
 - Parameningeal stage II
 - Stage IV with CNS involvement
 - Incomplete initial remission within 2 months (50–80% 2-year survival)

COMPLICATIONS

- Tumor lysis syndrome
 - Combination of hyperuricemia, hyperkalemia, and hyperphosphatemia with hypocalcemia, resulting in uric acid nephropathy that leads to renal failure
- GI obstruction, perforation, bleeding, intussusception
- Inferior vena cava obstruction and venous thromboembolism
- Neurologic (e.g., paraplegia, increased intracranial pressure)
- SVC syndrome and SMS: associated with lymphoblastic lymphomas that invade the thymus and nodes surrounding the vena cava and

airways

- Massive pleural effusion
- Cardiac tamponade or arrhythmia

ICD10

- C85.90 Non-Hodgkin lymphoma, unspecified, unspecified site
- C85.10 Unspecified B-cell lymphoma, unspecified site
- C83.70 Burkitt lymphoma, unspecified site

FAQ

- Q: Did I do something to cause this?
- A: No. Most cases are sporadic and not associated with diet, underlying

immune dysfunction, or viral illness.

- Q: Is this contagious?
- A: No. Siblings may have slightly higher inherent risk than the general population, but they are not at risk from the affected child.

NONTUBERCULOUS MYCOBACTERIAL INFECTIONS (ATYPICAL MYCOBACTERIAL INFECTIONS)

Rebecca Schein

BASICS

DESCRIPTION

Nontuberculous mycobacteria (NTMB) are mycobacteria other than the *Mycobacterium tuberculosis* complex bacteria (*M. tuberculosis*, *Mycobacterium africanum*, *Mycobacterium bovis*, *Mycobacterium canetti*, and *Mycobacterium microti*) or *Mycobacterium leprae* capable of causing disease in humans.

- NTMB are classified based on growth rate in culture media as “rapid” or “slow” growers.
- Disease from these infections most commonly presents as cervical lymphadenitis in children.

EPIDEMIOLOGY

- NTMB are ubiquitous in nature and found in soil, food, water, and animals.
- More than 120 species of mycobacteria have been identified.
- Each species has a different level of virulence and many species are associated with specific reservoirs or geographic areas. For example, *Mycobacterium marinum* is found in fish tanks and *Mycobacterium malmoense* is found in Northern Europe.
- Health care–related infections can occur, typically due to rapid-growing *Mycobacterium abscessus* or *Mycobacterium fortuitum*.
- Tap water is a major reservoir for a number of NTMB.

RISK FACTORS

- Cystic fibrosis
- Immune deficiency especially HIV
- Tympanostomy tubes

- Foreign bodies or medical hardware
- Interleukin-12 receptor deficiency

PATHOPHYSIOLOGY

- Rapid growers include the *M. fortuitum* and *Mycobacterium chelonae/abscessus* groups. These rapid growers show significant growth on culture media in 3–7 days.
- Slow-growing mycobacteria take more than 7 days and typically 4–6 weeks to grow in culture.
- Dirty wounds and breaks in oral, respiratory, or gastrointestinal mucosa are the common portals of entry.
- Infection is usually localized near the inoculation site and related regional lymph nodes.
- No evidence of person-to-person spread

ETIOLOGY

- Cervical adenitis is the most common presentation in children 1–5 years of age. In the United States, 80% of these cases are due to *Mycobacterium avium-intracellulare* (MAI).
- In healthy adults, pulmonary disease is the most common illness, typically caused by MAI, *Mycobacterium kansasii*, *Mycobacterium xenopi*, or *M. mageritense*.
- Other presentations may include skin and soft tissue infections, bone and joint infections, chronic ear infections, catheter-associated infections, and pneumonia.
- Disseminated disease is seen primarily with MAI in patients with advanced HIV.

DIAGNOSIS

HISTORY

- Travel history and area of residence
- Fever history and systemic complaints
- Length of symptoms—longer history is characteristic.
- Water and animal exposures
- Trauma history

- Recent surgery or hardware

PHYSICAL EXAM

- Lymphadenitis is typically unilateral, minimally tender, anterior cervical, or submandibular.
- Skin disease is usually an ulcer, a localized cellulitis, a draining abscess, or a persistent nodule.
- Pulmonary disease may be associated with fever, weight loss, and fatigue.
 - Mediastinal and hilar lymphadenopathy is common.
 - Lung findings are nonspecific.
- Otitis media in children with tympanostomy tubes presents with chronic drainage unresponsive to antibiotics.
- Disseminated disease is rare; findings include fever, night sweats, abdominal pain, and wasting.

DIAGNOSTIC TESTS & INTERPRETATION

- Definitive diagnosis requires isolation of NTMB in culture.
- Special media and laboratory facilities are required.
- Contamination of nonsterile sites can occur and may require 2 or more cultures to confirm diagnosis.
- Any growth from a draining wound is clinically significant.
- A tuberculin skin test may be positive as cross-reactivity occurs but is not diagnostic.
- PCR for identification of specific NTMB is becoming more readily available and may facilitate quicker diagnosis.

DIFFERENTIAL DIAGNOSIS

- *M. tuberculosis* complex
- Dimorphic fungi: *Histoplasma capsulatum*, *Coccidioides* species, *Blastomyces dermatitidis*, *Sporothrix schenckii*
- Malignancy typically leukemia/lymphoma
- *Bartonella henselae*: cat-scratch disease
- Viral or bacterial adenitis

TREATMENT

Treatment is variable depending on the site of infection and the specific mycobacterium isolated. In general, complete surgical excision of infected lymph nodes is curative.

MEDICATION

- MAI is treated orally with a macrolide (clarithromycin or azithromycin) plus ethambutol or rifampin. Azithromycin is used as prophylaxis in patients with AIDS.
- Other slow growers such as *M. kansasii*, *M. marinum*, and *Mycobacterium ulcerans* are treated with rifampin-based regimens in combination with ethambutol, macrolides, trimethoprim-sulfamethoxazole, doxycycline, and/or aminoglycosides.
- For rapid growers (*M. fortuitum*, *M. abscessus*, and *M. chelonae*), serious diseases are treated intravenously with an aminoglycoside plus meropenem or ceftazidime depending on susceptibilities. Milder disease or subsequent oral therapy is treated with clarithromycin, doxycycline, trimethoprim-sulfamethoxazole, or ciprofloxacin based on susceptibility testing.
- Combination therapy is indicated in immunocompromised hosts.

SURGERY/OTHER PROCEDURES

- Isolated lymphadenitis is treated with complete surgical excision. Typically, antimicrobials are not beneficial in this situation.
- Any infected hardware should be removed and serious localized disease debrided.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Medical treatment is typically for a minimum of 3–6 months.
- Follow-up should last 1 year after completion of therapy.

PATIENT EDUCATION

- Chemoprophylaxis for patients with CD4 count <50 cells/ μ L
- Avoid tap water contamination of central lines.

PROGNOSIS

- For localized disease and adenitis, prognosis is excellent.

COMPLICATIONS

- Chronic draining wounds can occur and treatment is typically long-term antimicrobials in combination with surgical debridement.
- Disseminated disease—occurs in immunocompromised patients

CODES

ICD10

- A31.9 Mycobacterial infection, unspecified
- A31.1 Cutaneous mycobacterial infection
- A31.8 Other mycobacterial infections

FAQ

- Q: When should I worry about NTMB?
- A: NTMB should be on the differential for any child with persistent lymphadenitis or a chronically draining wound.

- Q: When should NTMB be considered as a cause of lymphadenitis?
- A: Most lymphadenitis is due to an acute viral or bacterial infection and will improve with time or respond to a short course of antibiotics. NTMB should be suspected in a healthy toddler (age 1–5 years) who presents with a subacute or chronic lymphadenitis. Other considerations should include cat-scratch disease, malignancy, and tuberculosis.
- Q: If infected node is excised, should I treat with antibiotics?
- A: Surgical excision is the treatment of choice of NTMB adenitis. Most studies show that antibiotics are not beneficial after complete surgical excision.

NOSEBLEEDS (EPISTAXIS)

Bethlehem Abebe-Wolpaw • Kristina W. Rosbe

BASICS

DESCRIPTION

- Epistaxis: bleeding from the nostril, nasal cavity, or nasopharynx
- Classified as anterior when noted through the nares or posterior when noted through the nasopharynx

EPIDEMIOLOGY

- More than 50% of children aged 6–15 years will experience epistaxis.
- Rarely seen in children younger than age 2 years
- Anterior epistaxis more common in children
- Occurs more frequently in the cold winter months when there is low humidity and when upper respiratory tract infections are more frequent

RISK FACTORS

- Mucosal dryness (also known as rhinitis sicca) is a frequent precursor to episodes of epistaxis as are upper respiratory tract infections.
- Children with allergic rhinitis are more prone to epistaxis.

GENERAL PREVENTION

- Keeping nasal passages moist with the use of humidifiers and saline nasal sprays or ointments (e.g., Vaseline) help reduce mucosal irritation and dryness.
- Ensure fingernails are short and nasal trauma (i.e., nose picking, foreign body) is discouraged
- Use appropriate protective athletic equipment to avoid trauma.

PATHOPHYSIOLOGY

- Blood supply to the nasal cavity contains multiple anastomoses that originate from both the internal and external carotid arteries.
- Kiesselbach plexus located in the anteroinferior aspect of the nasal septum is the most common site of bleeding.
- The thin mucosal surface of the nasal septum and the lateral nasal walls

is fragile and thus prone to inflammation and drying.

ETIOLOGY

- Most episodes of epistaxis are due to local inflammation and/or trauma:
 - Upper respiratory infections, allergic rhinitis, rhinosinusitis, nasal vestibulitis, colonization of nasal cavity with *Staphylococcus aureus*
 - Digital trauma, facial trauma, foreign bodies, inhalants/irritants (intranasal corticosteroids, cocaine, heroin)
- In pediatric population, epistaxis is less likely a sign of systemic illness:
 - Bleeding disorders: von Willebrand disease, hemophilia, idiopathic thrombocytopenic purpura, hematologic malignancies
 - Coagulopathy secondary to systemic infection, hepatic disease, renal failure, chronic aspirin or NSAID use
- Local structural/vascular abnormalities
 - Septal deviation, rhinitis sicca, spurs, nasal polyps
 - Telangiectasias (Osler-Weber-Rendu disease)
 - Nasal neoplasms: juvenile angiofibroma, papillomas, hemangiomas

COMMONLY ASSOCIATED CONDITIONS

- Frequently associated with viral upper respiratory infections, allergic rhinitis, nose picking
- More than 90% of children with epistaxis do not have an underlying systemic cause.

DIAGNOSIS

HISTORY

- Frequency and duration
- Laterality of the nosebleed
- Local trauma (nose picking, foreign body)
- Upper respiratory tract infection
- Allergies
- Obstruction
- Discharge

- Medications or drug use
 - NSAIDs, aspirin, anticoagulants, cocaine
 - Alternative medicines: garlic, ginkgo, ginseng
- Personal or family history of bleeding disorders, easy bruising, significant bleeding from minor wounds, frequent or heavy bleeding
- Menstrual history if applicable

PHYSICAL EXAM

- Vital signs
- Use a good light source to perform direct visualization and inspection of nostril, nasal cavity, nasopharynx, and oropharynx.
 - Exam of the nose may be facilitated by application of a topical vasoconstricting agent and/or anesthetic agent to enhance view and slow any current bleeding.
- General exam with particular attention to the skin (bruising, petechiae, purpura, icterus, pallor), lymph nodes, liver, and spleen

DIAGNOSTIC TESTS & INTERPRETATION

- Most episodes are minor and do not require intervention or medical evaluation.
- If history and physical exam are reassuring, diagnostic evaluation is not warranted in healthy children with easily controlled anterior epistaxis.
- If suspicious findings on history or physical exam or child has chronic recurrent epistaxis, laboratory evaluation including complete blood count with platelet count and coagulation panel are indicated.
- Studies suggest that 5–10% of children with chronic recurrent nosebleeds may have mild undiagnosed von Willebrand disease so consider further laboratory tests to include plasma von Willebrand factor (VWF) antigen, VWF activity, and factor VIII activity.
- Persistent unilateral bleeding warrants nasal endoscopy to rule out neoplasm.

DIFFERENTIAL DIAGNOSIS

Epistaxis is a common occurrence in healthy children. A detailed history and physical exam should help identify children with systemic causes for epistaxis, including bleeding disorders and malignancies.

TREATMENT

ACUTE

- Elevate the head.
- Direct pressure, applied by gently squeezing the nostrils, is usually sufficient to stop most nosebleeds.
- Vasoconstricting agents (0.25% phenylephrine, 0.05% oxymetazoline, 1:1,000 epinephrine, or 1–5% cocaine) will help reduce bleeding as well as improve visualization.
- Absorbable hemostatic agents, such as Floseal, a bovine-derived gelatin matrix, can also be used for refractory bleeding.
- Parental reassurance is an important, but often neglected, aspect of therapy.

CHRONIC

- Aggressive moisturization including saline irrigation, Vaseline applied with a Q-tip, and sleeping with a humidifier are important for prevention.
- Avoidance of trauma such as repetitive digital manipulation
- Silver nitrate cautery can be performed selectively on prominent vasculature on the anterior septum known as Kiesselbach plexus. This should only be done unilaterally to avoid the risk of septal perforation. If adequate time is given for healing (approximately 1 month), cautery can be performed on the contralateral side.
- For persistent bleeding despite silver nitrate cautery, more powerful cauterization such as Bovie electrocautery can be performed. This procedure is generally not tolerated in patients without general anesthesia.
- In rare cases that do not respond to cautery, vessel embolization by an interventional radiologist or surgical vessel ligation may be required.

ISSUES FOR REFERRAL

Otorhinolaryngologic consultation may be needed for severe nosebleeds or when posterior nasal packing, fracture reduction, surgery, or embolization is required. Nasal endoscopy is now routinely used.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Nosebleeds are easily controlled and self-limited in most instances.
- Referral to an otorhinolaryngologist is indicated for patients with specific local abnormalities, such as polyps, tumors, or vascular malformations, or severe nosebleeds, recurrent nosebleeds, and/or posteriorly located nosebleeds.
- Identification of systemic illness may require referral to the appropriate specialist.

Patient Monitoring

- Blood clots in the nasopharynx should be removed to enhance visualization.
- Failure to detect a posterior location within the nasal cavity as the source of bleeding may interfere with measures to control bleeding.
- After nasal packing, it is essential to examine the oropharynx to confirm adequate hemostasis.
- Absorbable-type packing should be used, if required, in patients with bleeding disorders. Removable packings are prone to rebleeding on removal.
- Impregnation of nasal packings with antibiotic ointment reduces the risk of toxic shock syndrome.

PATIENT EDUCATION

Families should be given instructions in basic first aid for nosebleeds because minor insults, such as sneezing or excessive manipulation, may cause nosebleeds to recur.

PROGNOSIS

- Uncomplicated epistaxis is most often self-limited or resolves with simple first-aid techniques.
- Refractory or recurrent epistaxis may require more specialized techniques by an otorhinolaryngologist.

COMPLICATIONS

- Usually uncomplicated

- Rare complications: significant blood loss, airway obstruction, aspiration, and vomiting

CODES

ICD10

R04.0 Epistaxis

FAQ

- Q: How should I explain to a child to stop a nosebleed that occurs at home?
- A: The child or parent should apply pressure by compressing the lateral cartilaginous surface of the external nose together for at least 5 minutes. It is important to keep the head elevated but not hyperextended to avoid aspiration of the blood. This can be accomplished either by sitting or standing while bending forward slightly at the waist. Avoid lying down or tilting the head backward. Avoid checking prior to 5 minutes have elapsed to see if bleeding has

ceased.

- Q: When should I work-up a patient to ensure there is not an underlying systemic cause for epistaxis?
- A: Most children do not require laboratory evaluation. If the history or physical is concerning or the child has chronic recurrent epistaxis, initial laboratory evaluation may include complete blood count with platelets and coagulation panel. In addition, you can consider checking for von Willebrand disease, as data suggests that up to 5–10% of children with chronic recurrent epistaxis may have a mild form of the disease.

OBESITY

Susma Vaidya • Nazrat Mirza

BASICS

DESCRIPTION

Excess adiposity correlates closely with increased health risk for multiple medical and psychological disorders. Body mass index (BMI) is an easily obtained clinical measure to assess for increased body fat and concomitant health risks. BMI is calculated as weight in kilograms divided by height in meters squared. In children, age- and sex-specific percentiles define obesity.

- Children ≥ 2 years of age
 - BMI 85–94%: overweight
 - BMI 95–98% or BMI ≥ 30 kg/m²: obese
 - BMI ≥ 99 %: severe obesity
- BMI reference standards are not available for children < 2 years of age. In this age group, overweight is defined as weight-for-length ≥ 95 % for age and sex.

EPIDEMIOLOGY

Prevalence

2009–2010 U.S. National Health and Nutrition Exam Surveys (NHANES) data:

- Younger than age 2 years: 9.7% overweight (≥ 95 percentile weight-for-length)
- 2–5 years of age: 12.1% obese
- 6–11 years of age: 18% obese
- 12–19 years of age: 18.4% obese
- Higher rates in boys than girls
- Highest rates among Blacks and Hispanics

RISK FACTORS

- Obesity is most often a multifactorial condition with several risk factors:

- Parental obesity
- Maternal obesity in pregnancy
- Maternal history of gestational diabetes
- Intrauterine growth retardation
- Rapid weight gain in first 6 months of life
- Low socioeconomic status
- Genetics
 - Obesity with developmental delay and/or dysmorphic features: Bardet-Biedle, Cohen, Prader-Willi
- Endocrine
 - Obesity with poor linear growth: Cushing syndrome, hypothyroidism

GENERAL PREVENTION

- Encourage exclusive breastfeeding at prenatal visit and support breastfeeding throughout the 1st year of life.
- In formula-fed infants, watch for signs of overfeeding and rapid weight gain in 1st year of life. Educate families on the difference between hunger and oral suck reflex. Avoid rice cereal in the bottle.
- Recognize parental obesity as a significant risk.
- Incorporate early nutrition and activity counseling.
- Careful attention to BMI (and weight-for-length for children <2 years) with intensive counseling for children crossing percentiles.
- Stress importance of portion size and nutrient-rich foods (fruits and vegetables) as infants transition to a solid diet.
- Daily physical activity; limit screen time.

PATHOPHYSIOLOGY

Complex interaction between genetics, hormones, environment, and behavior

- Short-term energy regulation: adaptation of meal size in response to energy needs. Hypothalamic neurons modulate sensitivity of nucleus tractus solitarius (NTS) neurons to satiety signals adjusting for changes in body fat mass.
- Long-term energy regulation: Hypothalamus senses and integrates energy balance signals including hormones such as insulin, leptin,

- ghrelin, and nutrients such as fatty acids, amino acids, and glucose.
- Leptin
 - A negative feedback regulator—plays an important role in energy homeostasis.
 - Communicates to hypothalamus changes in energy balance and fuel stored as fat.
 - Increased fat mass results in increased leptin signaling which limits energy intake and supports energy expenditure.
 - Decreased leptin promotes increased food intake, positive energy balance, and fat accumulation.
 - Ghrelin
 - Derived from the stomach, it is the only known peripherally acting orexigenic hormone. It stimulates appetite.
 - All other gut-derived hormones are anorectic and limit food, optimize digestion and absorption, and avoid overfeeding.
 - Adiponectin
 - Insulin sensitizing, anti-inflammatory, and antiatherogenic
 - Increased visceral fat results in reduced levels of adiponectin and increased proinflammatory milieu leading to insulin resistance and endothelial dysfunction. This predisposes to metabolic syndrome, diabetes, and atherosclerosis.

ETIOLOGY

Energy imbalance

- Excessive caloric intake: Calorie-rich foods and beverages consumed preferentially over nutrient-rich foods. Portion size is inappropriately large for age.
- Low-caloric expenditure: excessive sedentary time with TV, computers, video games, and handheld devices; limited daily physical activity

COMMONLY ASSOCIATED CONDITIONS

- Endocrine
 - Type 2 diabetes mellitus
 - Metabolic syndrome
 - Polycystic ovarian syndrome (PCOS)

- Low vitamin D level
- Cardiovascular
 - Hypertension
 - Dyslipidemia
- Respiratory
 - Sleep apnea
 - Asthma
- Gastrointestinal
 - Nonalcoholic fatty liver disease (NAFLD)
 - Nonalcoholic steatohepatitis (NASH)
 - Gallstones
 - Gastroesophageal reflux (GER)
- Orthopedic
 - Slipped capital femoral epiphysis (SCFE)
 - Blount disease (tibial bowing)
- Skin conditions
 - Acanthosis nigricans
 - Hirsutism
- CNS: pseudotumor cerebri
- Psychiatric
 - Binge-eating disorder
 - Mood disorder: anxiety and depression
 - Low self-esteem

DIAGNOSIS

HISTORY

- Birth history: birth weight, maternal gestational weight gain, gestational diabetes
- Growth history: weight trajectory and age where percentiles were crossed
- Medical and/or social stressors
- Medical history: asthma, medications, obesity comorbidities
- Motivation
 - Parental concern and desire for change and willingness to modify

- family's behavior
 - Child's concern and motivation (as age appropriate)
- Family history
 - Obesity
 - Diabetes
 - Cardiovascular disease
 - Dyslipidemia
 - Eating disorders
- Dietary history
 - Sugar-sweetened beverages consumed
 - Frequency of fruits and vegetables
 - Frequency and type of snack foods
 - Frequency of fast food
- Eating behavior
 - Family meals
 - TV viewing during meals
 - Recognition of satiety
 - Binge eating with or without loss of control
- Physical activity
 - Total screen time including phone and handheld devices
 - Duration, intensity, and frequency of physical activity
- Sleep duration and pattern
- Previous attempts at weight loss
 - Medication use (prescribed and OTC)
 - Weight loss programs
- Review of systems
 - Headache: pseudotumor cerebri
 - Snoring/pauses in breathing, daytime somnolence: obstructive sleep apnea (OSA)
 - Abdominal pain: reflux, gallstones
 - Joint pains: hip pain (SCFE)
 - Social isolation, emotional eating, behavior difficulties: depression
 - Skin color changes (acanthosis nigricans)
 - Irregular menses/amenorrhea: PCOS
 - Polydipsia, polyuria: diabetes

PHYSICAL EXAM

- Anthropometrics: weight, height, BMI, and BMI percentile
- Blood pressure for age, sex, and height percentile
- General physical findings suggestive of endocrine or genetic condition
 - Short stature
 - Dysmorphic facies
 - Developmental delay
- Head, ears, eyes, nose, throat (HEENT)
 - Papilledema
 - Tonsillar hypertrophy and narrow pharyngeal opening
- Cardiopulmonary
 - Poor aeration, wheezing
 - Heart murmur
- Abdomen
 - Hepatomegaly
 - Abdominal pain
- Genitourinary: Tanner stage
- Musculoskeletal
 - Range of motion at hips
 - Abnormal curvature of lower leg
 - Limp
- Skin
 - Acanthosis nigricans
 - Hirsutism
 - Striae
- Psychological
 - Mood: assess for evidence of depression
 - Bullying, social isolation

DIAGNOSTIC TESTS & INTERPRETATION

Laboratory Tests: Initial

- BMI 85–94%ile without risk factor: fasting Lipid profile
- BMI 85–94%ile age ≥ 10 years with risk factors: fasting lipid profile, ALT, AST, fasting glucose
- BMI ≥ 95 %ile Age ≥ 10 years: fasting Lipid profile, ALT, AST, fasting glucose, other tests as indicated by health risks

Abnormal Results

- Lipid panel: Obese children often have elevated LDL and triglycerides and low HDL.
 - High LDL ≥ 130 mg/dL
 - High triglyceride:
 - 0–9 years old ≥ 100 mg/dL
 - 10–19 years old ≥ 130 mg/dL
 - Low HDL < 40 mg/dL
- ALT value > 2 times normal or > 60 IU/L merits gastroenterology consult.
- Fasting glucose ≥ 126 mg/dL or random glucose ≥ 200 mg/dL supports a diagnosis of diabetes and warrants endocrinology consult.
 - HgbA1c $\geq 6.5\%$ suggests possible diabetes.
 - Fasting glucose ≥ 100 mg/dL or HgbA1c $\geq 5.7\%$ and $\leq 6.4\%$ indicates impaired fasting glucose and a prediabetic state.

Diagnostic Procedures/Other

- Polysomnogram: history of snoring with pauses in breathing, narrow pharyngeal airway, or tonsillar hypertrophy (OSA)
- AP and frog-leg views of the hips: knee pain or hip pain, limitation or pain with internal rotation of hip (SCFE)
- Knee and lower extremity radiographs: abnormal curvature of the lower extremities, especially asymmetry (Blount disease)
- Echocardiogram: hypertension (LVH)
- Ambulatory blood pressure monitoring: elevated blood pressure/hypertension
- Abdominal ultrasound: elevated LFTs or abdominal pain (NAFLD, gallstones)
- Head CT: headache and papilledema on ocular exam (pseudotumor cerebri)

TREATMENT

MEDICATION

- Orlistat: an intestinal lipase inhibitor that is the only FDA-approved

medication for obesity in children ≥ 12 years

- Limits nutrient absorption
- Side effects: abdominal pain, oily stools, flatulence, fat-soluble vitamin deficiencies; self-limited success, poor compliance
- 5% weight loss, similar to placebo
- Not recommended for routine use

ADDITIONAL TREATMENT

General Measures

- Prevention and treatment include healthy lifestyle behavior: Goal is to start with small incremental changes in lifestyle.
 - Eliminate consumption of sugar-sweetened beverages including juice and sports drinks.
 - Encourage nonfat milk and water.
 - Increase servings of nutrient-rich foods such as fruits and vegetables with every meal and for snacks.
 - Avoid skipping meals.
 - Reduce eating out or takeout foods.
 - Encourage family meals.
 - Educate families about portion size as soon as solids are started and in early childhood.
 - Advise 1 hour/day of moderate physical activity.
 - Limit screen time to <2 hours a day.
- Weight loss goals
 - Weight maintenance may be appropriate in younger children, as BMI will improve with increase in height.
 - Older children and severely obese children can lose up to 2 lb a week.

SURGERY/OTHER PROCEDURES

Bariatric surgery indication

- Adolescents with a BMI ≥ 40 kg/m² or BMI ≥ 35 kg/m² with concomitant comorbidities such as diabetes and hypertension
- Lack of sustained weight loss on supervised weight-reduction program for 6 to 12 months
- Physical, emotional, and cognitive maturity

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Assess BMI monthly and achievement of dietary and physical activity goals.
- Follow patient more frequently with weight gain and/or refer for nutrition counseling or a weight management program at a tertiary care center.
- Refer to subspecialist with diagnosis of accompanying comorbidities.

PROGNOSIS

- Success is greater in younger children and children with lower BMIs.
- Better success if whole family involved in healthy lifestyle change
- Better success with self-monitoring
- Less success with severe obesity
- Poor prognosis if untreated mental health issues and/or lack of motivation

ADDITIONAL READING

CODES

ICD10

- E66.9 Obesity, unspecified
- E66.3 Overweight
- R63.5 Abnormal Weight Gain

FAQ

- Q: How do I broach such a sensitive topic with families?
- A: Review growth charts at every well-child visit and discuss any concerning increase in BMI. Describe in terms of healthy weight and the need to avoid comorbidities which become more likely with increasing BMI.
- Q: How do I counsel a family not interested in making lifestyle changes?
- A: Discuss the risk that an unhealthy BMI poses for the child. Describe small simple changes the family can make to alleviate this risk. Avoid assigning blame. Abnormal lab values may motivate a family to make changes.

OBSESSIVE-COMPULSIVE DISORDER

Holly H. Martin Manisha Punwani

BASICS

- Obsessive-compulsive disorder (OCD) is a psychiatric illness manifested by recurrent and persistent obsessions and compulsions.
- Obsessions are defined as intrusive, unwanted thoughts, images, or impulses that cause the patient distress, and attempts are made to ignore or suppress these thoughts.
- Compulsions are repetitive actions that patient feels driven to perform in response to an obsession. The behaviors are aimed at preventing or reducing anxiety or distress or preventing some dreaded event or situation.
 - It is not necessary that children recognize these thoughts or behaviors to be excessive or unreasonable.
 - The obsessions or compulsions cause marked distress, are time consuming (>1 hour daily), and cause impairment in daily functioning.
 - Not attributed to physiologic effects of a substance nor are explained by another mental disorder
 - Specified as “with good or fair insight,” “with poor insight,” “with absent insight/delusional beliefs,” or tic-related

EPIDEMIOLOGY

- There are at least 1 in 200—or 500,000—children and adolescents that have OCD. This figure is similar to the number of children who have diabetes.
- OCD can start at any time from preschool to adulthood.
- Although OCD does occur at earlier ages, there are generally two age ranges when OCD first appears. The first range is between ages 10 and 12 years and the second between the late teens and early adulthood.

RISK FACTORS

- Familial heritability pattern

- Moderate genetic component based on twin studies
- Acute streptococcal infection (PANDAS)

COMMONLY ASSOCIATED CONDITIONS

- Depression
- Anxiety disorders
- Tourette syndrome
- Trichotillomania

DIAGNOSIS

HISTORY

- The diagnostic evaluation should entail gathering data through separate interviews with the child/adolescent and the parents.
- Current symptoms should be elicited within attention to severity, duration, and level of functional impairment.
- Core symptoms should be elicited concerning the content of obsessions and the nature of compulsions. These are most frequently checking behaviors, repetition rituals, or a focus on symmetry and organization.
- Sensitivity in assessing violent or sexually intrusive thoughts is necessary, as children may be uncomfortable disclosing these.
- Compulsions may manifest in physical action or in mental repetition.
- Assess the amount of functional impairment by estimating the time spent occupied by obsession and compulsions and how it interferes with their daily lives.
- Explore their level of insight into the irrationality of the symptoms. Diagnostically, children do not have to recognize the symptoms to be excessive. Assess any parental accommodation of the ritualized behaviors, such as excessive cleaning.
- Determine if the onset was acute, severe, and temporally associated with symptoms of a streptococcal infection.

PHYSICAL EXAM

No pertinent findings

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- No pathognomonic laboratory findings
- If onset is acute, severe, and associated with symptoms of a streptococcal infection, consider obtaining an ASO titer.

Diagnostic Procedures/Other

Diagnostic scales: Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS)

DIFFERENTIAL DIAGNOSIS

- Pervasive developmental disorders
- Delusional disorder
- Obsessive-compulsive personality disorder
- Body dysmorphic disorder
- Anorexia nervosa
- Trichotillomania
- Tourette syndrome
- Schizophrenia
- Sydenham chorea
- Pediatric autoimmune neuropsychiatric disorders associated with strep infections (PANDAS)

TREATMENT

GENERAL MEASURES

There are 2 types of treatment for OCD, psychosocial treatment and pharmacotherapy.

- Cognitive behavioral therapy (CBT) is most effective and well-studied psychosocial treatment:
 - Selective serotonin reuptake inhibitors (SSRIs) are the 1st-line agents for medication management.
 - Start intervention with CBT alone and add medication if treatment response is limited.
- Emphasis is placed on graduated exposure with response prevention.
- Parental education is an important aspect of treatment adherence.
- Pitfalls

- Failing to use appropriate psychosocial treatments especially school-based modifications
- Not identifying the extent of the functional impairment
- It is important to recognize
 - The child’s fear of the internal thoughts he or she is having
 - The parents’ desire to have a “normal” child and thus their tendency to minimize/reassure the child who has concerns

MEDICATION

- SSRIs (1st-line) once-daily oral dosing; initiate 1/2 the starting dose for children with anxiety disorders:
 - Fluoxetine (Prozac) (10–60 mg)
 - Sertraline (Zoloft) (25–200 mg)
 - Fluvoxamine (Luvox) (25–200 mg)
 - Side effects include GI upset, headaches, dizziness, and agitation.

ALERT

A black box warning by the FDA indicates that all antidepressants may increase suicidal thinking and behavior in children and adolescents.

- Close monitoring is recommended (see next section).
- Tricyclic antidepressants (TCAs) are 2nd-line agents:
 - Clomipramine (Anafranil) (25–250 mg PO once daily)
 - Side effects include dizziness, xerostomia, blurred vision, postural hypotension, tachycardia, sedation, and constipation.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

- Monitoring of response to psychosocial treatment should be performed routinely every 2–3 months.
- If medication is initiated, close monitoring on a weekly basis is recommended for the 1st 4 weeks, followed by monthly monitoring.
- CBT is performed on a weekly or twice weekly regimen.
- Monitoring of any emerging comorbidities is suggested.

PROGNOSIS

- OCD is a chronic condition. Treatments have been demonstrated to show significant response, but remission of symptoms is rare.
- Childhood onset is a poor prognostic indicator.

ADDITIONAL READING

CODES

ICD10

- F42 Obsessive-compulsive disorder
- F63.3 Trichotillomania
- R46.81 Obsessive-compulsive behavior

FAQ

- Q: Is OCD inherited?
- A: Although no specific genes for OCD have been identified, there appears to be familial relationship to its inheritance.

- Q: What causes OCD?
- A: There is no proven cause of OCD. Research suggests that OCD involves problems in communication between the front part of the brain (the orbital cortex) and deeper structures (the basal ganglia).
- Q: Is there a cure?
- A: OCD is a chronic condition, but effective treatments are available.

OMPHALITIS

Jessica P. Clarke-Pounder • W. Christopher Golden

BASICS

DESCRIPTION

Omphalitis, an infection of the umbilical stump, begins in the neonatal period as a superficial cellulitis but may progress to necrotizing fasciitis, myonecrosis, or systemic disease.

EPIDEMIOLOGY

- Episodes of omphalitis are usually sporadic, but rare epidemics occur.
- Mean age of onset is 5–9 days in term infants and 3–5 days in preterm infants.
- Incidence varies from 0.2 to 0.7% of live births in developed countries and up to 21% of live births in developing countries.

RISK FACTORS

- Low birth weight
- Prior umbilical catheterization
- Septic delivery
- Male sex

GENERAL PREVENTION

- There are multiple methods used for umbilical cord care, many of which are acceptable.
- Antimicrobial agents applied to the umbilicus may decrease bacterial colonization and prevent omphalitis, particularly in developing countries.
- Effective methods of umbilical cord care:
 - Clean, dry cord care (AAP/WHO recommended)
 - Triple dye
 - Topical 4% chlorhexidine
 - 70% alcohol solution
- There is significant evidence to support the use of topical 4%

chlorhexidine to prevent omphalitis in developing countries, although it does delay time to cord separation.

- There is no evidence that application of an antiseptic to the umbilical cord is better than clean, dry cord care in a hospital setting.

PATHOPHYSIOLOGY

- Potential bacterial pathogens normally colonize the umbilical stump after birth.
- These bacteria invade the umbilical stump, leading to omphalitis.
- Established aerobic bacterial infection, necrotic tissue, and poor blood supply facilitate the growth of anaerobic organisms.
- Infection may also extend beyond the subcutaneous tissues to involve fascial planes (fasciitis), abdominal wall musculature (myonecrosis), and umbilical and portal veins (phlebitis).

ETIOLOGY

- Most cases of omphalitis are polymicrobial.
- The most common organisms include gram-positive cocci (*Staphylococcus aureus*, group A streptococci) and gram-negative enteric bacilli (*Escherichia coli*, *Klebsiella pneumoniae*, and *Proteus mirabilis*).
- Gram-positive organisms predominate; however, antistaphylococcal cord care has led to an increase in colonization and infection with gram-negative organisms.
- Anaerobic bacteria, including *Bacteroides fragilis* and *Clostridium perfringens*, are most likely in cases complicated by necrotizing fasciitis or myonecrosis.
- *Clostridium tetani* and *Clostridium sordellii* are seen primarily in developing countries when cow dung is used in cord care.

COMMONLY ASSOCIATED CONDITIONS

- Leukocyte adhesion deficiency
 - Omphalitis may be the initial manifestation of one of the leukocyte adhesion deficiencies (LADs).
 - LADs are rare, autosomal recessive immunologic disorders affecting leukocyte adhesion to blood vessel walls.
 - Cord separation requires the influx of leukocytes; therefore, this

deficiency causes delayed separation and can cause concomitant omphalitis.

- Infants also may present with leukocytosis, absence of pus formation, impaired wound healing, and recurrent infections localized to the skin and mucosal surfaces.
- Treatment involves prompt recognition of infection and use of appropriate antibiotics. Severe cases may need hematopoietic stem cell transplantation.
- Neutropenia
 - Omphalitis complicated by sepsis can be associated with neutropenia.
 - Other syndromes of neonatal neutropenia may present initially with omphalitis.
 - Neonatal alloimmune neutropenia: Maternal IgG antibodies cross the placenta and cause immune-mediated destruction of fetal neutrophils bearing antigens differing from mother's.
 - Other causes of neutropenia: autoimmune neutropenias, X-linked agammaglobulinemia, hyper-IgM immunodeficiency syndromes, HIV, glycogen storage disease type IB, or disorders of amino acid metabolism
- Anatomic abnormalities
 - Patent urachus: The urachus, a tubular structure connecting the bladder to the umbilicus, should obliterate by the 5th gestational month. If it remains patent, a continuous, significant amount of urine can drain from the umbilicus.
 - Persistent omphalomesenteric duct: congenital malformation where a communication exists between the umbilicus and the gut. Drainage consists of intestinal secretions.
 - Excessive granulation tissue: results from delayed healing of cord stump. Drainage is serosanguinous and pink.
- Considerations in preterm infants:
 - Preterm infants are more susceptible secondary to immature immune defenses (including the skin) and possible umbilical catheterization.
 - These infants are more likely to present with omphalitis at an earlier

age and with low neutrophil counts.

DIAGNOSIS

HISTORY

- Identify risk factors such as prolonged membrane rupture and septic delivery.
- Symptoms such as fever, irritability, lethargy, respiratory distress, or feeding intolerance may indicate systemic dissemination of the infection.
- A history of urine or stool discharge from the umbilicus suggests an underlying anatomic abnormality.
- Family history may reveal individuals with metabolic disorders or recurrent infections.

PHYSICAL EXAM

- Varies with the extent of disease
- Localized infection
 - Abdominal tenderness
 - Periumbilical edema and erythema
 - Purulent or malodorous discharge from the umbilical stump
- Indications of more extensive local disease, such as necrotizing fasciitis or myonecrosis:
 - Periumbilical ecchymoses or gangrene
 - Abdominal wall crepitus
 - Progression of cellulitis despite antimicrobial therapy
- Signs of systemic disease are nonspecific and include thermoregulation and evidence of multiorgan dysfunction:
 - Fever or temperature instability
 - Tachycardia, hypotension, poor perfusion
 - Respiratory distress
 - Abdominal distention, diminished bowel sounds
 - Cyanosis, petechiae, jaundice
 - Lethargy, hypotonia

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Umbilical stump Gram stain and culture for aerobic and anaerobic organisms
 - Identify potential organisms and antimicrobial susceptibility patterns. Cultures of umbilical discharge may reflect only colonization of the stump and are not proof of an etiologic role in the underlying process. If myonecrosis is suspected, muscle specimens should be cultured.
- Blood culture
 - Identify systemic dissemination of infection
- CBC with differential
 - Identify neutropenia or leukocytosis
 - An immature-to-total neutrophil ratio >0.2 is suggestive of systemic infection.
 - Thrombocytopenia may be present.
- D-dimers, prothrombin time, partial thromboplastin time, and fibrinogen
 - Indicated for sepsis or disseminated intravascular coagulation

Imaging

Radiographs (case dependent)

- Abdominal radiographs
 - Intestinal ileus may indicate systemic spread of infection; portal venous or intramural air requires immediate surgical consultation.
- Abdominal CT
 - Confirms involvement of fascia and muscle and delineates the extent of infection
 - May identify anatomic abnormalities
- Voiding cystourethrogram
 - Reveals patent urachus

Diagnostic Procedures/Other

Lumbar puncture: for any neonate with signs of focal/systemic illness or a positive blood culture

DIFFERENTIAL DIAGNOSIS

- The characteristic clinical picture of omphalitis allows diagnosis on

clinical grounds.

- Determine the presence of associated complications, such as necrotizing fasciitis, myonecrosis, or systemic infection.
- Consider an underlying immunologic or metabolic disorder.

TREATMENT

MEDICATION

Empiric coverage

- Antistaphylococcal agent (oxacillin, vancomycin) plus an aminoglycoside (e.g., gentamicin) or cefepime
- Consider local antibiotic susceptibility patterns when choosing antibiotics, paying particular attention to hospital and community incidence of methicillin-resistant *S. aureus*.
- Add anaerobic coverage (e.g., metronidazole or clindamycin) with necrotizing fasciitis or myonecrosis.
- Duration of therapy is typically 7–14 days.

ADDITIONAL TREATMENT

General Measures

Antibiotics and supportive care

ISSUES FOR REFERRAL

If systemic illness is present, infants may need referral to a tertiary care center and consultation by a pediatric infectious disease specialist or pediatric surgeon.

SURGERY/OTHER PROCEDURES

- Early and complete surgical debridement of affected tissue and muscle is important.
- Delay in diagnosis or surgical intervention allows local progression of infection and worsening systemic toxicity.

INPATIENT CONSIDERATIONS

Initial Stabilization

Emergency care: Immediate evaluation, intravenous antimicrobial therapy,

and supportive care are essential to survival.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Infants developing associated portal venous thrombosis require follow-up for complications owing to portal hypertension.

PROGNOSIS

- The outcome of infants with uncomplicated omphalitis is generally good.
- The mortality rate among all infants with omphalitis, including those who develop complications, is 7–15%.
- The mortality rate is significantly higher (38–87%) with necrotizing fasciitis or myonecrosis.

COMPLICATIONS

- Systemic sepsis (up to 13% of cases)
 - Evidenced by temperature instability, abdominal distension, respiratory distress, and/or hypotension
- Abscess
 - Retroperitoneal, pelvic, cutaneous, hepatic
- Peritoneal complications
 - Peritonitis can occur if the umbilical vein is involved in infection and is evidenced by poor feeding, bilious vomiting, and signs of systemic illness.
 - Portal vein thrombosis or hepatic abscess can occur with transmission via the umbilical vein.
 - Adhesive small bowel obstruction may be seen as a late complication.
- Myonecrosis
 - Infectious involvement of the muscle
 - Requires surgical treatment with resection
- Necrotizing fasciitis (8–16% of cases)
 - Bacterial infection of the subcutaneous fat and superficial and deep fascia

- Characterized by rapidly spreading infection and systemic toxicity

CODES

ICD10

- P38.9 Omphalitis without hemorrhage
- B95.0 Streptococcus, group A, causing diseases classd elswhr
- 95.8 Unsp staphylococcus as the cause of diseases classd elswhr

FAQ

- Q: Do all preterm infants require antiseptic treatment of the umbilical cord?
- A: No. Although preterm infants are at higher risk for omphalitis, there is no evidence to support antimicrobial treatment of the umbilical cord over clean, dry cord care in a hospital setting. If born in a developing country or out of asepsis, antimicrobial cord care is recommended.

- Q: Is omphalitis always restricted to the umbilical stump?
- A: No. Omphalitis can invade the periumbilical skin, the abdominal wall, and the peritoneum. Prompt treatment is necessary to prevent systemic spread of infection.

OSTEOGENESIS IMPERFECTA

Kara J. Connelly • Robert D. Steiner

BASICS

DESCRIPTION

Osteogenesis imperfecta (OI) is a genetic connective tissue disorder affecting primarily bones and soft tissues, characterized by bone fragility and susceptibility to bone fractures.

- Clinical severity is widely varied and dependent in part on the genetic etiology.
- Typical symptoms can include recurrent fractures, bone and/or spine deformities, short stature, blue or grey sclerae (occurring in approximately 80% of cases), dentinogenesis imperfecta (DI; occurring in approximately 40% of cases), and joint hypermobility.

EPIDEMIOLOGY

Incidence

1 in 10,000 births

Prevalence

6–7:100,000 persons

RISK FACTORS

Genetics

- The majority of cases (~85%) are due to autosomal dominant mutations in the genes encoding type I collagen, COL1A1 and COL1A2.
- Traditionally, OI has been classified due to clinical presentation, as initially described by Sillence. However, in the last decade, new dominant and recessive forms caused by mutations in several different genes have been described, which has altered the classification of OI. Modified classification typing is noted in parentheses below:
 - Type I (classic nondeforming OI with blue sclerae): usually normal stature, fractures infrequent, and usually in prepubertal years. No bowing of long bones. Blue sclerae. Early hypoacusia common.
 - Type II (perinatally lethal OI): death usually in perinatal period due

to pulmonary hypoplasia. Intrauterine fractures, shortened long bones, and blue sclerae are common.

- Type III (progressively deforming OI): severely shortened stature, severe deformities of long bones, prevalent vertebral fractures, scoliosis, chest deformities. Characteristic triangular face.
- Type IV (common variable OI with normal sclerae): DI common, short stature, bowing of long bones, vertebral fractures, scoliosis, and joint laxity. Patients are usually ambulatory. Sclerae are usually normal hue.
- Other clinical forms of OI
- OI with calcification in interosseous membranes (type V): autosomal dominant mutations of IFITM5 gene. Patients can develop hyperplastic calluses in long bones after fracture causing tender, firm swellings over bones. Blue sclerae and DI not common.
- Type VI: rare form of recessive OI due to mutations in SERPINF1 gene causing severe matrix mineralization defect. No blue sclerae, DI, or wormian bones. Rhizomelic shortening of extremities.
- Type VII: recessive mutation of CRTAP gene causing rhizomelia, early fractures, and osteopenia
- Type VIII: absence or severe deficiency of prolyl 3-hydroxylase activity due to mutations in the LEPRE1 gene
- Type IX: moderate to severe OI caused by defects in the PPIB gene
- Type X and XI: chaperone defects caused by SERPINH1 or FKBP10 mutations. Type XI due to FKBP10 mutations can cause progressively deforming OI or Bruck syndrome.

PATHOPHYSIOLOGY

- Mutations in COL1A1 or COL1A2 cause altered triple-helical collagen structure leading to abnormal collagen fibrils.
 - Procollagen molecules more susceptible to proteolytic degradation
 - Collagen fibrils are disorganized
 - Abnormal osteoid formation
 - Decrease in osteoid seams
- Recessive OI is caused by defects in genes whose products interact with type I collagen leading to many of the same cellular features, although the precise pathomechanisms are as yet incompletely

understood.

- Osteoblasts: increased osteoblast cellularity; however, reduction in differentiated cells capable of making mineralized matrix
 - Decreased bone formation during remodeling
- Osteoclasts: increased osteoclast number to remove defective matrix
- Growth retardation: Disruption of balance between bone formation and resorption is more pronounced during periods of rapid linear growth (i.e., childhood, puberty).

ETIOLOGY

- Failure of normal maturation of procollagen to type 1 collagen and failure of normal collagen cross-linking
- Abnormality of collagen production and organization

DIAGNOSIS

HISTORY

- Widely varied; may include recurrent fractures including fractures with little or no predisposing trauma
- May have positive family history, particularly if condition is due to an autosomal dominant mutation

PHYSICAL EXAM

- Severe congenital forms:
 - Intrauterine and perinatal fractures
 - Limbs deformed and short
 - Skull soft
 - Rib deformities and pulmonary hypoplasia leading to respiratory insufficiency
- Mild and moderate forms:
 - General: short stature
 - Head: triangular facies in type III OI
 - Eyes: blue or grey sclerae
 - Ears: hypoacusia (generally develops in adulthood)
 - Teeth: ~50% with DI: deciduous teeth more severely affected than permanent teeth, enamel normal, teeth easily broken but no increase

in cavities; malocclusion

- Spine: kyphoscoliosis; often associated with pectus carinatum or pectus excavatum. Barrel chest deformity common.
- Pelvis: trefoil pelvis, protrusio acetabuli
- Extremities: bowing of long bones, coxa vara deformity, cubitus varus, joint hypermobility

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Serum calcium and phosphorus levels
 - Normal
- Alkaline phosphatase
 - May be elevated after a fracture
- Type I collagen N-telopeptide normalized to urinary creatinine (NTx/uCr) highest in type III OI patients
- Diagnosis typically by DNA sequencing of genes implicated in OI from peripheral blood or cultured fibroblasts or analysis of collagen synthesis, structure, and electrophoretic mobility in cultured skin fibroblasts from skin biopsy.

Imaging

- Skull
 - Wormian bones: detached portions of primary ossification centers in adjacent membranous bones; can be seen in other conditions
- Long bones
 - Fractures: varying stages of healing
 - Osteopenia
 - Bowing deformity
 - Metaphyseal ends: honeycomb appearance
 - Acetabular protrusion
 - Popcorn calcifications
- Spine
 - Scoliosis
 - “Codfish vertebrae” due to compression fractures
 - Atlantoaxial subluxation
 - Spondylolisthesis

Diagnostic Procedures/Other

- Once diagnosis is established
 - Formal audiology assessment
 - Dental evaluation if DI
 - Consider screening for basilar impression with CT or MRI in more severe forms.
 - Bone densitometry may be helpful.

DIFFERENTIAL DIAGNOSIS

- In utero
 - Hypophosphatasia
 - Thanatophoric dysplasia
 - Campomelic dysplasia
 - Achondrogenesis
- Infancy and childhood
 - Child abuse
 - Idiopathic juvenile osteoporosis
 - Osteoporosis-pseudoglioma syndrome
 - Cole-carpenter syndrome
 - Hajdu-Cheney syndrome
 - Bruck syndrome
 - Hypophosphatasia
 - Leukemia
 - Osteopenia related to prematurity
 - Glucocorticoid-induced osteopenia
 - Cushing disease
 - Homocystinuria
 - Immobilization
 - Anticonvulsant therapy
- Hyperplastic callus formation in OI type V may be confused with osteogenic sarcoma.

TREATMENT

MEDICATION

- Antiresorptive agents (bisphosphonates)
 - Currently used in clinical trials and more widely in clinical practice in recent years
 - May improve bone mineral density, pain, and mobility
 - May lessen fracture risk
 - Most common side effects: flulike syndrome during initial treatment; hypocalcemia; delayed osteotomy healing
 - Long-term side effects unknown
 - Theoretically could be associated with atypical fractures and jaw osteonecrosis
- Adequate calcium (varies with age) and vitamin D intake (400–1,000 IU daily)
- Anabolic agents (growth hormone, insulin-like growth factor 1 [IGF-1], parathyroid hormone [PTH]): not considered routine treatment options, note PTH has black box warning now for pediatric indications
- Gene therapy: currently being developed; not yet available

ADDITIONAL TREATMENT

General Measures

- Intramedullary rodding with or without osteotomies: mainstay of care in severe cases
 - Often performed as early as 18 months of age
 - Should weight-bear as soon as possible after surgery
 - Many nonambulatory patients are able to walk after osteotomies.
- Spinal deformities
 - Seen in ~90%
 - Orthoses do not stop progression.
 - Treatment: spinal fusion or halo gravity traction and posterior spondylodesis
- Fracture treatment
 - Bone mineral density can decline after fracture while immobilized.
 - Postfracture physiotherapy critical

INPATIENT CONSIDERATIONS

Initial Stabilization

Emergency care

- For unstable fractures, such as femur fractures, spine instability
- Depends on location of fracture and details of individual situation

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Patient Monitoring

Multidisciplinary approach

- Pediatric endocrinologist or geneticist
 - Medical management of OI
- Pediatric orthopedic surgeon
 - Fracture repair, rodding, osteotomies, spinal fusion
- Physiotherapist
 - Postoperative rehabilitation, orthotics, physical therapy to improve mobility and stability of bones and increase muscle strength
- Psychologist/social worker
 - Adjustments and accommodations at school
 - Issues regarding self-esteem

PATIENT EDUCATION

- Techniques for safe handling, protective positioning, and safe movement are taught to parents.
- Physical education at school should be strongly encouraged, but children should not participate in contact sports. An individualized program may be necessary depending on OI severity.

PROGNOSIS

- Largely depends on severity of OI
- In general, the earlier the fractures occur, the more severe the disease.
- Tendency toward improvement after somatic growth is complete in adolescence with relatively lower bone removal and less frequent fractures.
- Future therapeutic options including gene therapy hold promise for improved treatment.

COMPLICATIONS

- Pathologic fractures
- Scoliosis
- Cardiorespiratory problems (restrictive lung disease in severe cases with severe kyphoscoliosis, aortic dilatation, mitral valve prolapse, aortic regurgitation)
- Hearing loss
- Short stature
- Basilar impression: descent of the skull on the cervical spine; may progress to brainstem compression or obstructive hydrocephalus

Q78.0 Osteogenesis imperfecta

FAQ

- Q: What is the typical life expectancy for persons with OI?
- A: Infants with perinatal/lethal (type II) OI do not survive the perinatal period and often die within the first 48 hours of life. For mild and moderate OI, life expectancy is normal. Life expectancy for patients with severe (type III) OI is widely variable and can be shortened by kyphoscoliosis contributing to restricted lung disease.
- Q: How is OI inherited?
- A: OI is often inherited in an autosomal dominant manner. New mutations are not uncommon, and this often provides the explanation for lethal cases of OI in families with no history of OI. More recently, autosomal recessive forms of OI (mainly severe and lethal) have been described.
- Q: How is OI differentiated from child abuse?
- A: Differentiation of OI from child abuse is usually straightforward once the history, physical examination, radiographic findings, and family history are carefully considered. However, in difficult cases, genetic and/or biochemical testing may be useful.

OSTEOMYELITIS

Blanca E. Gonzalez • Virginia M. Pierce

BASICS

DESCRIPTION

- Infection of any bone
- Most commonly occurs in the metaphysis of a long bone (especially the distal femur or proximal tibia)

EPIDEMIOLOGY

- One of the most common invasive bacterial infections in children, accounting for 1% of all pediatric hospitalizations
- 1/3 third occurs in children younger than 2 years of age and ~50% of cases occur in children ≤ 5 years of age.
- A history of minor trauma to the affected site is common but of unclear significance.
- Boys are more commonly affected than girls (2:1 ratio).

PATHOPHYSIOLOGY

- Hematogenous spread is most common in children (inoculation of bone during an episode of bacteremia). The infecting organism enters the bone via a nutrient artery and then is deposited in the metaphysis due to its rich vascular supply. The organism replicates in metaphyseal capillary loops, causes local inflammation, spreads through vascular tunnels, and adheres to the bone matrix. Increased pressure in the metaphysis allows pus to perforate through the cortex and lift the periosteum.
- In newborns and young infants, rupture of pus into the adjacent joint space is more common because blood vessels connect the metaphysis and epiphysis.
- Local spread from a contiguous focus of infection and direct inoculation (e.g., penetrating injury) are less common mechanisms of infection.

RISK FACTORS

- Sickle hemoglobinopathy
- Primary or acquired immunodeficiency, especially chronic granulomatous disease (CGD), and HIV
- Bone trauma (open fractures, puncture wounds, bites, surgical manipulation)
- Implanted orthopedic devices or indwelling vascular catheters
- Pressure ulcers

ETIOLOGY

- *Staphylococcus aureus* is responsible for 70–90% of osteomyelitis in all age groups, with MRSA an increasingly common problem.
- *Streptococcus pyogenes* accounts for ~10% of osteomyelitis and is more common in preschool and early school-aged children.
- *Streptococcus pneumoniae* causes ~10% of osteomyelitis in children younger than 3 years old, although a decline in pneumococcal infections has been seen with widespread vaccination. Conversely, *S. pneumoniae* remains an important cause of osteomyelitis in children infected with HIV.
- *Kingella kingae*, a gram-negative organism found in the respiratory tract, is an important pathogen in children younger than the age of 3 years, especially in those that attend day care centers.
- Group B *Streptococcus*, gram-negative enterics, and *Candida* spp. are important causative organisms in neonates.
- *Salmonella* spp. can be the cause in children with sickle cell disease and in patients from or traveling to tropical countries.
- *Pseudomonas aeruginosa* is a common cause following puncture wounds to the foot.
- There has been a significant decline in the incidence of *Haemophilus influenzae* type b (Hib) osteomyelitis since immunization with the Hib conjugate vaccine became widespread.
- Other more unusual pathogens may be seen in patients with specific risk factors (e.g., coagulase-negative staphylococci in the presence of prosthetic material, anaerobes after animal or human bites, *Aeromonas* after injuries sustained in fresh water settings).
- In a significant percentage of cases, a definitive causative

microorganism is not identified. The use of antibiotic prior to collection of samples, presence of fastidious organisms, low inoculum, or inappropriately collected samples, may be a factor in culture-negative osteomyelitis.

- Infections after open fractures or puncture wounds may be polymicrobial.

DIAGNOSIS

HISTORY

- Persistent, increasing pain and tenderness over the affected bone
- Restricted use of the involved limb (pseudoparalysis may be the only sign in a neonate), refusal to bear weight, or limp
- Fever, malaise, anorexia, irritability
- Children with vertebral and pelvic osteomyelitis may complain of poorly localized pain for several weeks, often resulting in delay in the diagnosis and treatment.
- In some patients, osteomyelitis will have an indolent, subacute presentation with the development of a minimally symptomatic abscess within the bone, eponymously known as a “Brodie abscess.”

PHYSICAL EXAM

- Swelling, warmth, and erythema of the soft tissues over the affected bone may be noted.
- Exaggerated immobility/pain with micromotion of an adjacent joint suggests pyogenic arthritis (alternatively or in addition to osteomyelitis).
- Multifocal osteomyelitis may be seen in neonates and in children with *S. aureus* sepsis syndrome.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- The white blood cell count may be normal or elevated.
- Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) levels are usually elevated.
- Blood cultures are positive in ~50% of patients.

- Bone needle aspiration cultures are positive in ~60–70% of cases.
- Some uncommon bacteria causing osteomyelitis are fastidious and difficult to culture; they may require molecular methods to establish the diagnosis (e.g., polymerase chain reaction).

Imaging

- Plain radiographs may show deep soft tissue swelling early in the course of infection and may help to suggest or exclude alternative diagnoses. Evidence of bone destruction and periosteal elevation are not typically seen until 10–14 days after the onset of symptoms.
- MRI is sensitive and specific and offers superior anatomic resolution, making it a more useful modality for surgical planning and for identification of intraosseous, subperiosteal, and soft tissue abscesses.
- Bone scans are especially useful if the site of infection is poorly localized or if there is concern for multifocal osteomyelitis. However, they may be positive in other illnesses that cause osteoblastic activity.

Diagnostic Procedures/Other

- Biopsy or aspiration of the infected bone (or an associated abscess) for Gram stain and culture is useful for determining the etiologic organism. Inoculating a portion of an aspirated sample into a blood culture bottle enhances yield for *K. kingae*.
- If a plan is in place to rapidly obtain a bone culture in a clinically stable patient, it is reasonable to defer initiation of antibiotic therapy until after the culture specimen is secured.
- Biopsy may help differentiate osteomyelitis from noninfectious bone pathology.

DIFFERENTIAL DIAGNOSIS

- Trauma
- Cellulitis
- Soft tissue abscess
- Pyomyositis or fasciitis
- Septic arthritis
- Congenital syphilis
- Aseptic bone necrosis or bone infarction (sickle cell disease)
- Tumor (e.g., Ewing sarcoma, osteoid osteoma, eosinophilic granuloma)

- Acute leukemia, neuroblastoma with bone invasion
- Chronic recurrent multifocal osteomyelitis (CRMO)
- Inflammatory arthritis or juvenile idiopathic arthritis
- Transient synovitis
- Bone cyst

TREATMENT

MEDICATION

- Empiric antibiotics should cover the most likely pathogens considering patient age, history of presentation, physical findings, and underlying medical conditions.
- Empiric therapy should always include an agent directed against *S. aureus*, usually nafcillin, oxacillin, or a 1st-generation cephalosporin. However, in areas where the rate of methicillin resistance among community *S. aureus* isolates exceeds 10%, an antibiotic effective against community-acquired MRSA should be selected (i.e., clindamycin or vancomycin).
- When clindamycin is considered for treatment of an identified MRSA isolate, the D-test (to exclude inducible macrolide, lincosamide, and streptogramin B resistance) should be performed by the clinical microbiology laboratory.
- Clindamycin and vancomycin are also usually effective against *S. pneumoniae* and *S. pyogenes* but are not effective in vitro against *K. kingae*. The latter organism is usually susceptible to most beta-lactam antibiotics (penicillins and cephalosporins).
- In addition to antistaphylococcal coverage, a 3rd generation cephalosporin, such as ceftriaxone or cefotaxime should be used to cover *Salmonella* spp. in patients with sickle cell disease.
- Gram-negative coverage should also be added to the empiric regimen for neonates.
- If the patient recently had a foot puncture wound, coverage for *P. aeruginosa* should be considered.
- If an organism is isolated and susceptibilities determined, antibiotic therapy should be modified based on the susceptibility profile.

ADDITIONAL TREATMENT

- Traditionally, 4–6 weeks of antibiotics have been recommended. Newer data is emerging suggesting that for non-MRSA hematogenous osteomyelitis, 20 days of therapy may be sufficient. However, this may require the use of more frequent dosing schedules as well as higher doses.
- Total treatment duration should be individualized based on the extent of infection, the promptness and completeness of surgical debridement (when indicated), the rate of clinical response, the presence or absence of distant foci of infection, and the patient’s underlying risk factors and comorbid conditions.
- If an intraosseous, subperiosteal, or soft tissue abscess is present, surgical debridement may be necessary in addition to antibiotic therapy.
- Surgical debridement is important in the management of osteomyelitis that is secondary to a puncture wound.
- After an initial period of parenteral antibiotic administration, many patients can be transitioned to an oral regimen to complete therapy (assuming the availability of an oral antibiotic with an appropriate spectrum of activity and adequate bone penetration as well as patient ability to adhere to and absorb an oral regimen). This sequential IV–oral approach reduces the risk of complications (e.g., catheter-associated bloodstream infection, catheter malfunction, and thrombosis) associated with the prolonged presence of a central venous catheter.
- The decline in CRP alongside improvement in clinical signs may be a good indicator of when it is safe to transition to oral therapy.
- The treatment of osteomyelitis should be done in consultation with an infectious disease specialist.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Most children who receive appropriate treatment have no long-term sequelae.

- Inflammatory markers (ESR and CRP) are typically measured serially until they normalize during the course of antibiotic therapy.
- Patients should be followed to ensure medication compliance, adequacy of treatment, side effects of therapy, and continued growth of the involved extremity.

COMPLICATIONS

- Septic arthritis
- Recurrence or progression to chronic osteomyelitis in ~5% of patients
- Disturbances of bone growth, limb length discrepancy
- Arthritis
- Pathological fractures

CODES

ICD10

- M86.9 Osteomyelitis, unspecified
- M86.00 Acute hematogenous osteomyelitis, unspecified site
- M86.10 Other acute osteomyelitis, unspecified site

FAQ

- Q: Can children with osteomyelitis present without fever and with normal CBCs and inflammatory markers?
- A: Fever along with leukocytosis and elevated inflammatory markers (CRP and ESR) are common in children who have acute hematogenous osteomyelitis. However, children with subacute or chronic osteomyelitis and with other forms of osteomyelitis, such as puncture wound osteochondritis, may not exhibit these findings.
- Q: What is the imaging modality of choice in a child suspected of having acute hematogenous osteomyelitis?
- A: MRI is the most sensitive and specific imaging study to detect acute osteomyelitis. Plain films do not reveal periosteal elevation for at least 10–14 days after infection. A bone scan is less specific than MRI and does not reveal extraosseous features of infection.

OSTEOSARCOMA

Sheila Thampi • Steven G. DuBois

BASICS

DESCRIPTION

Osteosarcoma is a malignant tumor of the bone and arises from mesenchymal cells. The malignant cells are usually pleomorphic spindle cells that lay down abnormal bone (osteoid formation).

EPIDEMIOLOGY

- Osteosarcoma is the most common pediatric primary bone cancer and is the 8th most common malignancy of childhood.
- A bimodal distribution is noted with the first peak in adolescence (median, age 16 years) and second peak during the 7th and 8th decade of life.
- Incidence of osteosarcoma parallels skeletal growth and is more frequently noted in tall individuals.
- Males are more commonly affected than females.
- In the United States, there are about 4.4 cases per million children and adolescents.
- Approximately 400 new pediatric cases of osteosarcoma are diagnosed each year in the United States.

RISK FACTORS

- Radiation exposure
- Hereditary retinoblastoma, in which patients with germline Rb gene mutation have increased risk of osteosarcoma with or without radiation exposure.
- Li-Fraumeni syndrome, in which patients have germline TP53 gene mutation and increased risk of a range of sarcomas, among other malignancies
- Rothmund-Thomson syndrome
- Bloom syndrome
- Enchondromatosis

- Hereditary multiple exostoses
- Fibrous dysplasia
- Paget disease of the bone, although less relevant to pediatric populations

PATHOPHYSIOLOGY

- The histologic hallmark of osteosarcoma is the presence of osteoid.
- Most cases of pediatric osteosarcoma are high-grade cancers, although lower grade variants are seen.
- No classic genetic change, although karyotypes are typically highly abnormal
- Major subtypes of osteosarcoma include osteoblastic, chondroblastic, fibroblastic, telangiectatic, and small cell.
- At diagnosis, 80% of patients will have localized disease and 20% will have metastatic disease.
- In 80% of tumors, the metaphysis of long bones will be involved, such as the femur, tibia, and humerus, with distal femur the most common primary site. In 20% of tumors, other sites of involvement will include the pelvis, facial bones, and shoulder blade.
- The most common sites of metastatic disease are lungs and bone. Involvement of regional lymph nodes is rare.

ETIOLOGY

- The etiology of most cases is unknown.
- Abnormal TP53 and/or Rb function implicated in laboratory studies of osteosarcoma
- Radiation exposure is a known cause of osteosarcoma and usually presents 10–20 years after exposure.

DIAGNOSIS

SIGNS AND SYMPTOMS

History

- Pain and palpable mass are the most common clinical symptoms.
- Pain is often described as dull or aching at the tumor site.
- Pain is often initially attributed to an injury in active children or

adolescents.

- Symptoms of pain can vary prior to presenting to medical attention but warrant further investigation if present for several weeks to months and if it disrupts sleep.
- Presence of bone metastasis may result in pain at sites distant from the primary tumor.
- Systemic symptoms, such as fever and weight loss, are unusual.

Physical Exam

- Presence of a firm, often tender mass
- Swelling at the tumor location
- Depending on location of the tumor, one can have a loss of function, limp, or decreased range of motion

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- 30% of patients will have an elevated lactate dehydrogenase (LDH).
- An elevated erythrocyte sedimentation rate (ESR) can be seen.
- May see an elevated alkaline phosphatase (AP), particularly with metastatic disease
- Leukocytosis may suggest osteomyelitis.

Imaging

- Conventional x-ray may show
 - Osteolytic and sclerotic lesion
 - Periosteal reaction including Codman sign (shadow from a lifted periosteum), onion-skinning as new layers of periosteum are laid down, and sunburst appearance reflecting calcified bone beyond periosteum
 - Pathologic fracture
- An MRI from joint to joint of involved bone will show full extension of the tumor and involvement of surrounding structures.
- A technetium bone scan will show areas of intense primary tumor uptake and screen for bone metastasis.
- A chest CT should be performed to evaluate for pulmonary metastasis.
- Use of positron emission tomography with [F-18]-fluorodeoxyglucose (FDG-PET) is increasing, as it can characterize size, location of tumor,

and can allow for assessment of response.

Diagnostic Procedures/Other

The diagnosis of osteosarcoma is a tissue diagnosis.

ALERT

Biopsy should be performed at the center that will provide definitive treatment for the patient with a suspected primary malignant bone tumor. The placement of biopsy is critical to the planning of surgical local control and inappropriate biopsy could lead to adverse outcomes.

DIFFERENTIAL DIAGNOSIS

- Benign tumors
 - Unicameral bone cyst
 - Aneurysmal bone cyst
 - Osteoblastoma
 - Eosinophilic granuloma
 - Osteochondroma
 - Fibrous dysplasia
- Malignant tumors
 - Ewing sarcoma
 - Chondrosarcoma
 - Fibrosarcoma
 - Metastatic lesions
- Infection
 - Osteomyelitis
 - Septic arthritis
- Trauma: fracture with or without hematoma

TREATMENT

CHEMOTHERAPY

- Prior to the 1970s, overall survival for high-grade osteosarcoma was poor, as treatment primarily consisted of surgical resection allowing for relapse with metastatic disease. With the addition of both neoadjuvant and adjuvant chemotherapy, survival has improved.

- Neoadjuvant chemotherapy (before definitive surgery) allows for treatment of micrometastases and shrinkage of the primary tumor mass prior to resection.
- Neoadjuvant chemotherapy also allows time for complex endoprostheses to be constructed prior to planned limb salvage procedures.
- Response to neoadjuvant chemotherapy (percent of tumor that is necrotic at the time of complete resection) has proven to be an important prognostic factor.
- Most children and adolescents with high-grade osteosarcoma are treated based on or according to cooperative group chemotherapy protocols.
- In North America, the standard backbone of treatment is high-dose methotrexate, doxorubicin, and cisplatin. Treatment duration is usually 12 months, depending on the individual protocol, response to therapy, and tumor extent at diagnosis.
- Clinical trials in patients with newly diagnosed disease have investigated the role of ifosfamide and etoposide. The addition of interferon with chemotherapy did not improve survival.

SURGERY/OTHER PROCEDURES

- Complete surgical resection with wide margins is necessary for cure.
- Surgical options for osteosarcomas of the extremities include the following:
 - Amputation
 - Limb salvage with local resection and reconstruction of the limb
 - Rotationplasty for tumors at the knee
- Surgical resection alone is curative in low-grade osteosarcoma.
- Surgical resection of lung metastases at presentation or at relapse also plays an important role in management.

RADIOTHERAPY

Osteosarcoma is not a radiation-sensitive tumor although radiation has been used for palliative purposes to treat unresectable primary or metastatic lesions.

PHYSICAL THERAPY

Physical therapy is critical after either amputation or limb-sparing procedures.

ONGOING CARE

ISSUES FOR REFERRAL

- Children with a suspected malignant bone tumor should be immediately referred to a children's hospital with expertise in these tumors.
- Multidisciplinary teams include pediatric oncologists, orthopedic oncologists, pediatric surgeons, nurses, pharmacists, and social workers.

PROGNOSIS

- Patients with localized disease have an estimated 5-year overall survival of 60–70%, whereas patients with metastatic disease have an estimated 5-year overall survival of 20–30%.
- Key adverse prognostic factors are as follows:
 - Axial primary tumor location
 - Metastatic disease
 - Histologic necrosis <90% after neoadjuvant chemotherapy
 - Inability to achieve wide surgical margins during resection

COMPLICATIONS

Orthopedic

- Surgical site wound infections
- Limb length discrepancy after surgical treatment in growing children
- Phantom leg pain after amputation

Acute Chemotherapy Toxicity

- Myelosuppression
- Ototoxicity and tinnitus
- Mucositis
- Renal dysfunction

Late Effects

- Cardiomyopathy from doxorubicin

- Hearing loss and nephrotoxicity from cisplatin
- Reduced fertility from ifosfamide
- Secondary malignancy from radiation or chemotherapy

Patient Monitoring

- Patients should be followed by a pediatric oncologist with serial imaging of the primary site (MRI and x-rays) and lungs (chest CT or chest x-ray) to monitor for recurrence.
- Patients should be monitored for long-term side effects/complications of therapy, ideally within the context of a survivorship clinic.

CODES

ICD10

- C41.9 Malignant neoplasm of bone and articular cartilage, unsp
- C40.20 Malignant neoplasm of long bones of unspecified lower limb
- 40.00 Malig neoplasm of scapula and long bones of unsp upper limb

FAQ

- Q: How can we differentiate between malignant osteosarcoma and benign tumors?
- A: An experienced radiologist can look for defining features on imaging of malignant osteosarcoma that are not found with benign

tumors. However, only a biopsy can confirm a diagnosis of osteosarcoma.

- Q: What are long-term survival rates of patients who relapse after treatment?
- A: Unfortunately, patients who relapse after treatment do poorly and long-term survival is poor at 10–20%. Late relapses (>24 months after completion of treatment), surgical resection of relapsed disease, and unilateral lung involvement at relapse appear to be more favorable.
- Q: Do siblings of children with osteosarcoma need to be evaluated?
- A: If there is suspicion for a genetic risk factor (i.e., Li-Fraumeni syndrome), then siblings and families should be evaluated by a geneticist to determine if the risk factor is present. This will provide education for families and siblings. Otherwise, siblings of children with osteosarcoma that are asymptomatic do not need evaluation for osteosarcoma.
- Q: What are the differences between Ewing sarcoma and osteosarcoma?
- A: The two sarcomas are the most common malignant bone tumors in pediatrics and both require multimodal therapy, although the chemotherapy regimens are different. Ewing sarcoma can have both bone or soft tissue involvement and presence of different histologic features will allow differentiation from osteosarcoma.

OTITIS EXTERNA

Melissa Long

BASICS

DESCRIPTION

- Diffuse inflammation of external auditory canal with or without infection
- Also known as “swimmer’s ear”
- May be categorized as acute, chronic, or malignant
 - Acute: rapid onset, usually bacterial
 - Chronic: lasting longer than 4 weeks or occurring 4 or more times in 1 year, usually due to nonbacterial causes such as atopic or allergic contact dermatitis from contact with metal, plastic, or chemicals
 - Malignant or necrotizing: extension of infection to osteomyelitis of the base of the skull; more common in immunocompromised patients (e.g., HIV, diabetes)

EPIDEMIOLOGY

- Peaks in children age 5–14 years
- Uncommon in children younger than age 2 years
- Peaks in summer months in temperate climates; occurs year-round in warm/humid climates

Incidence

Annual incidence is 8.1/1,000 in the general population.

Prevalence

Affects 3–5% of the population

RISK FACTORS

- Prolonged exposure to water (e.g., frequent swimming, shampooing, long showers, excessive sweating) leading to impaired natural defense mechanisms in external ear
- Microfissures from trauma
- Debris from dermatologic conditions (e.g., atopic or seborrheic)

dermatitis)

- Use of external devices (e.g., hearing aids or ear plugs)
- Obstruction of ear canal (e.g., by impacted cerumen, foreign body, sebaceous cyst)
- Chronic otorrhea or purulent otorrhea from otitis media
- Drainage from tympanostomy tubes
- Hairy ear canal
- Anatomic abnormalities
 - Stenosis of ear canal
 - Exostoses (abnormal bone growth within the ear canal)
- Hx of radiotherapy leading to damaged epithelium, desquamation, and diminished cerumen production

GENERAL PREVENTION

- Elimination of predisposing factors when feasible is the key to prevention.
- Avoid exposure to excessive moisture.
 - There are no randomized trials evaluating preventive strategies but you may instruct swimmers to keep their ears as dry as possible by toweling off, tilting the head to assist with drainage, and using a hair dryer to the ear canal on the lowest setting.
 - Some experts also recommend the use of ear plugs and caps, although this is controversial because it may lead to cerumen impaction, predisposing to otitis externa (OE).
 - Use of a 1:1 alcohol-to-vinegar solution before and after swimming and again before bedtime also may decrease the rate of recurrence.
- Avoid trauma to the ear canal—in particular, avoid cotton-tip swabs or other cleaning devices.
- Manage underlying dermatologic conditions.

PATHOPHYSIOLOGY

- The ear canal is lined with apocrine and sebaceous glands that produce cerumen.
- Cerumen serves as a barrier to excessive moisture and may help prevent infection due to lysozyme activity and a slightly acidic pH that helps inhibit the growth of pathogenic bacteria.

- With prolonged exposure to water, cerumen may be washed away and no longer be able to serve this barrier function.
- Too much cerumen can also lead to entrapment of debris and water retention, thus predisposing to infection.
- In certain dermatologic conditions, the integrity of the keratin layer may be affected by excessive desquamation.
- Local trauma to the external canal may also predispose to infection.

ETIOLOGY

- In the United States, bacterial agents are implicated in more than 90% of cases and most commonly include *Pseudomonas aeruginosa* and *Staphylococcus aureus*.
- May be polymicrobial in up to 30% of cases
- Fungal causes due to *Aspergillus niger* and *Candida* species
- Viral infection (in particular, varicella-zoster leading to Ramsay Hunt syndrome) account for a minority of cases.

DIAGNOSIS

HISTORY

- Symptoms are rapid in onset (generally within 48 hours) and include otalgia, pruritus, a sense of fullness, drainage, and occasionally impaired hearing.
- 90% of cases are unilateral.
- May have a low-grade fever but temperature over 101°F (38.3°C) suggests more serious infection and likely extension beyond the external ear canal.
- Ask about potential predisposing factors including swimming, dermatologic conditions, or trauma.
- Important to know status of immune system (e.g., history of diabetes, HIV infection)

PHYSICAL EXAM

- Examine external canal, tympanic membrane (TM), regional lymph nodes, and skin for dermatologic conditions.
- Signs of inflammation include tenderness or pain with manipulation of

the pinna and with pressure on the tragus, erythema and edema of the external auditory canal, and otorrhea.

- More severe forms of OE may involve regional lymphadenopathy or frank lymphadenitis, cellulitis extending beyond the external canal, and/or perichondritis.
- May be difficult to visualize TM due to edema and debris
 - Can clear debris with ear curette or suction
 - Avoid lavage until TM is known to be intact.
 - Pneumatic otoscopy can assess for TM mobility for diagnosis of otitis media.
- Although rare in children, consider malignant OE if there is necrosis of the skin of the canal, exposed bone or granulation tissue, severe pain, and/or cranial nerve palsy.
- Consider viral infection (Ramsay Hunt syndrome) if there are vesicular lesions with facial paralysis, loss of taste, and decreased lacrimation on the affected side.

DIAGNOSTIC TESTS & INTERPRETATION

Labs and Diagnostic Procedures

- In uncomplicated OE, testing is generally not indicated.
- Consider bacterial culture of drainage with Gram stain and/or fungal culture in cases of severe illness or treatment failure.
- Consider viral testing if vesicular lesions are present.
- If concerned for malignant OE by history or exam, consider lab work (including erythrocyte sedimentation rate) and imaging (MRI generally preferred over CT scan).

DIFFERENTIAL DIAGNOSIS

- Important to rule out life-threatening causes of otalgia and otorrhea
 - Clear persistent fluid may occur after traumatic head injury, leading to cerebrospinal fluid otorrhea.
 - Purulent otorrhea could be due to acute otitis media associated with mastoiditis, brain abscess, or venous sinus thrombosis.
 - With bloody drainage, must consider traumatic perforation of the TM, barotrauma leading to hemotympanum, or a tumor
- Other infections

- Furunculosis in the external auditory canal (also known as localized OE)
- Otomycosis
- Infected sebaceous cyst
- Acute otitis media
- Chronic suppurative otitis media with ruptured TM
- Drainage through tympanostomy tubes
- Miscellaneous
 - Foreign body
 - Cholesteatoma
 - Contact dermatitis (e.g., to metal, plastics)

TREATMENT

MEDICATION

- For uncomplicated OE, topical antibiotics are the treatment of choice, as they are both effective and well tolerated.
- A 2010 Cochrane review found no difference among topical antibiotic preparations in terms of clinical or microbiologic cure rates. There was also insufficient evidence to suggest that the addition of corticosteroids to topical antibiotic preparations leads to improved outcomes.
- Choice of topical antibiotic therapy should be guided by the following:
 - Effectiveness
 - Consideration of potential adverse effects
 - Patency of the tympanic membrane
 - Expected adherence
 - Risk of developing drug resistance
 - Cost and availability
- Aminoglycoside preparations (e.g., neomycin) should be avoided when the patency of the tympanic membrane cannot be confirmed because of the associated ototoxicity to the middle ear. Note that neomycin can cause an allergic contact dermatitis. Note that neomycin is often combined with polymyxin B for antipseudomonal coverage and hydrocortisone.
- Fluoroquinolone preparations are safe to use in cases of nonintact TM

and are dosed once or twice daily, which may increase adherence.

- Tips for medication administration
 - Consider warming the ototopical agent to body temperature prior to administration to decrease likelihood of dizziness from caloric stimulation.
 - Preferable for parent to administer treatment, even for older children
 - Patient should lie with affected ear upward.
 - Drops should fill the canal.
 - Manipulate the pinna/tragus to help disperse the medication.
 - Remain in that position for 3–5 minutes.
 - Leave canal open to dry (do not insert cotton ball).
- Duration of treatment is usually 7–10 days, with expected improvement of symptoms within 3 days and resolution by 6 days.
- For those with symptoms persisting beyond the 7- to 10-day period, treatment should continue until symptoms resolve to a maximum of 14 days, at which point, treatment failure should be considered. At that time, a culture may guide further antimicrobial therapy.
- Oral antibiotics should be considered only in complicated OE (coexisting acute otitis media, lymphadenitis, or facial cellulitis) and in immunocompromised individuals who are at higher risk for developing necrotizing or malignant OE.

ADDITIONAL TREATMENT

General Measures

- Pain management
 - For mild to moderate pain, acetaminophen or ibuprofen and application of heat or cold packs often will suffice.
 - For severe pain, a short course of narcotics may be required because pain may intensify during first 48 hours of treatment.
 - There is no data to suggest that benzocaine otic drops are effective for pain management and in fact they may limit the effectiveness of the topical antibiotic by interfering with its contact with the epithelium of the ear canal.
- Clearing aural debris
 - In moderate to severe cases of OE when thick drainage obstructs the view of the TM, it may be necessary to clear debris with light

suction or manual removal.

- Do not use irrigation until you have confirmed the TM is intact.
- May need to refer to ear, nose, and throat (ENT) physician for aural toilet under microscopic guidance
- Edema
 - In cases in which edema has progressed to cause >50% narrowing of the canal, a medication wick may be necessary (e.g., ¼-inch ribbon gauze or compressed cellulose) to ensure adequate delivery of antimicrobial therapy directly to the epithelium.
 - Do not use a cotton ball because it could fall apart and pieces could become trapped in the canal.
- The wick may fall out on its own as edema resolves or may be removed by clinician.
- Keep the area dry and refrain from swimming for the duration of treatment or at least until symptoms resolve.
- Refrain from using hearing aids until symptoms resolve.

ISSUES FOR REFERRAL

Referral to an otolaryngologist may be indicated for aural cleaning, severe disease, treatment failure, or suspicion of malignant OE.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Reevaluate if symptoms do not improve within 48 hours of initiating treatment, progression of symptoms despite treatment, or severe illness.
- Immunocompromised patients should be followed closely due to risk for developing malignant OE.

PROGNOSIS

- Excellent in uncomplicated OE with symptom improvement in 2–3 days and resolution of symptoms in 6 days
- Recurrence is common if steps are not taken to address predisposing factors.

COMPLICATIONS

- Stenosis of the ear canal, cellulitis, lymphadenitis, chondritis, parotitis, chronic OE (rare in children)
- Malignant OE in immunocompromised patients (also rare in children)
- Reaction to antibiotic preparation (pruritus, local reaction, rash, discomfort, otalgia, dizziness, vertigo)

CODES

ICD10

- H60.90 Unspecified otitis externa, unspecified ear
- H60.339 Swimmer's ear, unspecified ear
- H60.509 Unsp acute noninfective otitis externa, unspecified ear

FAQ

- Q: How should I clean my child's ear?
- A: The external ear can be cleaned with a washcloth. Cotton swabs or other objects should not be inserted into the ear canal, as they may

cause trauma or lead to impaction of cerumen. If there is concern for impacted cerumen causing symptoms such as ear fullness, pain, or hearing loss, then a physician should be consulted for discussion of methods for removal.

- Q: Is there a role for oral antibiotics in the treatment of OE?
- A: In uncomplicated OE where the infection is limited to the external canal, topical antibiotics are sufficient. If infection extends beyond the external canal (e.g., otitis media or cellulitis), then an oral antibiotic is advised.
- Q: How should treatment of OE differ if one cannot visualize the tympanic membrane due to accumulated debris and/or edema?
- A: In cases where the tympanic membrane cannot be confirmed to be intact, do not perform lavage. Debris can be removed by curette in the primary care physician's office or the patient may be referred to an otolaryngologist for removal under microscopic guidance. Choose a topical antimicrobial agent other than an aminoglycoside due to its toxic effects on the middle ear. Depending on the certainty of your diagnosis of OE, consider whether the history suggests a coexisting acute otitis media necessitating presumptive treatment with oral antibiotics.

OTITIS MEDIA

C. Matt Stewart • Rosalyn W. Stewart

BASICS

DESCRIPTION

Otitis media is a general term for middle ear inflammation with or without symptoms. It can be acute or chronic.

- 2 specific diagnoses
 - Otitis media with effusion, middle ear effusion (MEE)
 - Acute otitis media (AOM)
 - Uncomplicated/nonsevere
 - Severe
 - Recurrent

EPIDEMIOLOGY

- Most common condition for which antibacterial agents are prescribed for children in the United States
- Peak incidence between 6 and 12 months of age
- By age 3 years, 50–85% of children have had AOM.

RISK FACTORS

- Age <2 years
- Gender: male > female
- Family history of AOM
- Anatomic differences, craniofacial abnormalities
- Environmental tobacco smoke exposure
- Exposure to large numbers of other children
 - Day care
 - Siblings in home

GENERAL PREVENTION

- Breastfeeding for at least 3–6 months
- Decreased pacifier use after 6 months
- Vaccines

- Pneumococcal conjugate vaccine
- Influenza vaccine
- Reduction in secondhand smoke
- Reduction of day care crowding

PATHOPHYSIOLOGY

- Eustachian tube dysfunction leads to MEE. If effusion is not cleared by the mucociliary system, bacteria and viruses have a good environment for growth.
- Severe eustachian tube dysfunction occurs during 66% of upper respiratory infections (URIs) in school-aged children and in 75% of URIs in day care–aged children.

ETIOLOGY

- Nontypeable *Haemophilus influenzae*: 35–50%
- *Streptococcus pneumoniae*: 25–40%
- *Moraxella catarrhalis*: 5–10%
- Viruses: 40–75%
 - High rate of coinfection with bacteria
 - Without bacterial coinfection: 5–22%
- Group A *Streptococcus* (3%)
- *Staphylococcus aureus* (2%)
- Gram-negative organisms such as *Pseudomonas aeruginosa*: 1–2%
 - More common in neonatal AOM

DIAGNOSIS

HISTORY

- Recent abrupt onset of signs and symptoms of middle ear inflammation and MEE
- Ear pain for <48 hours
- New-onset otorrhea not caused by acute otitis externa
- Fever
- Irritability
- Past medical history, including underlying disorders (e.g., cleft palate, Down syndrome), immune deficiency, and previous history of otitis

media

- Recent treatment with antibiotics
- Exposure to large numbers of children (school, child care, large family)

PHYSICAL EXAM

- Look for other causes of fever and irritability in children: URIs, pharyngitis, lymphadenitis, meningitis, urinary tract infection, and bone and joint infections.
- Physical exam is best done with pneumatic otoscopy:
 - The patient should be adequately restrained if uncooperative.
 - Cerumen should be removed if view of tympanic membrane (TM) is inadequate.
 - Visualize TM at rest and with gentle positive and negative pressure via pneumatic otoscopy.
- The presence of an MEE is determined by the characteristics of the TM:
 - Contour: normal, retracted, full, or bulging; associated bulla(e)
 - Color: gray, pink, yellow, white, or red; hemorrhagic
 - Translucency: translucent or opaque
 - Mobility: normal, decreased, or absent
- Middle ear inflammation is indicated by the following:
 - Erythema of the TM
 - Otagia
- MEE is indicated by the following:
 - Bulging of the TM
 - Limited or absent mobility of the TM
 - Air–fluid level behind the TM
 - Otorrhea
- A diagnosis of AOM is suggested if an MEE is present along with ear pain, fever, erythema, fullness, or bulging of TM.
- The concomitant presence of conjunctivitis (otitis media–conjunctivitis syndrome) suggests the presence of *H. influenzae* or a virus as a causative organism.
- AOM should not be diagnosed when pneumatic otoscopy and/or tympanometry do not show MEE.

DIAGNOSTIC TESTS & INTERPRETATION

Diagnostic Procedures/Other

- Tympanometry
 - Easily performed by office personnel
 - Provides information on middle ear pressure and TM compliance
 - Sensitive in detecting MEE but poor positive predictive value
- Tympanocentesis
 - For episodes of AOM that are resistant to antibiotic therapy, tympanocentesis and culture and sensitivity of the middle ear fluid may help guide antibiotic therapy.
- Tympanocentesis or myringotomy may also be required as part of the treatment of suppurative complications.

DIFFERENTIAL DIAGNOSIS

- MEE: TM may appear dull with a diffuse light reflex, fluid bubbles may be visible, and mobility may be decreased.
- Otitis externa
- Auricular lesions like a furuncle or laceration
- Other causes of fever, including viral URIs, pharyngitis, pneumonia, meningitis, UTIs, and bone and joint infections
- Pharyngitis and dental pain may be mistaken for otalgia.

TREATMENT

MEDICATION

Note: AOM management should include pain evaluation and treatment.

- Antibiotic therapy for AOM in children ≥ 6 months of age with severe signs or symptoms (moderate or severe otalgia or otalgia of 48 hours or temperature $\geq 39^{\circ}\text{C}$ [102.2°F])
- Antibiotic therapy for bilateral AOM in children 6–23 months of age without severe signs or symptoms
- Antibiotic therapy or observation with close follow-up if joint decision-making with caregiver for unilateral AOM in children 6–23 months of age without severe signs or symptoms
 - Observation and follow-up and antibiotic therapy if child worsens

or fails to improve in 48–72 hours

- Initial treatment
 - Amoxicillin (80–90 mg/kg/24 h PO divided b.i.d.)
 - When child has not received amoxicillin in past 30 days
 - Does not have concurrent purulent conjunctivitis
 - Not allergic to penicillin
- Antibiotic treatment after 48–72 hours of no improvement
 - Amoxicillin-clavulanate (90 mg/kg/24 h amoxicillin and 12.8 mg/kg/24 h clavulanate PO divided b.i.d.)
 - Has received amoxicillin in the last 30 days
 - Concurrent purulent conjunctivitis
 - History of recurrent AOM unresponsive to amoxicillin
- Initial oral antibiotic treatment if penicillin allergy
 - Cefdinir (14 mg/kg/24 h QD or divided b.i.d.)
 - Cefuroxime (30 mg/kg/24 h divided b.i.d.)
 - Cefpodoxime (10 mg/kg/24 h divided b.i.d.)
 - Ceftriaxone (50 mg IM or IV per day for 1 or 3 days)
- Treatment after 48–72 hours of no improvement
 - Ceftriaxone (50 mg IM or IV per day for 1 or 3 days)
 - Clindamycin (30–40 mg/kg/24 h PO divided t.i.d.), with or without 3rd-generation cephalosporin

ADDITIONAL TREATMENT

General Measures

- Do not use prophylactic antibiotics to reduce frequency of episodes of AOM in children with recurrent AOM.
- Adjunctive therapy
 - Fever relief with acetaminophen or ibuprofen
 - Pain may be treated with acetaminophen, ibuprofen, or topical anesthetic drops.

ISSUES FOR REFERRAL

- Consider otolaryngology referral:
 - Tympanostomy tubes for recurrent AOM if
 - 3 episodes in 6 months
 - 4 episodes in 1 year with 1 episode in the preceding 6 months

- Persistent and/or recurrent otitis with abnormal hearing and/or speech

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Expect symptomatic improvement within 48–72 hours of treatment; may need to switch antibiotic and/or evaluate for complications
- Follow-up exam should be scheduled 3–4 weeks after completion of antibiotic therapy to ensure resolution of AOM.
- If effusion is present, follow up monthly. For persistent effusions of >3 months' duration, a hearing evaluation is recommended.

PROGNOSIS

- Symptoms of acute infection (fever and otalgia) are relieved within 48–72 hours in most patients.
- Treatment failures are more likely with increased severity of disease and younger age.
- Development of another infection within 30 days usually represents a recurrence caused by a different organism rather than a relapse.
 - Recurrences are frequent and more common in younger children and if initial episode is severe.
- 30–70% of treated children will have an effusion at 2 weeks.
 - MEE may persist for weeks to months.

COMPLICATIONS

- Hearing loss
 - Acute conductive hearing loss is common and usually resolves as the effusion resolves.
 - Fluid of long-standing duration may lead to permanent conductive hearing loss.
 - Sensorineural hearing loss may result from spread of infection into the labyrinth.
- TM perforation
- Chronic suppurative otitis media
- Tympanosclerosis

- Cholesteatoma
- Acute mastoiditis
- Petrositis
- Labyrinthitis
- Facial nerve paralysis
- Bacterial meningitis
- Epidural abscess
- Subdural empyema
- Brain abscess
- Lateral sinus thrombosis

- H65.199 Other acute nonsuppurative otitis media, unspecified ear
- H65.499 Other chronic nonsuppurative otitis media, unspecified ear

FAQ

- Q: When should children with AOM be treated?
- A: Antibiotic therapy for AOM in children ≥ 6 months of age with severe signs or symptoms. Antibiotic therapy for bilateral AOM in children 6–23 months of age without severe signs or symptoms
- Q: What is the antibiotic of choice for initial therapy of AOM?
- A: The initial therapy is amoxicillin. The antibiotic treatment after 48–72 hours of no improvement is amoxicillin-clavulanate.
- Q: What can be done to prevent the development of AOM in an individual child?
- A: Pneumococcal conjugate vaccine. Annual influenza vaccine. Encourage breastfeeding for at least 6 months. Encourage avoidance of tobacco smoke exposure.

PALLOR

David T. Teachey

BASICS

DESCRIPTION

- Pallor is defined as paleness of the skin and may be a reflection of anemia or poor peripheral perfusion.
- The normal range for hemoglobin is age dependent.
- Anemia can be defined functionally as the inability of hemoglobin to meet cellular oxygen demand.
- Parents often fail to notice pallor of gradual onset.
 - Grandparents or others who see the child less often may be the first to suspect pallor.

RISK FACTORS

- Ages between 6 months and 3 years or adolescent females
 - Peak age ranges for iron deficiency
- Gender
 - Some red cell–enzyme X-linked defects such as glucose-6-phosphate dehydrogenase (G6PD) and phosphoglycerate kinase deficiencies are sex linked.
- Race
 - African: hemoglobins S and C, α - and β -thalassemia trait, G6PD deficiency
 - Southeast Asian: hemoglobin E and α -thalassemia
 - Mediterranean descent: β -thalassemia and G6PD deficiency

Genetics

Familial history: Some of the congenital hemolytic anemias are autosomal dominant.

DIAGNOSIS

- Determine first that the child appears pale, not simply fair skinned.

Second, decide if there is a medical emergency associated with circulatory failure. If not, the goal is to investigate the etiology and intervene appropriately.

- Phase 1: Assess for signs of shock.
 - If present, initiate emergency procedures as required to stabilize the patient, such as airway, breathing, and circulation.
- Phase 2: If patient is stable, perform history, physical examination, and CBC with reticulocyte count to establish time of onset of pallor, associated symptoms, and level of anemia.
- Phase 3: Follow specific diagnostic workup based on findings in phase 2.

SIGNS AND SYMPTOMS

- Pallor
- Other signs and symptoms dependent on etiology

HISTORY

- Acute versus chronic onset
 - Helps with differential diagnosis
- Associated symptoms: weight loss, fever, night sweats, cough, and/or bone pain
 - Suggest an underlying systemic illness, such as leukemia, infection, or rheumatologic disorder
- Jaundice, scleral icterus, dark urine
 - Suggest hemolysis
- Age <6 months
 - May represent a congenital anemia or isoimmunization
- Premature infant
 - Increased risk of both iron and vitamin E deficiency
 - Exaggerated hyperbilirubinemia can be the presenting symptom of isoimmune hemolytic or other congenital hemolytic anemia.
- Pica
 - Often associated with plumbism and iron deficiency
- Medications
 - Can cause bone marrow suppression and/or hemolysis
- Milk intake

- Introduction of cow's milk at <12 months of age is associated with iron deficiency.
- Drinking a lot of cow's milk (>24 oz/day) puts a toddler at risk for iron deficiency.
- Recent trauma and/or surgery
 - Blood loss can result in iron deficiency.
- Recent infection
 - Can be associated with hemolysis or bone marrow suppression
 - Most common form of mild anemia in childhood
- Family history
 - Familial history of splenectomy and/or early cholecystectomy can be a clue for a previously undiagnosed hemolytic anemia.

PHYSICAL EXAM

- Rapid respiratory rate, decreased BP, weak pulses, slow capillary refill
 - Indications of uncompensated anemia and/or shock
- Frontal bossing and prominence of the malar and maxillary bones
 - Extramedullary erythropoiesis
- Enlarged spleen
 - Hemolytic anemias, malignancy, infection
- Glossitis
 - Vitamin B₁₂ deficiency
 - Iron deficiency
- Scleral icterus or jaundice
 - May indicate hemolysis
- Systolic flow murmur
 - Anemia
- Bruits
 - May indicate vascular malformations
- Petechiae and bruising
 - May indicate an associated thrombocytopenia, coagulopathy, or vasculitis
- Dysmorphic features
 - Diamond-Blackfan and Fanconi anemia are associated with other congenital defects, including thumb abnormalities, short stature, and congenital heart disease.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC with red cell indices
 - Establishes the diagnosis of anemia, distinguishes by size: normocytic, macrocytic, microcytic
- Reticulocyte count
 - Distinguishes between decreased production and increased destruction of red cells
- Coombs test and antibody screen
 - Identifies immune-mediated red cell destruction
 - Can have false positives and negatives
- Peripheral blood smear
 - Specific morphologic findings can be diagnostic.
- Iron studies: iron-binding capacity, serum iron, ferritin, transferrin
 - Iron deficiency anemia or anemia of chronic disease
- Hemoglobin electrophoresis with quantification
 - Hemoglobinopathy
- Lead studies: serum lead, free erythrocyte protoporphyrin
 - Plumbism
- Stool guaiac
 - Occult blood loss
- Osmotic fragility
 - Red cell membrane defects (spherocytosis)
 - Any spherocytic anemia may be positive.
- Quantitative red cell–enzyme assays
 - Inherited RBC enzyme deficiencies
- Serum folate, RBC folate, and serum vitamin B₁₂ levels
 - Deficiency

Diagnostic Procedures/Other

Bone marrow aspiration and biopsy: if malignancy or bone marrow failure syndrome suspected

DIFFERENTIAL DIAGNOSIS

- Congenital
 - Hemoglobinopathies: sickle cell syndromes, thalassemia

- syndromes, other unstable hemoglobins
- Erythrocyte membrane defects: hereditary spherocytosis, elliptocytosis, stomatocytosis, pyropoikilocytosis, infantile pyknocytosis
 - Erythrocyte enzyme defects: G6PD deficiency, pyruvate kinase deficiency
 - Diamond-Blackfan anemia: congenital pure red cell aplasia (rare)
 - Fanconi anemia: constellation of varied cytopenias, multiple congenital anomalies, abnormal bone marrow chromosomal fragility
- Infectious
 - Septic shock
 - Can get mild anemia after mild infections in childhood (anemia of inflammation)
 - Infection-related bone marrow suppression: parvovirus B19 infection
 - Infection-related hemolytic anemias: Epstein-Barr virus, influenza, coxsackievirus, varicella, cytomegalovirus, Escherichia coli, Pneumococcus species, Streptococcus species, Salmonella typhi, Mycoplasma species
 - Nutritional/toxic/drugs
 - Iron deficiency anemia: common cause of anemia in children, especially those <3 years of age and in female adolescents
 - Plumbism: anemia usually due to coexisting iron deficiency; very high lead levels associated with altered heme synthesis
 - Vitamin B₁₂ and/or folate deficiency: results in a megaloblastic anemia
 - Medication-induced bone marrow suppression: chemotherapy; antibiotics, especially trimethoprim-sulfamethoxazole
 - Drug-related hemolytic anemia: antibiotics, antiepileptics, azathioprine, isoniazid, nonsteroidal anti-inflammatory drugs
 - Trauma
 - Acute blood loss
 - Tumor
 - Leukemia with bone marrow infiltration
 - Metastatic tumors with bone marrow infiltration

- Genetic/metabolic
 - Metabolic derangements: severe electrolyte disturbance, pH disturbance, inborn errors
 - Shwachman-Diamond syndrome: marrow hypoplasia with associated pancreatic insufficiency and associated failure to thrive
- Other:
 - Transient erythroblastopenia of childhood: acquired pure RBC aplasia
 - Aplastic anemia: bone marrow failure syndrome with at least 2 of the 3 blood cell lines eventually affected
 - Systemic diseases: anemia of chronic disease, chronic renal disease, uremia
 - Hypothyroidism
 - Sideroblastic anemia: defective iron use within the developing erythrocytes
 - Autoimmune and isoimmune hemolytic anemias
 - Microangiopathic hemolytic anemias: thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome (HUS), disseminated intravascular coagulation (DIC)
 - Mechanical destruction: vascular malformation, abnormal or prosthetic cardiac valves

TREATMENT

INITIAL STABILIZATION

- Severe anemia of unclear etiology with hemodynamic instability
 - Transfuse with packed RBCs cautiously.
 - In an autoimmune hemolytic process, the child is at risk for a transfusion reaction, and there may be delay in obtaining cross-matched blood.
 - Obtain blood for diagnostic studies before transfusion if possible.
- Circulatory failure without anemia
 - Requires intensive monitoring and access to critical care in an emergency department or intensive care unit
 - Fluid resuscitation and/or inotropic pressor support as needed

- Acute blood loss
 - Treat circulatory failure as described.
 - Transfuse with packed RBCs, platelets, and fresh frozen plasma as needed.
- Malignancies
 - Emergency care should be directed toward treatment of circulatory failure and possible associated infection and then to rapid diagnosis and treatment of the malignancy.
 - Consultation with an oncologist should be sought as soon as possible.

GENERAL MEASURES

- Treat underlying cause.
- Consider packed RBC transfusion if in extremis or severe anemia and low likelihood of recovery in near future.
- Consider emergent plasmapheresis if with microangiopathic hemolytic anemia.
- Consider immunosuppressive medications (corticosteroids, intravenous immunoglobulin (IVIG) if with autoimmune hemolytic anemia.
- Iron deficiency anemia
 - Elemental iron

MEDICATION

Elemental iron for patients with iron deficiency

- 4–6 mg/kg/24 h PO divided b.i.d.–t.i.d.
- Absorbed best with acidic drinks, including orange juice; dairy products decrease absorption.
- Reticulocyte should improve 72 hours after starting iron therapy; the hemoglobin may take a week to rise.
- Iron should be continued for at least 3 months to replenish iron stores.

ONGOING CARE

ISSUES FOR REFERRAL

- Severe or unexplained anemia
- Anemias other than dietary iron deficiency or thalassemia trait

- Recurrent iron deficiency
 - May suggest ongoing bleeding or iron malabsorption
- All bone marrow failure or infiltrative processes

R23.1 Pallor

PANCREATIC PSEUDOCYST

Amit S. Grover • Menno Verhave

BASICS

- A pancreatic pseudocyst is a peripancreatic (or intrapancreatic) fluid collection associated with a history of pancreatitis, that is surrounded by a well-defined inflammatory wall, and that has no solid component.
 - The term “pseudocyst” is often incorrectly used to define various types of fluid collections associated with pancreatitis. As a result, medical literature on pseudocysts is not consistent in its descriptions or its findings.
 - An important distinction between “fluid collections” associated with pancreatitis is that some consist of fluid alone, whereas others arise from necrosis of pancreatic parenchyma and/or peripancreatic tissues. The latter type of fluid collection involves a solid component (with variable amounts of fluid), which distinguishes them from pseudocysts.
- Types of fluid collections:
 - Acute peripancreatic fluid collection (APFC)
 - ▢ A fluid collection that develops in the early phase of interstitial edematous acute (typically mild) pancreatitis
 - ▢ Lack a well-defined wall on CT scan
 - ▢ NOT associated with necrotizing pancreatitis
 - ▢ Remain sterile, and usually resolve without intervention
 - ▢ If APFC persists beyond 4 weeks, likely to develop into a pancreatic pseudocyst; although this is considered a rare outcome.
 - Pancreatic pseudocyst
 - ▢ Refers specifically to a peripancreatic (or less commonly, an intrapancreatic) fluid collection
 - ▢ Surrounded by a well-defined inflammatory wall and containing NO solid material
 - ▢ Pancreatic pseudocysts develop more than 4 weeks after the onset

- of interstitial pancreatitis.
- Acute necrotic collection (ANC)
 - ▢ A collection of BOTH variable amounts of fluid and solid (necrotic) material related to pancreatic and/or peripancreatic necrosis
 - ▢ Occur within the first 4 weeks of disease, and can resemble an APFC in the first few days of acute pancreatitis
 - ▢ As necrotizing pancreatitis develops and necrosis evolves, solid component become evident.
 - ▢ May be multiple and may involve the pancreatic parenchyma alone, the peripancreatic tissue alone, or most commonly both
 - ▢ May be infected or sterile
 - ▢ Generally associated with more severe sequelae of AP
 - Walled-off necrosis (WON)
 - ▢ Collection of varying amounts of liquid and solid material surrounded by a mature, enhancing wall of reactive tissue
 - ▢ Represents a mature, encapsulated ANC
 - ▢ Develops no earlier than 4 weeks after episode of necrotizing pancreatitis
 - ▢ May be multiple and present at sites distant from the pancreas
 - ▢ May be sterile or infected

PATHOPHYSIOLOGY

- Pseudocysts occur when there is disruption in the pancreatic ductular system, or its intrapancreatic branches, without any evidence of pancreatic or peripancreatic necrosis.
- This results in the extravasation of pancreatic enzymes evoking an inflammatory response.
- The inflammatory reaction leads to a fluid collection that is rich in pancreatic enzymes (APFC).
- If the duration of the fluid collection is >4 weeks, becomes localized (intrapaneareatic or extrapancreatic), and develops a fibrin capsule, it becomes a pseudocyst.
- A pseudocyst does not have a true epithelial lining.
- If there is communication between the pseudocyst and the pancreatic duct, the enzyme level in the fluid remain elevated; if there is no

communication, the enzyme level falls with time.

DIAGNOSIS

HISTORY

Acute or chronic pancreatitis

- Suspect pancreatic pseudocyst in patients recovering from acute pancreatitis, or in the patient with chronic pancreatitis, who has recurrent/persistent abdominal pain, a palpable abdominal mass, or persistently elevated serum pancreatic enzymes.

PHYSICAL EXAM

- Abdominal tenderness
- Abdominal mass
- Nausea and vomiting
- Weight loss
- Jaundice
- Abdominal distention
 - Mass/ascites
- In many situations, no clinical signs are seen.
- Clinical signs may be secondary to complications:
 - Jaundice in hepatobiliary obstruction
 - Lower limb edema in compression of inferior vena cava
 - Ascites in peritonitis
 - Pleural effusion

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Serum pancreatic enzyme levels:

- Persistently elevated enzymes in blood can be a clue, but is not an absolute indicator.
- Elevated enzymes in fluid drained from a peripancreatic or intrapancreatic fluid collection with no solid component is consistent with a pancreatic pseudocyst.

Imaging

- CT scan
 - Reveals pseudopancreatic cyst; can also be used to gauge size of pseudocyst and its relationship to adjacent organs
- Ultrasonography
 - Visualizes pancreatic pseudocysts
 - Can be used to follow cyst size over time
- Endoscopic ultrasonography (EUS)
 - Common modality in adult patients and increasingly used in pediatrics
 - Can be used to diagnose presence and size of pseudocyst; can also be used to guide peroral fluid aspiration and drainage
- Endoscopic retrograde cholangiopancreatography (ERCP)
 - Used in some cases to delineate the pancreatic ductular system before drainage to distinguish ductal stenosis, disruption, stones, and other obstructions

DIFFERENTIAL DIAGNOSIS

- Congenital/genetic
 - Congenital cysts
 - Polycystic disease
 - Von Hippel-Lindau disease
 - Cystic fibrosis
- Infections
 - Pancreatic abscess
 - Echinococcal (hydatid) cyst
 - Taenia solium cyst
- Tumor
 - Serous cystadenoma
 - Mucinous cystadenoma
 - Cystic islet cell tumors
 - Teratoma
 - Pancreatoblastoma
 - Cystadenocarcinoma
 - Franz tumor
 - Angiomatous cystic neoplasms
 - Lymphangiomas

- Hemangioendothelioma
- Miscellaneous:
 - Splenic cyst
 - Adrenal cyst
 - Enterogenous cyst
 - Duplication cysts
 - Endometriosis

TREATMENT

GENERAL MEASURES

- Medical management:
 - Most cases resolve with supportive care.
 - If eating precipitates pain, short-term nasojejunal feedings or parenteral nutrition may be warranted.
 - Follow up with ultrasound or CT scan to make sure there are no complications.
 - >60% have complete resolution by the end of 1 year.
 - Usually, no medications are used for managing pseudocysts.
 - Somatostatin analogue (octreotide) has been reported to be used to decrease fluid collection along with drainage.
 - Antibiotics are used in situations of infected pseudocyst.
- Drainage
 - Most often used in the setting of WON
 - Indications: infection, rupture with cardiopulmonary compromise, biliary and gastric outlet obstruction, persistent symptoms, rapid enlargement, failure of large pseudocysts (>6 cm) to shrink after 6 weeks
 - Modalities:
 - ▣ Percutaneous drainage (aspiration or catheter drainage) is done in cases in which the pseudocyst has a less mature wall.
 - ▣ Percutaneous aspiration has a high recurrence rate of 63% and failure rate of 54%.
 - ▣ Continuous drainage has a recurrence rate of 8% and a failure rate of 19%.

- Endoscopic procedures are becoming the 1st-line drainage modality, as they are less invasive than surgery.
- Endoscopic procedures include transmural cystoenterostomies and transpapillary route procedures such as stent placement for pseudocysts that communicate with the main pancreatic duct.
- Endoscopic procedures in experienced hands report success rates of 82–89%, complication rates of 10–20%, and recurrence rates of 6–18%.

SURGERY/OTHER PROCEDURES

- Reserved for failed endoscopic procedures, difficult to access areas of WON and multiple WONs
- Includes internal drainage (cystogastrostomy, cystoduodenostomy, and Roux-en-Y cystojejunostomy), resection, and external drainage
- Success rate is 85–90%.
- Recurrence rate is 0–17%.
- Mortality rate is between 3 and 5%.

ONGOING CARE

PROGNOSIS

Majority of pseudocysts resolve without intervention.

COMPLICATIONS

- Perforation/rupture
 - Cardiopulmonary compromise secondary to pleural effusion and ascites
 - Peritonitis and ascites, which can be fatal
- Hemorrhage
 - Erosions of vessels lining the cyst cause intracystic bleeding and rapid increase in the cyst size.
 - Bleeding may occur directly into stomach, duodenum (clinically manifesting as GI bleeding), or peritoneal cavity.
- Obstruction
 - Biliary obstruction: jaundice
 - Portal obstruction: portal hypertension

- Gastric outlet obstruction
- Inferior vena cava obstruction: peripheral edema
- Urinary obstruction
- Colonic obstruction
- Infection of pseudocysts is rare in children compared to adults:
 - Associated with high mortality rate for children and adults
 - Management usually requires surgical drainage.

CODES

ICD10

K86.3 Pseudocyst of pancreas

PANCREATITIS

Amit S. Grover • Menno Verhave

BASICS

DESCRIPTION

- Inflammation within the pancreas characterized by 3 phases: early trypsin activation within acinar cells; followed by surrounding intrapancreatic inflammation; and finally, extrapancreatic inflammation with systemic inflammatory responses
- Classified into acute and chronic
 - Acute pancreatitis (AP)
 - Variable presentation, however, most often characterized by acute onset of abdominal pain, nausea, and vomiting with elevation of pancreatic enzymes
 - Nonverbal children may present with irritability; infants may present with lethargy and fever.
 - Often self-limited, with reversible changes, but can progress if not appropriately managed
 - Severe AP is rare in children; however, a high suspicion should always be maintained, as severe disease can progress rapidly and result in significant morbidity and mortality.
 - Chronic pancreatitis (CP)
 - Characterized by irreversible morphologic changes and fibrotic replacement of the pancreatic parenchyma
 - Clinically characterized by recurrent abdominal pain or evidence of exocrine and/or endocrine insufficiency
 - Often the result of a persistent and continued pancreatic inflammation secondary to acute attacks

ETIOLOGY

- Biliary tract disease
 - Gallstones
- Medications
 - L-asparaginase, azathioprine/6-MP, mesalamine, sulfonamides,

thiazides, furosemide, tetracyclines, valproic acid, corticosteroids, estrogens, procainamide, ethacrynic acid, and others

- Toxins
 - Alcohol, organophosphates, scorpion poison, snake poison
- Trauma
 - Bicycle handle injuries
 - Motor vehicle collisions
 - Child abuse
 - Postoperative
 - ▢ Endoscopic retrograde cholangiopancreatography (ERCP)
- Systemic disease
 - Shock/hypoxemia/SEPSIS
 - Inflammatory bowel disease (IBD)
 - Cystic fibrosis
- Idiopathic
- Less common
 - Infections
 - ▢ Bacterial: typhoid, mycoplasma
 - ▢ Viral: measles, mumps, Epstein-Barr virus, coxsackie B, rubella, influenza, echovirus, hepatitis A and B
 - ▢ Parasites: *Ascaris lumbricoides*, *Echinococcus granulosus*, *Cryptosporidium parvum*, *Plasmodium falciparum*
 - Metabolic diseases:
 - ▢ Hyperlipidemia
 - ▢ Hypercalcemia
 - ▢ Diabetic ketoacidosis
 - ▢ Uremia
 - ▢ Inborn errors of metabolism
 - Systemic diseases:
 - ▢ Hemolytic uremic syndrome
 - ▢ Celiac disease
 - ▢ Diabetes mellitus
 - ▢ Vasculitis: systemic lupus erythematosus (SLE), Henoch-Schönlein purpura, Kawasaki disease
- Rare causes:

- Autoimmune pancreatitis: Rare condition divided into 2 subtypes.
 - Type I often grouped with IgG4-related disease and systemic manifestations.
 - Type II does not have IgG4 association, however, is more common in younger patients and associated with IBD.
- Congenital anomalies:
 - Pancreatic divisum
 - Annular pancreas
 - Anomalous pancreaticobiliary junction
 - Biliary tract malformations
 - Duplication cyst of the duodenum/gastropancreatic/common bile duct

DIAGNOSIS

HISTORY

- Pain
 - Onset, location, and severity can be variable in children.
 - Aggravated by food intake
 - Nonverbal patients (i.e., younger age, developmental delay) may present with increased irritability.
- Vomiting
 - May or may not always be present
 - May be bilious
 - May present as feeding intolerance
- Trauma
 - Even trivial abdominal trauma should be a red flag.
 - Evaluate for evidence of child abuse.
- Family history
 - Hereditary pancreatitis
 - Hypertriglyceridemia (I, IV, or V)
 - CFTR mutations/FH of CF
- Prior history of, or risk factors for, cholelithiasis
- Toxic exposures (i.e., EtOH, pesticides)
- Review of systems:

- Associated fever may suggest infectious etiology.
- Diminished urine output raises concern for third-space losses.
- Shortness of breath raises concern for pulmonary involvement (i.e., effusions).

PHYSICAL EXAM

- General exam
 - Growth parameters (weight and height), vital signs, capillary refill, pulse oximetry, pallor, jaundice, edema, and clubbing
 - Abnormal vital signs (heart rate, respiratory rate, and blood pressure) can be indicative of the systemic inflammatory response syndrome (SIRS), a poor prognostic sign.
 - Clubbing can be an indicator of cystic fibrosis.
- GI
 - Mouth: Presence of aphthous lesions raises possibility of Crohn disease.
 - Inspection: abdominal distention or flank fullness (ascites or pseudopancreatic cyst); bluish discoloration of the flanks (Grey Turner sign) and periumbilical region (Cullen sign) in hemorrhagic pancreatitis
 - Palpation: for liver, gall bladder, spleen, and masses. Patients will have guarding, tenderness, and rebound tenderness, especially in the epigastric region and/or upper abdomen; palpable mass could be a pancreatic pseudocyst.
 - Percussion: dullness and fluid thrill consistent with ascites
 - Auscultation: bowel sounds decreased in ascites or absent in paralytic ileus
- Rectal exam
 - Perianal region for skin tags, fistulas, abscesses, or healed scars, which could be indicative of IBD; perirectal exam for mass, melena, or occult blood
 - Hematochezia can be suggestive of IBD.
- GU
 - Assess urinary output.
 - High specific gravity suggestive of reduced intravascular volume, result of third-space losses

- Respiratory system
 - Pleural effusion and acute respiratory distress syndrome (ARDS)
 - Diffuse respiratory findings could be indicative of cystic fibrosis.
- CNS
 - Stupor or coma

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
 - Hemoglobin may be decreased in hemorrhagic pancreatitis.
 - Leukocytosis may be present in infectious pancreatitis.
 - Hemoconcentration: elevated HCT
- Basic metabolic panel
 - Hemoconcentration due to third-space losses and intravascular depletion (elevated BUN, Cr)
 - Calcium may be elevated (etiology) or decreased (sequelae).
 - Glucose may be transiently elevated.
 - Bicarbonate may be low secondary to acidosis.
- Liver function tests:
 - Elevated transaminase levels suggest biliary cause.
 - Elevated bilirubin level/GGTP/Alk Phos suggestive of gallstone pancreatitis
- Amylase level
 - 3-fold elevation of amylase levels increases specificity for the diagnosis of pancreatitis.
 - Starts rising 2–12 hours after the insult and remains elevated for 3–5 days
 - Degree of elevation does not have any correlation to the severity or the course of the illness.
 - Other causes of elevated amylase levels include bowel obstruction, acute appendicitis, biliary obstruction, salivary duct obstruction, diabetic ketoacidosis, cystic fibrosis, pneumonia, salpingitis, ruptured ectopic pregnancy, ovarian cyst, cerebral trauma, burns, renal failure, and macroamylasemia.
- Lipase level

- Lipase levels are more specific than amylase for the diagnosis of pancreatitis.
- Starts rising 4–8 hours after the insult and remains elevated for 8–14 days
- 3-fold increase in the level is very sensitive and specific for pancreatitis.
- Levels do not correlate with severity or with clinical outcome.
- Other causes of elevated lipase levels include intestinal perforation, intestinal obstruction, appendicitis, mesenteric infarction, cholecystitis, diabetic ketoacidosis, renal failure, and macrolipasemia.
- Urinalysis
 - Urine specific gravity is a simple indicator of intravascular volume.
 - Elevated value can suggest third-space losses, a harbinger for severe disease.

Imaging

- Abdominal x-rays:
 - Sentinel loop: distended small intestinal loop near the pancreas
 - Colon cutoff sign: absence of gas shadow in the colon distal to the transverse colon
 - Multiple fluid levels in paralytic ileus
 - Calcification or stones in pancreas or gallbladder
 - Diffuse haziness: ascites
- Chest x-ray
 - Pleural effusion or ARDS
 - Diaphragmatic involvement
- US abdomen
 - Best initial test
 - Will demonstrate pancreatic size; echogenicity; associated fat stranding; ductal diameter/disruption; and calcifications, cholelithiasis, CBD dilation, ascites, and free fluid within abdomen
 - Limited by obesity and bowel gas
 - Endoscopic US (EUS) is more useful than the transabdominal US study but is difficult in children; used if pancreatic biopsy is indicated

- CT scan
 - May be used if history of trauma to look at extent of injury to pancreas and other intra-abdominal structures
 - Best to show evidence of pancreatic necrosis with AP from any cause, however, not sensitive within the first 48 hours
 - Reveals pathology in the pancreaticobiliary system in most instances
 - Involves exposure to radiation
- Magnetic resonance cholangiopancreatography (MRCP)
 - Good for ductal visualization (especially if secretin stimulated)
 - Can reveal anatomic abnormalities/obstructive lesions, that is, pancreatic divisum
 - Can mitigate need for ERCP, unless there is concern for choledocholithiasis +/- ascending cholangitis
 - Good for distinguishing pseudocyst versus walled-off necrosis
 - No exposure to radiation
- ERCP
 - Indicated in persistent/CP for delineation of pancreatic ducts and for therapeutic interventions (i.e., sphincterotomy or stent placement)
 - Risk of post-ERCP pancreatitis in 10–20% of cases
 - In adults, administration of rectal indomethacin has been shown to reduce this risk.

TREATMENT

FLUID RESUSCITATION

- Aggressive volume resuscitation with isotonic solutions is the cornerstone of therapy for AP.
- Under-resuscitation is associated with increased risk of mortality from AP.
- Targeted approach involving bolus (20 mL/kg), followed by continuous infusion at 1.5–2× maintenance (contraindicated if presence of fluid-sensitive cardiac disease) with serial monitoring q6–8h

MEDICATION

- Antibiotics
 - No evidence to support the routine use of antibiotics in patients with acute necrotizing pancreatitis unless:
 - Sepsis is suspected.
 - An extrapancreatic infection (bacteremia, pneumonia, UTI) is present.
 - Patient is on chemotherapy and/or is neutropenic.
- Pain management
 - Effective analgesia should be a priority.
 - Combination of intermittent IV narcotics +/- PCA

ADDITIONAL TREATMENT

Nutrition

- Initially, patient should remain NPO for pancreatic rest.
- New evidence suggests early feeding may not be beneficial.
- Postpyloric feeds can be considered if initial trial of enteral feeding fails.
- If prolonged NPO course and failure of postpyloric feeds, consider parenteral nutrition.

SURGERY/OTHER PROCEDURES

- If gallstone impaction with choledocholithiasis, should consider ERCP + sphincterotomy + stent
- Severe third-spacing can lead to abdominal compartment syndrome, necessitating surgical decompression.
- Development of walled-off necrosis with persistent pain may benefit from necrocytectomy (endoscopic or surgical).

ONGOING CARE

PROGNOSIS

AP is usually a self-limiting disorder in children.

COMPLICATIONS

- Pancreatic edema
- Peripancreatic fat necrosis

- Acute pancreatic fluid collections
- Pancreatic necrosis
- Pancreatic pseudocyst or walled-off necrosis
- Pancreatic ductal strictures
- Pancreatic ductal dilatation
- Systemic complications:
 - Shock and multiorgan failure
- GI and hepatobiliary
 - Paralytic ileus
 - Ascites, peritonitis
 - Stress ulcer
 - Intestinal hemorrhage
 - Portal vein thrombosis/splenic vein thrombosis/obstruction
 - Bile duct obstruction
- Pulmonary
 - Atelectasis, pleural effusion, pneumonitis, ARDS
- Cardiovascular
 - Hypotension/circulatory collapse
 - Pericarditis/pericardial effusion
 - EKG changes
- Sudden death

- K85.8 Other acute pancreatitis

PANHYPOPITUITARISM

Craig A. Alter • Stacy E. Dodt

BASICS

DESCRIPTION

Technically, “panhypopituitarism” (pan meaning “all”) requires deficiency of all 8 pituitary hormones; however, the term generally is used for deficiencies of >1 pituitary hormone.

EPIDEMIOLOGY

- Congenital forms affect both sexes equally and are diagnosed early in childhood.
- The epidemiology of acquired or secondary forms depends on the underlying cause.

RISK FACTORS

Genetics

Most cases are not thought to be genetic; however, there are rare autosomal recessive, autosomal dominant, and X-linked forms.

PATHOPHYSIOLOGY

- Pathology is based on specific deficiency or deficiencies.
- Growth hormone (GH): hypoglycemia in newborns and poor growth in patients older than 6–12 months
- Adrenocorticotrophic hormone: hypocortisolism
- Thyroid-stimulating hormone (TSH): hypothyroidism
- Luteinizing hormone (LH)/follicle-stimulating hormone (FSH): hypogonadism
- Antidiuretic hormone: diabetes insipidus
- Prolactin: Hyperprolactinemia can accompany hypothalamic causes of hypopituitarism.

ETIOLOGY

- Idiopathic (some may be due to hypophysitis, [inflammation of the pituitary gland])

- Congenital
 - Absence of the pituitary (empty sella syndrome is a risk)
 - Pituitary malformations (ectopic posterior pituitary, hypoplastic infundibular stalk, hypoplastic pituitary)
 - Genetic disorders due to mutations in genes or transcription factors (POUF1, HESX1, LHX3, LHX4, OTX2, SOX2, SOX3, PTX2, PROP1, etc.)
 - Familial panhypopituitarism
 - Rathke cleft cyst
- Acquired
 - Birth trauma or perinatal insult
 - Surgical resection of the gland or damage to the stalk
 - Traumatic brain injury
 - Hypophysitis
 - Iron deposition secondary to chronic transfusion therapy (e.g., β -thalassemia)
- Infection
 - Viral encephalitis
 - Bacterial or fungal infection
 - Tuberculosis
- Vascular
 - Pituitary infarction
 - Pituitary aneurysm
- Cranial irradiation
- Tumors:
 - Craniopharyngioma
 - Germinoma
 - Glioma
 - Pinealoma
 - Primitive neuroectodermal tumor (medulloblastoma)
- Histiocytosis
- Sarcoidosis

COMMONLY ASSOCIATED CONDITIONS

- Midline defects such as cleft lip/palate, hypotelorism, single central maxillary incisor

- Septo-optic dysplasia (de Morsier syndrome)
- Holoprosencephaly

DIAGNOSIS

HISTORY

- Birth history
 - Infants with hypopituitarism are usually normal or small for gestational age, in contrast to hyperinsulinemic infants, who are typically large for gestational age.
 - Documented or symptoms of hypoglycemia, which include poor feeding, lethargy, irritability, or seizures
 - Prolonged hyperbilirubinemia: may be first sign of hypothyroidism and/or hypopituitarism
- Complications during pregnancy or delivery:
 - Birth trauma may be associated with pituitary injury.
 - Breech delivery or vacuum extraction has been associated.
- History of surgeries and previous diseases: Congenital hypopituitarism is often associated with midline facial defects, such as a single central incisor, bifid uvula, or cleft palate, which require repair.
- Growth pattern: Plot previous lengths/heights and look for growth pattern. GH deficiency usually manifests as poor linear growth by the end of the 1st year of life.
- Delayed puberty
 - Children with delayed puberty show further growth failure in adolescence.
 - Sense of smell should be assessed to rule out Kallmann syndrome (isolated central hypogonadism and anosmia).
- Increased thirst and urination: Children with hypothalamic disorders may present with symptoms of diabetes insipidus.
- Complaints of headache and/or a visual defect: can be symptoms of a brain tumor. Focal neurologic symptoms are highly suggestive of CNS pathology.

PHYSICAL EXAM

- Height and weight
 - Patients with panhypopituitarism have normal to small size in the newborn period.
 - May have poor linear growth after 6–12 months of life
- Micropenis in male newborns: Neonatal penis should be ≥ 2.5 cm in length; micropenis suggests gonadotropin and/or GH deficiency.
- Delayed puberty if no breast development by 13 years of age in girls, and no testicular enlargement by 14 years of age in boys.
- May have other anatomic midline defects
- Physical exam pearls:
 - Penile and testicular size: Measure stretched phallic length (from pubic ramus to glans) with patient lying supine and phallus at 90 degrees to the body; use Prader beads to assess testicular volume.
 - Midline defects: Palpate for submucosal cleft palate and look for single central incisor.
 - Visual field testing: Visual field defects suggest a brain tumor.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Liver function tests (LFTs): LFTs in newborns with congenital hypopituitarism are often elevated and accompanied by conjugated hyperbilirubinemia, as opposed to simple congenital hypothyroidism, in which unconjugated hyperbilirubinemia exists.
- Thyroid function tests: Total and free T_4 will be low, but TSH may be low, normal, or elevated.
- Serum insulin-like growth factor-1 (IGF-1) and insulin-like growth factor-binding protein-3 (IGFBP-3): may be low, but normal growth factors do not exclude GH deficiency in children with brain tumors. IGF-1 may be low due to poor nutrition.
- GH stimulation tests: should be performed by a pediatric endocrinologist
- Basal serum cortisol: Draw at 8 a.m. in children with a normal diurnal rhythm.
- Cortrosyn stimulation test: more helpful in the diagnosis of primary adrenal insufficiency than secondary (adrenocorticotrophic hormone) or tertiary (corticotropin-releasing hormone) deficiency

- Metyrapone or corticotropin-releasing hormone stimulation test
 - Tests for adrenocorticotrophic hormone or corticotropin-releasing hormone deficiency
 - Must be performed by a pediatric endocrinologist
- Estradiol, testosterone, ultrasensitive LH and FSH: Measure concentrations in first 6 months of life and again after age 11 years. Best measured in the morning
- Water deprivation test
 - Definitive test for antidiuretic hormone deficiency (diabetes insipidus)
 - Should be performed by a pediatric endocrinologist
- Comments on testing:
 - Measurement of water intake and urine output over 24 hours at home can help diagnosis of diabetes insipidus.
 - Baseline serum tests (prolactin, 8-a.m. cortisol, T₄, free T₄, IGF-1, IGFBP-3, serum and urine osmolality, testosterone, estradiol, ultrasensitive LH and FSH) can all be done in a nonfasting state.
 - Stimulation tests must be performed by a pediatric endocrinologist.

Imaging

- Bone age: typically significantly delayed in GH deficiency and/or hypothyroidism
- MRI with contrast of brain with fine cuts through the hypothalamus and pituitary
 - Look for tumors, but also size of pituitary, infundibulum, and presence of normal “bright spot” in posterior pituitary.
 - Absence of the “bright spot” is highly associated with central diabetes insipidus of any etiology, although can be present in normal infants.
 - Ectopic pituitary consistent with GH deficiency and other anterior pituitary deficiencies.

ALERT

- If adrenocorticotrophic hormone deficient, stress dosing of glucocorticoids is necessary.
- Replacing thyroid hormone in a child with untreated adrenal

insufficiency can precipitate adrenal crisis.

- A patient with diabetes insipidus who does not have an intact thirst mechanism and access to free water is at high risk for acute hypernatremia.

DIFFERENTIAL DIAGNOSIS

- Hyperinsulinism (HI) in newborns
- Isolated hormone deficiency, such as GH deficiency in newborns
- Constitutional growth delay

TREATMENT

MEDICATION

- Recombinant human GH (rhGH) by SC injection daily: 0.15–0.3 mg/kg/week
- Desmopressin acetate (DDAVP): available in oral and intranasal formulations. Rarely given subcutaneously. Dose is variable.
 - Acute hypernatremia may be managed with DDAVP, IV vasopressin, or fluids alone.
 - Some infants with diabetes insipidus can be managed initially with thiazide diuretics.
- Estrogen/testosterone: started at puberty at low doses and slowly increased over ~2 years to mimic endogenous secretion of sex steroids
 - Infants with micropenis may be given monthly testosterone for 3 doses to aid penile enlargement.
- Estrogen given as topical or oral forms to girls, whereas testosterone initially given as injection to boys every month
- Levothyroxine PO: 25–200 mcg daily, based on weight, age, and free T₄ levels
- TSH levels may not be useful in monitoring therapy for central hypothyroidism, even after treatment is initiated.
- Hydrocortisone
 - Replacement doses if needed: 8–15 mg/m²/24 h PO, divided b.i.d. or t.i.d.
 - In stress circumstances such as fever, severe illness, vomiting, or

surgery, doses increased to 50–100 mg/m²/24 h PO.

- If dosed IV, provide a loading dose of 50–100 mg/m² IM or IV followed by 50–100 mg/m²/24 h divided q4h; oral stress doses should be divided q8h.
- To calculate hydrocortisone dose, estimate body surface area (BSA) using a nomogram or the following formula: $BSA (m^2) = \text{square root of } (\text{height [cm]} \times \text{weight [kg]}/3,600)$.
- Duration: long-term therapy: monitored by a pediatric endocrinologist
 - rhGH: in children and adolescents: until growth velocity drops to 2.5 cm/year; puberty is complete.
 - GH-deficient adults may benefit from lifelong rhGH because of the GH impact on body composition, lipid profile, and cardiac function.
 - Patient should again undergo GH provocative testing of rhGH therapy to determine if adult treatment is necessary.
 - DDAVP: for life, as needed to control symptoms of polyuria/polydipsia
 - Sex steroids: Begin around age 12 years; may be continued for lifetime
 - Levothyroxine for life
 - Hydrocortisone: replacement dose based on individual's need; stress dose coverage for life

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Initially, every 3 months by a pediatric endocrinologist
- When pituitary hormones are replaced, expect the following:
 - GH: immediate resolution of hypoglycemia; and improved growth velocity within 3–6 months
 - T₄ levels should normalize within 4–6 weeks.
 - Side effects of GH therapy: headache, vision problems, seizures, changes in activity level, limp, knee or hip pain

PROGNOSIS

- For congenital forms, the prognosis is excellent with endocrine

replacement.

- Diabetes insipidus in infants can be challenging to manage.
- For secondary forms, the overall prognosis depends on the primary disease.

COMPLICATIONS

- Hypoglycemia in the newborn period
- Short stature
- Adrenal crisis
- Dehydration/hyponatremia

ALERT

- rhGH therapy can be associated with idiopathic intracranial hypertension (pseudotumor cerebri).
- rhGH deficiency/therapy can also be associated with slipped capital femoral epiphysis (SCFE). Carefully evaluate any limp or knee, or hip pain in patients on rhGH therapy. SCFE mandates orthopedic consultation.
- Diagnosis of panhypopituitarism must be considered in patients with hypoglycemic seizures.
- The family and the patient must understand the importance of taking stress doses of steroid appropriately (e.g., with surgery, vomiting, or febrile illnesses).
- 20% of normal children will fail a single GH provocative test.
- TSH levels are generally not helpful when evaluating pituitary/hypothalamic causes of hypothyroidism. The unbound free T_4 level (by equilibrium dialysis) is the most useful test both to establish the diagnosis and to monitor L-thyroxine replacement therapy.

E23.0 Hypopituitarism

FAQ

- Q: When do I give stress doses of steroid, and for how long?
- A: Whenever the patient has fever, vomiting, serious illness, or surgery. Continue until 24 hours after stress resolves (e.g., the day after fever breaks or vomiting stops).
- Q: Is it acceptable to replace thyroid hormone while the evaluation of other pituitary hormones is pending?
- A: You must ensure the patient is adrenally sufficient; if not, glucocorticoids must be initiated prior to thyroid hormone replacement.
- Q: Do all state newborn screens detect central hypothyroidism?
- A: No. Many states initially screen for elevated TSH levels.

PARVOVIRUS B19 (ERYTHEMA INFECTIOSUM, FIFTH DISEASE)

Julia Shaklee Sammons

BASICS

DESCRIPTION

Parvovirus B19 (B19) is a small, single-stranded DNA virus of the family Parvoviridae. There are three major genetic variants (1–3). B19 is a common infection in humans, most often associated with the childhood exanthem, erythema infectiosum, or fifth disease.

EPIDEMIOLOGY

- B19 infections are ubiquitous worldwide, occurring most often in school-aged children.
- Humans are the only hosts.
- Incubation period is 4–14 days but can be as long as 21 days.
- Modes of transmission
 - Contact with respiratory secretions
 - Percutaneous exposure to blood or blood products (1,011 virions/mm of serum in patients with hereditary hemolytic anemias)
 - Vertical transmission from mother to fetus

Incidence

Attack rates: 15–60% of susceptibles (i.e., seronegative) will become infected upon exposure.

Prevalence

- Seroprevalence of B19 IgG antibodies
 - >5 years old: 2–9%
 - 5–18 years old: 15–35%
 - Adults: 30–60%
 - Elderly: 90%

GENERAL PREVENTION

- B19 transmission can be decreased through routine infection control

practices, including hand hygiene and appropriate disposal of contaminated facial tissues.

- For hospitalized children with suspected aplastic crisis, immunocompromised patients with chronic infection and anemia, and patients with papular purpuric gloves and socks syndrome secondary to B19, droplet precautions in addition to standard precautions are recommended.
- No additional preventive measures are needed for normal hosts with rash.
- Due to the potential risks to the fetus from B19 infections, pregnant health care workers should adhere to strict infection control procedures and avoid contact with immunocompromised hosts with B19 infection or those with aplastic crisis.
- Due to high prevalence of B19 in the community, routine exclusion of pregnant women from the workplace where B19 infections are suspected (e.g., schools, day care) is not recommended.

PATHOPHYSIOLOGY

- Parvovirus B19 inhibits erythropoiesis by lytically infecting RBC precursors in the bone marrow.
- It is associated with a number of clinical manifestations, ranging from benign to severe.

COMMONLY ASSOCIATED CONDITIONS

- Erythema infectiosum, or fifth disease, is the most common form of infection caused by B19 and occurs in up to 35% of school-aged children.
- Asymptomatic infection may occur in ~20% of children and adults.
- Transient aplastic crisis secondary to B19 infection may cause severe anemia in patients with hereditary hemolytic anemias or any condition that shortens the RBC lifespan, such as sickle cell disease or spherocytosis.
- Polyarthropathy syndrome (symmetric joint pain and swelling, typically of the hands, knees, and feet) is seen in up to 80% of adults, especially women. Arthralgias and arthritis occur infrequently in children. When present, arthritis in children most often involves the

knees.

- Hydrops fetalis may develop after maternal B19 infection with intrauterine involvement (typically within the first 20 weeks of pregnancy).
- Chronic anemia/pure red cell aplasia due to persistent B19 infection has been reported in immunocompromised patients.
- Papular purpuric gloves and socks syndrome (PPGSS) consists of painful and pruritic papules, petechiae, and purpura localized to the hands and feet and is often associated with fever.
- B19 is one of the most common viruses identified in cases of myocarditis, although its role in pathogenesis is unclear.
- Reports of neurologic manifestations (including meningitis, encephalitis, and peripheral neuropathy), hemophagocytic syndrome, hepatitis, and Henoch-Schönlein purpura have also been associated with B19 infection.

DIAGNOSIS

Diagnosis depends on recognition of typical symptoms and the results of laboratory testing.

HISTORY

- Erythema infectiosum (fifth disease)
 - Characterized by an erythematous facial rash with a distinctive “slapped cheek” appearance, often accompanied by circumoral pallor
 - A symmetric, macular, often lace-like rash occurs on the trunk, spreading outward to the rest of the body and extremities. The rash is often pruritic and may intensify with exposure to sunlight, heat, or exercise. It occasionally involves the palms and soles. Rarely, the rash can be papular, vesicular, or purpuric. It may last for ~7 days, but can persist >20 days.
 - A brief, mild prodrome of systemic symptoms, including headache, sore throat, myalgias, and low-grade fevers, often precedes the appearance of rash by 7–10 days.

- The child is usually well-appearing and remains active and playful.
- Aplastic crisis
 - Prodromal symptoms in B19-infected children with sickle cell disease or other hereditary hemolytic anemias are nonspecific and consist of fever, malaise, and headache. Rash is usually absent.
 - Symptoms are usually self-limited, lasting 7–10 days.
 - Severe anemia, CHF, stroke, and acute splenic sequestration have also been associated.
- Chronic anemia/pure red cell aplasia
 - In immunocompromised patients, B19 infection may persist for months, leading to chronic anemia with B19 viremia.
 - Low-grade fever and neutropenia may accompany anemia.

PHYSICAL EXAM

Fifth disease

- An erythematous facial rash with a “slapped cheek” appearance, often associated with circumoral pallor
- Truncal, macular, lacy-appearing rash spreading to the arms, buttocks, and thighs
 - Often pruritic and may become more intense with exercise or heat exposure
- Occasionally can be found on the palms and soles, and rarely can be papular, vesicular, or purpuric

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- There is no practical in vitro system for isolation or culture of the virus.
- Antibodies
 - Detection of parvovirus B19-specific IgM or IgG antibodies as determined by EIA or radioimmunoassay
 - The presence of B19-specific IgM antibodies is diagnostic in patients with symptoms of erythema infectiosum or aplastic crisis. IgM- and IgG-specific antibodies are detected in 90% of such patients by 3–7 days of illness.
 - B19-specific IgG antibodies persist for life, whereas specific IgM antibodies begin to decrease 30–60 days after onset of illness.

- Polymerase chain reaction (PCR) techniques
 - B19 DNA can be detected by PCR in serum for up to 9 months following the initial viremic phase. B19 DNA has also been shown to persist in solid tissues following primary infection, even in healthy individuals. Thus, identification of B19 DNA does not necessarily signify acute infection.
 - Immunocompromised patients with chronic marrow suppression may be unable to produce B19-specific IgG or IgM antibodies. In such cases, PCR for B19 viral DNA is the diagnostic method of choice.
 - PCR may also be used to detect virus in the fetus.
- Hematocrit and reticulocyte count in patients with aplastic crisis
 - Laboratory studies reveal reticulocytopenia, usually with counts of <1%. During the illness, the patient's hematocrit may fall as low as 15%.

DIFFERENTIAL DIAGNOSIS

B19 infection should be considered in all patients with arthritis or viral exanthems with a consistent history and exam.

TREATMENT

GENERAL MEASURES

- There is no specific antiviral therapy for B19 infection.
- Most patients require supportive care only. However, transfusions may be required for treatment of severe anemia in patients with aplastic crisis.
- IV immunoglobulin (IVIG) therapy has been given with some success to patients with chronic marrow suppression secondary to B19 infection.
- The mainstay of treatment for an infected fetus is delivery, but intrauterine transfusions may be lifesaving.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

Expected course of illness

- The rash of erythema infectiosum in a child or adult may last up to 20 days. It may, at times, fade and/or intensify, depending on sunlight exposure, exercise, or body surface temperature changes (e.g., bathing).
- During aplastic crisis secondary to B19, the reticulocyte count usually remains low (often <1%) for ~8 days before spontaneous recovery.

PROGNOSIS

- The prognosis is quite good for all manifestations of B19 infections.
- Most patients recover spontaneously and require only supportive care.

COMPLICATIONS

- Parvovirus B19 during pregnancy
 - 30–50% of pregnant women are susceptible to B19 infection.
 - Fetal loss, intrauterine growth retardation, or hydrops fetalis may result from maternal infection with B19 during pregnancy. Fetal death occurs in 2–6% of cases.
 - B19 has not been proven to cause congenital anomalies.
 - The greatest risk for B19 infection affecting the fetus exists in the first 20 weeks of gestation.
 - The risk of fetal death after exposure, if antibody status is unknown, is <1.5%.
 - There is no indication for elective abortion in cases of maternal infection.
- Arthritis/arthropathy
 - Although most cases of polyarthritis resolve within 2 weeks, persistent symptoms for months to even years (rarely) have been reported.

CODES

ICD10

B08.3 Erythema infectiosum [fifth disease]

FAQ

- Q: When may children with B19 infection return to school?
- A: Children are contagious only during the prodromal phase of illness, which is often unrecognized. Once the rash appears, they are no longer infectious and may return to school or day care.
- Q: What can be done to reduce risk of fetal infection?
- A: Because B19 infections during pregnancy may result in fetal death, and B19 infections often occur in community outbreaks, fetal risks following maternal exposure to persons with recognized B19 infection are a frequent concern. Risk to the fetus appears to be greatest if the infection occurs prior to the 20th week of gestation. Among pregnant women of unknown antibody status, the risk of fetal death after exposure to B19 is estimated to be <1.5%. Routine exclusion of pregnant women from the workplace when B19 infection is suspected is not recommended. However, pregnant teachers who are at risk for infection may consider a leave of absence during community outbreaks of B19.

PATENT DUCTUS ARTERIOSUS

Alexander Lowenthal

BASICS

DESCRIPTION

- Patent ductus arteriosus (PDA) is the persistence into postnatal life of the normal fetal vascular conduit between the central pulmonary and systemic arterial systems. Normally, the ductus arteriosus (DA) functionally closes within the first 1–3 days of life. Structural closure is usually completed by the 3rd week of life. If the DA remains patent beyond 3 months of life, it is considered abnormal and is unlikely to close spontaneously (spontaneous closure rate 0.6% per year).
- In the infant with a normal left aortic arch, the DA connects the main pulmonary artery (MPA) at the origin of the left pulmonary artery to the descending aorta, distal to the origin of the left subclavian artery.
- Many variations can occur, although they are less common. The main, proximal right, or proximal left pulmonary artery may be connected to virtually any location on the aortic arch or proximal portions of the brachiocephalic vessels.
- 5 distinct clinical conditions are associated with PDA:
 - Isolated cardiovascular lesion in premature infants
 - Isolated cardiovascular lesion in otherwise healthy term infants and children
 - Incidental finding associated with more significant structural cardiovascular defects
 - Compensatory structure in cases of neonatal pulmonary hypertension without congenital heart disease (CHD)
 - Critical compensatory structure in some cyanotic or left-sided obstructed lesions

EPIDEMIOLOGY

- As an isolated defect, PDA is the 6th most common congenital cardiovascular lesion.
 - Represents 5% of all types of CHD

- 1 per 2,000 live births
- If “silent” PDA are included, the rate may be as high as 1:500 live births.
- Female-to-male ratio: 2:1

RISK FACTORS

- Prematurity
 - Increases with the degree of prematurity (50–80% in preterm infants <26 weeks’ gestation)
 - 60–70% of preterm infants of <28 weeks’ gestation receive medical or surgical therapy for a PDA.
- Incidence of PDA varies significantly depending on environmental factors (altitude), management style (e.g., amount of maintenance fluid prescribed, surfactant administration), and presence of coexisting diseases (e.g., respiratory distress syndrome, hypoxemia, fluid overload, necrotizing enterocolitis, sepsis, hypocalcemia).
- Higher rate of PDA in babies with trisomy 21, Wolf-Hirschhorn syndrome (4p deletion), Char syndrome, Carpenter syndrome, Holt-Oram syndrome, and incontinentia pigmenti

PATHOPHYSIOLOGY

- The PDA is derived from the distal portion of the left 6th embryonic arch, connecting the left pulmonary artery to the descending aorta.
 - The PDA is formed by the 8th week of fetal life.
 - It is necessary for fetal circulation throughout the remainder of gestation.
- Fetal blood flows from the MPA to the DA to the aorta, thus bypassing the pulmonary vascular bed and supplying systemic blood flow. With the 1st postnatal breaths, the pulmonary vascular resistance falls abruptly, the DA constricts, and pulmonary blood flow is directed into the lungs.
- With a PDA, excessive blood flow will continue from the aorta into the pulmonary artery, causing increased pulmonary blood flow and volume overloading of the left side of the heart.
- In premature infants and term infants with pulmonary hypertension, delayed closure represents an impaired developmental process,

whereas in the healthy full-term infant, PDA probably reflects an anatomic abnormality of the ductal tissue.

ETIOLOGY

- Prematurity
- Rubella infection in the 1st trimester
- Genetic or familial factors
- High altitude
- Idiopathic

DIAGNOSIS

HISTORY

- Premature infants
 - Variable: ranging from asymptomatic to complete cardiovascular collapse
 - Increased ventilatory support, pulmonary hemorrhage, respiratory or metabolic acidosis from low cardiac output, and excessive pulmonary blood flow
 - Tachypnea, feeding intolerance, apnea, bradycardia, necrotizing enterocolitis, and decreased urine output
- Infants and older children
 - Small PDA: usually asymptomatic, with incidental heart murmur found on routine exam
 - Moderate PDA: possible congestive heart failure (CHF), poor feeding, and poor weight gain
 - Large PDA: symptoms as above and recurrent respiratory infections

PHYSICAL EXAM

- Premature infants
 - Tachypnea, rales, tachycardia ($\pm S_3$ gallop)
 - Hyperdynamic precordium and bounding pulses with wide pulse pressure (due to diastolic “runoff” from the aorta to the pulmonary artery)
 - The typical PDA murmur in a premature infant is a pansystolic murmur audible at the left upper or midsternal border.

- With a large PDA and equalization of pressure between the MPA and the aorta, no murmur may be heard.
- Hepatomegaly may exist with heart failure (late sign).
- Infants and older children: Findings vary with size of shunt.
 - Small PDA
 - ▢ Pansystolic murmur may be heard at the 2nd left intercostal space.
 - ▢ Murmur becomes continuous (i.e., extends into diastole), as the pulmonary vascular resistance decreases over the 1st months of life.
 - Moderate or large PDA
 - ▢ The murmur is louder, has a harsh quality, and acquires a machine-like quality often being heard posteriorly. In that case, a systolic thrill may be felt at the left upper sternal border.
 - ▢ Tachycardia, bounding pulses with a wide pulse pressure, and a mid-diastolic low-frequency rumbling murmur may be audible at the apex with a large PDA.
 - ▢ With severe left ventricular failure the classic PDA signs may disappear, but there will be findings consistent with CHF (tachycardia, S₃ gallop at the apex, hepatomegaly, tachypnea, rales).
 - ▢ In extreme cases, pulmonary hypertension may occur, with the murmur shortening, the diastolic component disappearing, and S₂ becoming accentuated. At advanced stages of irreversible pulmonary vascular disease, cyanosis begins to appear, often more pronounced in the lower limbs, with reversal of shunting.

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

- ECG
 - Usually normal with a small PDA
 - Left atrial enlargement and left ventricular hypertrophy with moderate and large PDA
 - Biventricular hypertrophy in later stages
- Chest x-ray
 - Usually normal with a small PDA, although prominence of main

and peripheral pulmonary arteries may be seen

- In moderate and large PDAs, these findings become more pronounced, along with an enlarged heart. Increased pulmonary vascular markings are proportionate to the left-to-right shunt. Pulmonary edema can be seen if CHF develops. In premature infants with respiratory distress syndrome, there is evidence of deteriorating lung disease with unclear cardiac borders.
- Echocardiogram
 - Delineates the PDA and assesses the size of the left atrium and the left ventricle
 - Doppler techniques assess the ductal flow pattern and may be useful for estimating the pulmonary artery pressure.
- Cardiac catheterization
 - Most often not essential for diagnosis
 - Indicated for suspected concomitant pulmonary hypertension
 - Can be performed for treatment via transcatheter closure techniques

DIFFERENTIAL DIAGNOSIS

- Aortopulmonary window
- Systemic or pulmonary arteriovenous communications
- Ruptured sinus of Valsalva
- Coronary artery fistula
- Truncus arteriosus
- Aortic insufficiency
- Innocent venous hum in older children
- Pulmonary atresia with collaterals
- Ventricular septal defect with aortic regurgitation
- Ventricular septal defect in infancy

TREATMENT

GENERAL MEASURES

- Premature infant
 - Supportive treatment (careful use of oxygen, respiratory assistance, correction of metabolic acidosis)

- Management of CHF with fluid restriction and diuretics
- If PDA persists or patient is symptomatic, closure of PDA is indicated.
- Medical closure: Indomethacin is most often used; ibuprofen is as effective.
 - Contraindications to medical management include renal failure (creatinine >1.8 mg/dL), thrombocytopenia (platelets <100,000), and associated conditions (necrotizing enterocolitis, intraventricular hemorrhage).
- Surgical closure is indicated if medical treatment fails or use of indomethacin is contraindicated.
- Infants and older children
 - Medical management of CHF with digoxin, diuretics, and afterload reduction
 - PDA is no longer a stated indication for subacute bacterial endocarditis (SBE) prophylaxis, but clinical practice may vary.
 - Spontaneous closure rate is low, and closure with indomethacin is not usually effective in this group of patients.
 - Closure is indicated whenever a symptomatic or hemodynamically significant PDA exists.
 - For asymptomatic audible PDA, closure can be performed electively and is primarily performed to reduce the risk of endocarditis. Recommendations for closure of an asymptomatic, incidentally found (“silent” ductus) PDA are not standard.
 - Most infants and children can have a PDA safely and effectively closed during cardiac catheterization, obviating the need for a surgical procedure.

SURGERY/OTHER PROCEDURES

Surgical closure of PDA can be achieved by 1 of 3 techniques:

- Open surgical ligation and division: mostly in premature infants
- Video-assisted thoracoscopic ligation: depends on the institution
- Transcatheter occlusion with coils or other devices

ONGOING CARE

PROGNOSIS

- Outcome in treated premature infants is generally good but depends mostly on the degree of prematurity and the presence of associated conditions.
- Outcome in term infants and older children is excellent if no complications have occurred.
- PDA among adults may be associated with significant mortality with or without surgery.
- After closure of PDA, no endocarditis prophylaxis is needed if complete obliteration of flow is achieved. Most cardiologists continue prophylaxis for 6 months after the procedure that closed the PDA if closed by a coil or device.

COMPLICATIONS

- Pulmonary edema and CHF
- Pulmonary hemorrhage
- Pulmonary vascular obstructive disease
- Increased chronic lung disease
- Failure to thrive
- Recurrent respiratory infections
- Lobar emphysema or collapse
- Infective endarteritis
- Thromboembolism of cerebral arteries
- Aneurysm of the ductus
- Intracranial hemorrhage
- Necrotizing enterocolitis
- Renal dysfunction

Q25.0 Patent ductus arteriosus

PELVIC INFLAMMATORY DISEASE

Krishna K. Upadhyia • Maria E. Trent

BASICS

DESCRIPTION

- Pelvic inflammatory disease (PID) refers to a spectrum of upper female genital tract inflammatory disorders, including endometritis, salpingitis, tubo-ovarian abscess (TOA), and peritonitis.
- Definitive diagnosis of PID can be made by laparoscopy; however, diagnosis is usually made based on clinical findings.
- Centers for Disease Control (CDC) guidelines state that empiric PID therapy should be initiated in sexually active young women with pelvic or lower abdominal pain, if no other cause for the illness can be identified and the patient has the following:
 - Uterine tenderness, OR
 - Adnexal tenderness, OR
 - Cervical motion tenderness
- Additional criteria enhance the specificity of the diagnosis of PID, but are not required for the diagnosis:
 - Oral temperature $>38.3^{\circ}\text{C}$ (101°F)
 - Abnormal cervical or vaginal discharge
 - Abundant WBCs on a wet mount of vaginal secretions
 - Elevated ESR or CRP
 - Laboratory-documented evidence of infection with *Neisseria gonorrhoeae* or *Chlamydia trachomatis*
- Definitive diagnostic criteria:
 - Histopathologic evidence of endometritis on endometrial biopsy
 - Transvaginal sonography or MRI showing thickened fluid-filled tubes with or without free pelvic fluid or TOA
 - Laparoscopic abnormalities consistent with PID

EPIDEMIOLOGY

- There are an estimated 750,000 cases of PID annually in the United States.

- In 2011, there were 90,000 initial visits to physician offices for PID:
 - Visits for PID declined between 2002 and 2011.
 - Increased screening and treatment of chlamydia likely led to this decline.
- Cases of PID are disproportionately higher among adolescent girls and racial minorities

RISK FACTORS

- Factors that increase PID risk include the following:
 - Multiple sexual partners
 - Intercourse with a partner who has multiple sexual partners
 - Prior history of sexually transmitted infection (STI) or PID
 - Intercourse without condoms
 - Douching
 - Recent (within past 20 days) insertion of intrauterine device (IUD)
- Cases of PID are highest among the following:
 - Sexually active adolescents and young women younger than age 25 years
 - Women in communities with high prevalence of gonorrhea and chlamydia
 - Patients presenting to STD clinics

GENERAL PREVENTION

- Consistent condom use
- Regular STI screening
- Partner screening for STIs
- Limit number of sexual partners.
- Avoid douching.

PATHOPHYSIOLOGY

- Ascending infection spreading from vagina/cervix to upper genital tract by the following:
 - Migration
 - Sperm transport
 - Refluxed menstrual blood flow
- Up to 75% of cases occur within 7 days of menses.

ETIOLOGY

- Polymicrobial origin
- Many cases are associated with *N. gonorrhoeae* (GC) and *C. trachomatis* (CT).
- *Mycoplasma genitalium* and *Ureaplasma urealyticum* have been associated with laparoscopic PID and infertility.
- Other vaginal, enteric, and respiratory flora associated with PID include the following:
 - *Gardnerella vaginalis*, *Escherichia coli*, *Bacteroides* species, *Haemophilus influenzae*, group B–D streptococci, *Streptococcus pneumoniae*, and group A *Streptococcus*.

DIAGNOSIS

ALERT

- Clinical criteria for PID are designed to have high sensitivity because the consequences for untreated PID are significant.
- If PID is suspected based on clinical presentation and examination, treatment should be initiated prior to results of other supportive testing.

HISTORY

- Should be taken from the patient in a private interview:
 - Confidentiality policies should be reviewed with the patient in advance of history.
- Abdominal or pelvic pain is a common presenting complaint:
 - “Classic” presentation of shuffling gait or “chandelier sign” is rare.
- Some cases may be mild with relatively few symptoms:
 - Subclinical or “silent” PID can result in infertility and chronic pelvic pain.
- Other presenting symptoms may include the following:
 - Vaginal discharge
 - Abnormal vaginal bleeding
 - Dyspareunia
 - Dysuria
 - Right upper quadrant pain

- Complete history should be taken including past medical, gynecologic, gastrointestinal, and urinary history
- Sexual history should be elicited in a sensitive manner; and should include number of partners, new partners, condom use, contraceptive method use, history of sexual assault.

PHYSICAL EXAM

- Evaluate the patient for signs of general discomfort.
- Review vital signs for fever, tachycardia.
- Careful abdominal exam to evaluate for tenderness, rebound, or guarding
 - Evaluate right upper quadrant for tenderness associated with perihepatitis.
- Pelvic exam is essential to PID diagnosis and must be performed for any sexually active female with abdominal pain or genital complaints.
- External genital exam should assess for external lesions, inguinal adenopathy.
- Speculum exam should note vaginal discharge or lesions, signs of cervical friability or discharge.
 - Collect vaginal swabs for pH and wet prep.
 - Collect cervical swabs for STI testing.
 - Collect swab for Gram stain if materials and equipment available.
- Bimanual exam to evaluate for cervical motion tenderness, uterine tenderness, and adnexal tenderness or fullness.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Urine β -hCG
- Vaginal pH (pH >4.5 is abnormal)
- Wet mount and KOH (>10 WBC/HPF is suggestive of infection)
- Nucleic acid amplification test for GC, CT, and *Trichomonas vaginalis*
 - If the patient reports sexual assault or abuse at the time of evaluation, bacterial cultures should also be obtained.
- Urinalysis and culture
- Consider collecting CBC, CRP to support the diagnosis.
- Testing for other STIs including HIV and syphilis should also be done.

Imaging

- In patients with adnexal fullness or other signs suggestive of TOA, obtain transvaginal ultrasound.
- Signs of PID on imaging include the following:
 - Thickened or fluid-filled fallopian tubes
 - Free pelvic fluid
 - Tubo-ovarian abscess

Diagnostic Procedures/Other

- Laparoscopy
- Endometrial biopsy
- These tests can provide definitive evidence of PID, but are not routinely used.

DIFFERENTIAL DIAGNOSIS

- Pelvic pain may be the presenting complaint for a variety of disease processes.
- Gynecologic
 - Ectopic pregnancy
 - Intrauterine pregnancy
 - Endometriosis
 - Hemorrhagic ovarian cyst
 - Ovarian cyst
 - Ovarian tumor
 - Ovarian torsion
 - Tubal torsion
 - Septic abortion
 - Vaginal foreign body
 - Hematometocolpos
 - Chemical irritants
- Urinary
 - Urinary tract infection
 - Acute pyelonephritis
- Gastrointestinal
 - Acute appendicitis
 - Acute cholecystitis

- Heme/vascular
 - Pelvic thrombophlebitis
- Other:
 - Functional abdominal pain
 - Sexual assault
 - Sexual abuse

TREATMENT

ALERT

- All CDC-recommended treatment regimens for PID require 14-day treatment duration.
- Fluoroquinolones not recommended for PID treatment because of GC resistance

MEDICATION

Parenteral treatment regimens:

- Regimen A:
 - Cefotetan 2 g IV every 12 h OR cefoxitin 2 g IV every 6 h PLUS
 - Doxycycline 100 mg PO b.i.d. × 14 days
 - May add metronidazole 500 mg PO b.i.d. × 14 days for severe cases or suspected anaerobes
- Regimen B:
 - Clindamycin 900 mg IV every 8 hours PLUS
 - Gentamicin loading dose IV or IM (2 mg/kg), followed by a maintenance dose (1.5 mg/kg) every 8 hours OR
 - Gentamicin 3–5 mg/kg every 24 hours
 - After 24 hours or clinical improvement, can switch to oral doxycycline 100 mg PO b.i.d. or clindamycin 450 mg PO q.i.d. to complete 14 days of total therapy
- Alternative regimen:
 - Ampicillin/sulbactam 3 g (ampicillin) IV q6h PLUS
 - Doxycycline 100 mg PO b.i.d. × 14 days

Oral treatment regimens:

- Regimen A:

- Ceftriaxone 250 mg IM (single dose) PLUS
- Doxycycline 100 mg PO b.i.d. × 14 days
- May add metronidazole 500 mg PO b.i.d. × 14 days
- Regimen B:
 - Cefoxitin 2 g IM (single dose) PLUS
 - Probenecid 1 g PO (single dose) PLUS
 - Doxycycline 100 mg PO b.i.d. × 14 days
 - May add metronidazole 500 mg PO b.i.d. × 14 days
- Alternate regimen:
 - Other parenteral 3rd-generation cephalosporin PLUS
 - Doxycycline 100 mg PO b.i.d. × 14 days
 - May add metronidazole 500 mg PO b.i.d. × 14 days

ADDITIONAL TREATMENT

General Measures

- Criteria for hospitalization:
 - Surgical emergency
 - Pregnancy
 - Lack of response to outpatient therapy
 - Inability to tolerate or follow outpatient regimen
 - Severe illness (e.g., fever, nausea/vomiting)
 - Suspected or confirmed TOA
- Strong consideration of hospitalization should be given for early and middle adolescents who may require additional supports for optimal management.
- Patients should be counseled to:
 - Abstain from intercourse for at least 14 days.
 - Notify their partners for STI testing and treatment.
 - Use condoms consistently and correctly.
 - Limit number of sexual partners.
 - Consider contraception if not currently using and not desiring pregnancy.
 - Return if worsening symptoms or not able to tolerate the prescribed treatment.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- All patients diagnosed with PID should have follow-up within 72 hours to assess the following:
 - Treatment tolerance/adherence
 - Symptom improvement
- If patients are not improving additional evaluation may be necessary including the following:
 - Bimanual examination
 - Pelvic imaging
 - Hospitalization
- Return for repeat STI testing in 3 months.

PROGNOSIS

- Dependent on treatment adherence and number of episodes of PID
- Women with documented GC or CT infection have higher rates of reinfection within 6 months of treatment.
- Each additional episode of PID increases risk of infertility and chronic pelvic pain.

COMPLICATIONS

- Short-term
 - Perihepatitis (in 15% of patients)
 - Periappendicitis
- Long-term
 - Ectopic pregnancy
 - Infertility (10–15% of cases of PID)
 - Chronic pelvic pain

- N70.93 Salpingitis and oophoritis, unspecified

FAQ

- Q: My patient has negative testing for GC and CT, should I have her discontinue the medications if she has clinically improved?
- A: No. PID is a polymicrobial infection and the patient's improvement is likely secondary to broad-spectrum antibiotic treatment. The patient should continue antibiotics as prescribed.
- Q: My patient has problems with adherence, could I use directly observed doses of azithromycin in the office?
- A: Although use of azithromycin is not considered a standard and/or recommended therapy by the CDC, one RCT in Brazil successfully used ceftriaxone 250 mg and azithromycin 1 g at baseline and then repeated the dose in 1 week. Although patients had good results, this has not been replicated and the CDC currently recommends that metronidazole 500 mg b.i.d. be administered with azithromycin to improve anaerobic coverage.
- Q: My patient is 6 weeks pregnant. Can she really have PID?
- A: PID is less common during pregnancy given the bactericidal

protection afforded by the cervical mucous plug. However, it is possible for sperm to transport bacteria into the uterus during fertilization, infection to occur in the interim between implantation and full establishment of the mucous plug, and early loss of the mucous plug later in pregnancy. Caution should be used in caring for pregnant patients with PID because fetal wastage can occur due to infection. As such, the CDC recommends that these women be hospitalized for initial treatment.

PENILE AND FORESKIN PROBLEMS

Benjamin M. Whittam • Mark P. Cain • Richard C. Rink

BASICS

DESCRIPTION

Penile problems:

- Buried penis
 - Hidden or concealed penis, poor skin fixation at the penoscrotal/penopubic junction resulting in buried or hidden appearance
 - Buried penis may be normal in obese children with large suprapubic fat pad.
- Penile curvature (chordee)
 - Bending of the penis with erection, can be lateral, ventral (most common), or dorsal curve
 - Chordee is usually associated with abnormal foreskin
- Webbed penis
 - Penoscrotal webbing or poor separation of penile skin from scrotum, obscuring penoscrotal angle
- Balanitis
 - Inflammation of the glans
 - Probably overdiagnosed owing to physiologic drainage of smegma or urea dermatitis from failure to retract foreskin during voiding in toilet-trained boys
 - When infections present, there can be significant cellulitis of the penis, edema, and fever.
 - Most commonly caused by gram-positive organisms. Yeast is another causative organism.

Foreskin problems:

- Balanoposthitis
 - Inflammation of glans and prepuce
 - Seen in 4% of uncircumcised boys age 2–5 years
 - See balanitis.

- Phimosis/penile adhesions
 - Physiologic attachment of prepuce to glans, which it protects and gradually separates to allow retraction of the foreskin
 - Ring of fibrotic scar tissue that prevents the foreskin from being retracted
- Paraphimosis
 - When narrow prepuce is retracted behind the glans, constricting penile shaft causing glanular and foreskin edema and preventing replacement of prepuce over glans

Postcircumcision problems:

- Penile adhesions
 - Attachments of the foreskin back to the glans after circumcision
 - Penile skin bridges are dense scar adhesions that cannot be separated.
- Meatal stenosis
 - Urethral meatus narrowing
 - Significant meatal narrowing will produce an upwardly deflected urine stream, which is narrow and strong. In severe cases, straining, and prolonged voiding
- Epidermal inclusion cysts
 - Small, enlarging white lesions growing subcutaneously along the scar from circumcision

RISK FACTORS

Genetics

Epidermal inclusion cysts may occur from congenital rests of skin cells buried during development, but these are rare and occur along the median raphe of the penis or scrotum.

GENERAL PREVENTION

Some penile and foreskin problems may be prevented with proper hygiene and education of the caretakers.

ETIOLOGY

- Buried/webbed penis
 - Scrotal attachments attending along ventral penile surface to varying degrees

- Penis tethered by abnormal attachments of dartos tissue
- Penile curvature (chordee)
 - Asymmetry in tunica albuginea of corporal bodies and compliance of corpora cavernosa
- Balanoposthitis/balanitis
 - Unclear etiology: possible infection, mechanical trauma, contact irritation, and contact allergies
- Phimosis
 - Probably results from recurrent bouts of irritation of the foreskin from improper hygiene habits such as voiding through the foreskin or repetitive forceful retraction
- Penile adhesions
 - Physiologic adhesions: The prepuce has adhered down to the glans after circumcision.
 - Surgical adhesions (skin bridges): Adherence between the scar of the circumcision and the glans due to healing of the crushed tissue where the foreskin was removed and the glans
- Meatal stenosis
 - Narrowing of the urethral meatus secondary to recurrent irritation of the meatus, likely from rubbing against moist diapers. Occurs almost exclusively in circumcised boys
- Epidermal inclusion cysts
 - Caused by small islands of epithelium buried beneath the skin surface that progressively accumulate desquamated skin cells

DIAGNOSIS

HISTORY

- Issues with newborn circumcision
- Ability to retract foreskin
- Retraction of foreskin in uncircumcised males during voiding
- Penis straight with erection
- Character of urinary stream
- Ballooning of the foreskin with voiding
- Straining to void

- Presence of fever
- Penile discharge
- In older boys, inquire about sexual activity.

PHYSICAL EXAM

- Circumcised males
 - Size and position of meatus
 - Redundancy of preputial skin
 - Presence of adhesions to the glans and whether they involve the scar line between the shaft skin and the inner preputial skin
 - Lesions or erythema of glans or shaft
 - Watch patient void if meatal stenosis is suspected, usually upward deviated stream.
- Uncircumcised males
 - Ability to retract foreskin with gentle retraction
 - Presence of phimotic ring
 - Lesions or erythema of prepuce

ALERT

- Do not try to forcefully retract the foreskin in an infant or young child. It can take 3–5 years before the foreskin can be retracted.
- Do not circumcise infants with a buried or webbed penis, asymmetric foreskin, or those with a significantly deviated penile raphe.
- Never circumcise an infant with an abnormally located meatus (hypospadias, epispadias).
- Always replace the foreskin back over the glans after retraction (for cleaning, voiding, or examination) to prevent paraphimosis.
- Paraphimosis is an emergency. The sooner it is diagnosed, the easier it is to treat and reduce without surgery.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- In cases of balanitis with drainage, cultures may be taken by spreading foreskin (with hemostat) and sending drainage for culture.
- If urethral discharge is present, culture for gonorrhea and chlamydia in an adolescent male.

TREATMENT

MEDICATION

Balanitis/balanoposthitis

- If child is afebrile, oral antibiotics such as a 1st-generation cephalosporin would be the 1st line of treatment.
- If the child develops fever or there is progression of cellulitis, then treatment with IV antibiotics (cefazolin, clindamycin)

ADDITIONAL TREATMENT

General Measures

- Phimosis
 - Physiologic: no need for intervention
 - Good hygiene practices should be encouraged such as pulling the foreskin back to expose the meatus when voiding and not voiding through the foreskin. The foreskin should always be placed back over the glans after voiding (or any retraction) to prevent paraphimosis.
 - Pamphlets or Web sites that explain the care of the penis for uncircumcised males are helpful to give to the parents.
 - If there is a fibrotic ring of scar tissue preventing the retraction of the foreskin, a trial of betamethasone cream 0.05–0.01% applied to the foreskin t.i.d. for 4–6 weeks with daily gentle retraction may soften the scar tissue enough to resolve the phimosis. According to Orsola et al, use small amounts of cream only in the constrictive ring and do not use occlusive dressings.
 - In cases where conservative measures fail, a circumcision may be indicated.
- Penile adhesions
 - Physiologic: Practices in the past have included separation using anesthetic cream (EMLA). If there is redundancy of the foreskin or a prominent suprapubic fat pad that can tend to hide the penis in infants, adhesions often recur or require constant application of barrier creams or ointments to the penis and manual retraction of the redundant foreskin by the parents to prevent recurrence:

- In many cases, no treatment is necessary, as the adhesions will break down over a period of years.
 - If there are extensive adhesions with significant redundancy of foreskin, consideration should be given to revision of the circumcision if the adhesions are to be treated.
- Surgical (skin bridges)
 - These are due to scar tissue formation between the raw cut edge where the foreskin was removed and the glans.
 - As this represents true scarring and not two epithelial surfaces stuck together, the surfaces cannot be simply pulled apart like physiologic adhesions. They will not resolve with time, and if left in place, with growth, penile skin will be transferred to the glans, resulting in discoloration, especially in patients with darker skin tones.
 - These adhesions need sharp division either in the office with EMLA cream anesthesia or under general anesthesia if they are extensive.
- Meatal stenosis
 - When the narrowing at the meatus is producing an upwardly deflected, narrow stream (which can make aiming into the toilet difficult) or is causing straining and prolonged voiding, treatment is indicated.
 - A meatotomy can be done in the office using EMLA anesthesia or as an outpatient surgical procedure.
- Epidermal inclusion cysts
 - These subcutaneous islands of skin cells will progressively enlarge over time.
 - Complete excision is generally curative.
- Balanitis
 - When the inflammation and irritation seem to be from chronic dampness and exposure to urine, treat with barrier creams or ointments.
 - Keeping the area clean and dry will help prevent future episodes.
 - If there are small whitish plaques (not smegma), associated with redness, yeast may be present and an antifungal cream such as 1%

clotrimazole can be used to help speed the healing.

- Antibiotics as necessary (see “[Medication](#)”)
- In cases where there is purulent drainage and cellulitis of the penis, which can often be rapidly spreading over 24 hours, treatment with antibiotics is recommended.
- Genital infections of this nature should be taken quite seriously, and if treatment as an outpatient is attempted, close follow-up (return visit in 24–48 hours) is prudent.

ONGOING CARE

PATIENT EDUCATION

- It is important that all parents of uncircumcised boys teach them proper hygiene habits during toilet training.
- Guidance for parents:
 - Do not forcibly retract the foreskin.
 - Gently clean with warm water during baths and dry after.
 - Retract the skin when voiding in toilet-trained boys.
 - Always place the foreskin back over glans after voiding or retraction of foreskin.

CODES

ICD10

- **Q55.64 Hidden penis**

- Q54.4 Congenital chordee
- Q55.69 Other congenital malformation of penis

FAQ

- Q: The foreskin is stuck down to my son's penis. Does that mean he needs another circumcision?
- A: Not necessarily. If there is minor redundancy and a small physiologic adhesion, then no treatment is needed.
- Q: My uncircumcised son had some thick white drainage from his foreskin. Is that from an infection?
- A: Probably not. The thick white material is probably shed skin cells, which have been slowly separating the foreskin from the glans, this is also known as smegma (Greek for soap).

PERICARDITIS

Meryl S. Cohen

BASICS

DESCRIPTION

Inflammation of the pericardium, usually resulting in the accumulation of fluid in the pericardial space between the visceral (serosal tissue intimately related to the myocardium) and parietal (fibrosal layer composed of elastic fibers and collagen) pericardium. Pericarditis may be serous, fibrinous, purulent, hemorrhagic, or chylous.

EPIDEMIOLOGY

- Infectious pericarditis is more frequently seen in children younger than 13 years of age, with predominance in children younger than 2 years of age.
- Postpericardiotomy syndrome occurs in ~5–10% of children following uncomplicated cardiac surgery, particularly when the atrium has been entered.

PATHOPHYSIOLOGY

- Fine deposits of fibrin develop next to the great vessels, leading to altered function of the membranes of the pericardium, including changes in oncotic and hydrostatic pressure with subsequent accumulation of fluid in the pericardial space.
- Effusion is defined as excessive pericardial contents secondary to inflammation, hemorrhage, exudates, air, or pus.
- In postpericardiotomy syndrome, there appears to be a nonspecific hypersensitivity reaction to the direct surgical entrance into the pericardial space.

ETIOLOGY

- Infectious
 - Viral: coxsackievirus, echovirus, mumps, varicella, Epstein-Barr, adenovirus, influenza, human immunodeficiency virus

- Bacterial: Streptococcus, pneumococcus, Staphylococcus, meningococcus, Mycoplasma, tularemia, Haemophilus influenzae type B, Pseudomonas aeruginosa, Listeria monocytogenes, Pasteurella multocida, Escherichia coli
- Tuberculosis, atypical mycobacterium
- Fungal: candidiasis, histoplasmosis, actinomycosis
- Parasitic: toxoplasmosis, echinococcus, Entamoeba histolytica, Rickettsia
- Rheumatologic/inflammatory
 - Acute rheumatic fever
 - Rheumatoid arthritis
 - Systemic lupus erythematosus
 - Systemic sclerosis
 - Sarcoidosis
 - Dermatomyositis
 - Kawasaki disease
 - Familial Mediterranean fever
 - Inflammatory bowel disease
- Metabolic/endocrine
 - Hypothyroidism
 - Uremia (chemical irritation)
 - Gout
 - Scurvy
- Neoplastic disease
 - Lymphoma
 - Lymphosarcoma
 - Leukemia
 - Sarcoma
 - Metastatic disease to the pericardium
 - Radiation therapy induced
- Postoperative
 - Postpericardiotomy syndrome (after cardiac surgery)
 - Chylopericardium
- Other
 - Trauma

- Drug-induced (hydralazine, isoniazid, procainamide)
- Aortic dissection
- Postmyocardial infarction
- Idiopathic

DIAGNOSIS

HISTORY

- Dependent on etiology
- Signs and symptoms
 - Most common signs and symptoms:
 - Precordial chest pain
 - Fever
 - Cough
 - Shoulder pain aggravated by changes in position
 - Rapid accumulation of fluid may lead to the following:
 - Respiratory distress/dyspnea
 - Signs of hypotension
 - Change in mental status/loss of consciousness
 - Pain: often relieved if the child sits leaning forward
 - Slow, chronic accumulation may be associated with no symptoms at all until tamponade develops.
 - Other symptoms depend on the etiology of the pericarditis.
- Recent upper respiratory infection or gastroenteritis (viral pericarditis)
- Sepsis or other source of bacterial infection
- Symptoms of rheumatic disease
- Known thoracic neoplasm

PHYSICAL EXAM

- Pericardial friction rub is the pathognomonic finding (typically heard if only a small amount of fluid is in the pericardial space).
- Quiet precordium, tachycardia, hypotension, and muffled heart sounds may be heard when there is a large amount of fluid and/or tamponade.
- Evidence of right-sided heart failure:
 - Peripheral edema, jugular venous distention, and hepatomegaly

- Pulmonary edema: rare because the heart is underfilled, and left atrial pressure, although elevated, does not exceed right atrial pressure
- Pulsus paradoxus: an exaggerated decrease in systolic BP with inspiration
- Kussmaul sign: paradoxical rise in jugular venous pressure during inspiration, often considered diagnostic of tamponade

DIAGNOSTIC TESTS & INTERPRETATION

Lab

Electrocardiogram

- Nonspecific but generally demonstrates low-voltage QRS complexes secondary to dampening of the signal transmitted through the pericardial fluid
- One can also see diffuse ST segment elevation with or without T-wave inversion.
- These findings may be secondary to inflammation of the myocardium.
- Electrical alternans can be seen with large effusions.

Imaging

- Chest x-ray
 - Often shows enlargement of the cardiac silhouette (“water bottle sign”), usually in association with normal pulmonary vascular markings. However, heart size may appear normal in acute pericarditis.
 - Calcification may be seen in constrictive pericarditis.
- Computed tomography (CT)
 - CT can also demonstrate calcification of the pericardium with excellent sensitivity
- Echocardiogram
 - Most sensitive and specific test for pericardial thickening and fluid in the pericardial space
 - In the presence of a large effusion, the heart may appear to swing within the pericardial cavity.
 - In tamponade, diastolic collapse of the right atrium may be seen. Collapse of the left atrium and right ventricle occur in severe cases.
 - Tamponade can be diagnosed using Doppler inflow patterns of the

tricuspid and mitral valves. In tamponade, mitral inflow E-wave velocity decreases by more than 30% during inspiration, whereas the tricuspid inflow E-wave velocity increases by more than 50% during inspiration.

Diagnostic Procedures/Other

- Pericardiocentesis is performed when the etiology of the effusion is in question or tamponade has developed.
 - Fluid obtained should be sent to the lab for cell count, cytology, and culture (including bacteria, viruses, *Mycobacterium tuberculosis*, and fungi).
 - Complications include myocardial puncture, coronary artery/vein laceration, hemopericardium, and pneumothorax.
 - Echocardiogram or fluoroscopic guidance is useful for this procedure but is not required if there is impending cardiovascular collapse.
- Pericardial window
 - In cases of chronic pericardial effusion, removal of part or all of the pericardium may be performed (pericardial window).

DIFFERENTIAL DIAGNOSIS

- Acute myocarditis
 - History, physical examination, and laboratory findings of acute pericarditis can be quite similar to those found in acute myocarditis.
 - In addition, myocarditis can be associated with pericardial disease and vice versa.
 - Echocardiogram is an excellent tool to help differentiate between these two entities.
- Restrictive cardiomyopathy
- Other causes of chest pain
- Myocardial infarction

TREATMENT

GENERAL MEASURES

- Treatment should be directed toward the etiology of the disease.

However, no matter the cause, pericardiocentesis is required if there is an effusion that causes hemodynamic compromise. It may be life-saving in patients with bacterial pericarditis.

- Viral pericarditis usually resolves spontaneously in 3–4 weeks with bed rest and analgesics (NSAIDs).
- Bacterial pericarditis is potentially life threatening and requires immediate decompression of the pericardial space (often with open drainage and pericardial window creation), IV antibiotic therapy for at least 4 weeks, and supportive therapy (i.e., volume expansion, inotropes).
 - *S. aureus* is the most common organism responsible for bacterial pericarditis.
- Rheumatologic causes of pericardial inflammation usually respond to corticosteroids and/or salicylates and rarely require pericardiocentesis.
- Uremic pericarditis usually responds to dialysis, but pericardiectomy (surgical removal of the pericardium) may be necessary in chronic situations.
- Neoplastic pericarditis is addressed by treating the primary disease and performing pericardiocentesis if indicated for diagnostic and/or hemodynamic reasons.
- Hemorrhagic pericarditis with effusion accumulation secondary to trauma should be drained because of the risk of subsequent development of constrictive pericarditis.
- Constrictive pericarditis is treated with complete stripping of the pericardium (pericardiectomy). Often, immediate clinical improvement is not seen because there has been myocardial damage. However, eventual full recovery is the norm.
- Postpericardiectomy syndrome occurs 1–4 weeks after cardiac surgery.
 - Treat with anti-inflammatory drugs, bed rest, and occasionally steroids.
 - Pericardiocentesis is indicated if tamponade develops.

ONGOING CARE

- Most forms of pericarditis resolve on their own, or with anti-

inflammatory medication, over the course of several weeks.

- Follow-up is necessary to ensure that effusions have resolved and to assess for recurrence (up to 15% relapse).
- Patients with bacterial pericarditis require long-term antibiotic therapy and close follow-up to assess for the development of constrictive pericarditis.
- Signs to watch for include the following:
 - Postpericardiotomy syndrome: All cardiac surgical patients need an evaluation 2–4 weeks after surgery to assess for postpericardiotomy syndrome, with treatment and follow-up as necessary.
 - Signs of low cardiac output and right-sided heart failure indicate impending cardiac tamponade.
 - Constrictive pericarditis may present with a rapidly decreasing cardiac silhouette, calcifications on chest roentgenogram, and signs or symptoms of right-sided heart failure.

PROGNOSIS

- Most children recover fully from pericarditis, even if it is bacterial in etiology.
 - However, there is significant morbidity and mortality associated, especially in young infants, when the diagnosis is delayed and/or when *S. aureus* is the etiologic agent.
- Pericarditis can also recur in as many as 15% of patients.
- Prognosis varies with the cause of pericarditis but generally is related directly to the primary disease.

COMPLICATIONS

- Cardiac tamponade
 - Intrapericardial pressure increases at a rapid rate secondary to decreased compliance of the pericardial membranes, resulting in restriction of ventricular filling and eventual decrease in stroke volume and cardiac output.
 - The compliance of the pericardium is influenced by the disease process itself (i.e., the pericardium is thickened and stiff in bacterial and tuberculous pericarditis).
 - During cardiac tamponade, ventricular end-diastolic, atrial, and

venous pressures are all equal.

- In acute pericarditis, tamponade may occur with small amounts of fluid because of a rapid increase in the intrapericardial pressure. In contrast, large amounts of fluid may be tolerated if the accumulation is a chronic, slow process.
- Constrictive pericarditis
 - Thick, fibrotic, and often calcified pericardium is seen, usually a late result of purulent or tuberculosis pericarditis; it can occur months to years after the initial infection. It can also be seen in oncology patients with direct invasion of tumor into the pericardium or after significant radiation to the chest.
 - Poor compliance of the pericardium leads to diminished diastolic filling of the ventricle. Patients may complain of exercise intolerance and fatigue. Additionally, they may have signs of right heart failure.
 - This entity may be difficult to distinguish from restrictive cardiomyopathy.

CODES

ICD10

- I31.9 Disease of pericardium, unspecified
- I30.9 Acute pericarditis, unspecified
- I30.1 Infective pericarditis

FAQ

- Q: How does cardiac tamponade present?
- A: Patients with impending tamponade appear quite ill, with tachycardia, chest pain, and signs of right heart failure including jugular venous distention, hepatomegaly, ascites, and peripheral edema. They may also have signs of poor systemic perfusion secondary to low cardiac output. Chest x-ray may or may not show an enlarged cardiac silhouette, depending on how acutely the process occurs. It takes much less fluid to cause tamponade in an acute process than in a chronic process. Echocardiography is the standard diagnostic tool, and pericardiocentesis is the treatment.
- Q: What is pulsus paradoxus and how does one measure it?
- A: Pulsus paradoxus is an exaggerated response of the systolic BP to the normal respiratory cycle. Normally with inspiration, the systolic BP drops ~5 mm Hg secondary to the increased capacitance of the pulmonary veins from the increased systemic venous return. In tamponade, this response becomes more profound (>10 mm Hg), most likely secondary to diminished filling of the left heart. Pulsus paradoxus can also be seen in patients with severe respiratory distress associated with asthma and emphysema.
- To assess for pulsus paradoxus, measure the systolic BP first in expiration, then allow it to fall to the place where it is heard equally well in inspiration and expiration. A difference of >10 mm Hg is considered abnormal.

PERINATAL BRACHIAL PLEXUS PALSY

Jonathan A. Zelken • Richard J. Redett

BASICS

DESCRIPTION

- The brachial plexus contains sensory and motor nerves to the upper extremities, stemming from the cervical and thoracic spine (commonly C5–T1 roots).
- The brachial plexus contains a consistent pattern of nerves that innervate predictable muscles and skin regions.
- Brachial birth palsy is a proximal stretch, avulsion, or rupture type injury and may involve
 - C5–C6 (Erb palsy), most common, best prognosis
 - C5–C7, less common, worse prognosis
 - C5–T1, least common, flail extremity and worst prognosis

EPIDEMIOLOGY

- There is no predominance of gender, but variations in clinical care, preventive measures, and birth weight may explain estimates of incidence to range from 0.4 to 4 per 1,000 live births.
- Incidence drops from 0.2% with vaginal delivery to 0.02% after cesarean section as there is a probable mechanical basis for the plexopathy.
- Erb palsy is the most commonly encountered plexus injury.

RISK FACTORS

- Large size for gestational age, multiparity, prolonged labor, breech position, difficult delivery—especially when forceps- or vacuum-assisted
- Diabetic mothers and/or neonatal birth weight >4.5 kg
- Although there is no genetic basis per se, previous delivery leading to obstetric palsy is a risk factor.

GENERAL PREVENTION

- Careful positioning of the upper extremity during childbirth and conversion to cesarean section when necessary
- Prevention of long-term disability and contracture can be minimized with exercise of the child's joints and functioning muscles every day beginning at 3 weeks of age.

PATHOPHYSIOLOGY

- Seddon and Sunderland have described classification systems to describe degree of injury.
 - Neuropraxia
 - Mildest form, interruption of conduction, axons continuous
 - Good recovery
 - Axonotmesis
 - Axonal degeneration with loss of axonal continuity
 - Nerve intact. Epineurium and perineurium intact.
 - Neurotmesis
 - Most severe, nerve is completely contused. Axonal discontinuity
 - Nerve may be grossly intact, but epineurium, perineurium, and axons disrupted. Recovery difficult to predict.

ETIOLOGY

- Downward mechanical force on the shoulder during difficult delivery can lead to stepwise stretch injury leading to transient or permanent damage or total avulsion of nerve roots.
- Upward mechanical force, that is, after face delivery, leads to C8–T1 injury (Klumpke).
- Avulsion injury carries the worst prognosis, particularly if proximal to the cell body of the motor nerve (preganglionic), as these injuries cannot spontaneously recover.

ASSOCIATED INJURIES

Horner syndrome, phrenic nerve injury, and long thoracic nerve injury (winged scapula) may be observed and are associated with preganglionic injury and a poor prognosis.

DIAGNOSIS

HISTORY

- In neonates: obstetric history including birth weight, use of assistive devices, multiparity, perinatal difficulties, previous difficult deliveries, etc.
- Despite a prominent association between shoulder dystocia and neonatal brachial plexus palsy injury, some of these injuries occur without any shoulder dystocia.
- In older children: Consider recent infectious processes (viruses), tetanus shots, trauma, and tumor.

PHYSICAL EXAM

- Serial examination is key for predicting recovery.
- Active and passive ROM testing, bulk, deep tendon reflexes (DTRs), autonomic function, and evaluation for phrenic nerve injury and paravertebral muscle weakness are important adjunctive exams.
- Sensory testing may be more challenging because of age and overlap of dermatomes.
- Because of invariability of brachial plexus anatomy, injury patterns yield predictable disabilities.
- Erb palsy
 - Associated with downward force on the head and neck during delivery, leading to upper plexus injuries
 - Shoulder limp, adducted, internally rotated
 - Elbow extended, forearm pronated, wrist and fingers flexed (“waiter’s tip posture”)
 - Hand grip and intrinsic function generally preserved. Shoulder and elbow flexion is weak.
 - DTRs: biceps and brachioradialis absent, Moro asymmetric
- Klumpke palsy
 - Risk of injury to the lower brachial plexus results from traction on an abducted arm, as with an infant being pulled from the birth canal by an extended arm above the head.
 - Shoulder intact, elbow flexed, forearm supinated, wrists and fingers extended
 - Hand grip is weak, while shoulder and elbow function may be normal. Horner syndrome can be present.

- DTRs: triceps absent; Horner sign suggests ipsilateral T1 injury.
- Complete plexus injury (“flail”):
 - Entire extremity and shoulder girdle is flaccid, anesthetic, and areflexic.

DIAGNOSTIC TESTS & INTERPRETATION

- Plain radiographs may demonstrate clavicle injury and shoulder and elbow subluxation and dislocation.
- MRI neurography is generally favored over CT myelography and electromyography (EMG) and is less invasive.
- Previous cases using EMG data to determine whether an injury occurred in utero has been investigated; interpretation of all these modalities may lead to false positives and negatives.
- Somatosensory and motor evoked potentials are less useful as they generally corroborate physical exam findings.

FOLLOW-UP

- Following the diagnosis of brachial plexus palsy, neonates should be followed closely to determine if the injury will resolve spontaneously or will require further treatment.
- Patients should be followed by an experienced multidisciplinary brachial plexus team of therapists, pediatricians, and pediatric surgery subspecialists.

DIFFERENTIAL DIAGNOSIS

- Important to rule out clavicular, shoulder, elbow, and humeral injury as primary cause of limb paresis or weakness
- Central lesions resulting from tumors and strokes, as well as spinal cord lesions, should be considered.
- Congenital contractures and limb deformities can resemble brachial plexus injuries.
- Central paralysis is generally spastic and peripheral (i.e., brachial plexus or lower motor neuron) is flaccid.
- Horner syndrome may be associated with proximal injury.
- Parsonage-Turner syndrome may cause plexus inflammation and symptoms without obvious injury.

TREATMENT

REHABILITATION

- Therapy is paramount in managing symptoms of plexopathy.
- Goals include comfort, optimizing recovery, and assessing improvement.
- Stretching exercises, splints to prevent contracture, joint taping to stabilize shoulder, and sensory awareness activities are commonly used.

GENERAL MEASURES

- Palsies must be observed during the first weeks to months of life.
 - Immobilization of a flaccid limb encouraged very early for pain control
 - After 3 weeks of immobilization and fractures/dislocation have been ruled-out, ROM exercises should commence to prevent deformity and contracture.
- Majority of neonates with obstetric brachial plexus injury will resolve spontaneously.
- Classic Erb palsy has the best prognosis.
- The majority of upper brachial plexus birth injuries are transient.
- Global palsies have a poor prognosis with nonoperative treatment.
- Failure to recover antigravity biceps function by 3–6 months of age is a poor prognostic sign.
- Infants with C5–6 or C5–7 injuries may continue to demonstrate spontaneous improvement up to 9 months of age, thus precluding the need for early surgery.

PROGNOSIS

~75–85% of all patients regain very good to full strength and function, with 1/2 doing so rapidly (the mild group) and 1/2 more slowly (the moderate group).

SURGERY/OTHER PROCEDURES

- Indications for early surgical intervention
 - Pan-plexus (“flail”) lesions (generally warrant early intervention as

- soon as 3 months if no improvement)
- All brachial plexus injuries should be evaluated by a multidisciplinary team at 3, 6, and 9 months of age. Failure to improve at each examination is usually an indication for surgery. There are several different grading systems, which can be used to assess an infant's healing progress.
 - Nonsurgical measures
 - Neuromuscular electrical stimulation can be used as part of an infant's comprehensive therapy to help improve blood flow, preserve muscle bulk and minimize atrophy.
 - Botulinum toxin A therapy to impair preserved muscle groups allow weaker muscle groups to strengthen.
 - Primary surgery
 - Surgical outcome is best if performed by 6–12 months and probably not useful if done after 24 months; ongoing care
 - Exploration generally confirms clinical and radiographic findings.
 - Injured nerves generally present as neuromas.
 - Neurolysis to free uninjured nerve from scar versus
 - Excision of neuroma en bloc with interpositional nerve grafting
 - Excision is favored when nerve transmission across the injured site is significantly diminished (<50%) or absent, immobilization of a flaccid limb encouraged very early for pain control
 - Autologous sural nerve is an excellent donor, and it is reversed when interposed to maximize signaling to the CNS
 - When there is insufficient nerve graft, neurotization—attachment of functional motor nerves to distal recipient nerves—is a useful adjunct.
 - Common donor nerves include the spinal accessory, contralateral C7 nerve root, and intercostal nerves.
 - Use of nerve conduits and adjunctive neurotrophic factors is under investigation.

ONGOING CARE

SECONDARY SURGERY

Tendon transfers (generally wait 2–4 years to assess long-term nerve

recovery) improve flexibility and functional mobility of affected joints.

- Shoulder: transfer of preserved internal rotators to impaired abductors and external rotators
- Elbow: triceps to biceps repair, pectoralis to biceps repair, latissimus to biceps repair
- Forearm: Biceps rerouting and pronator lengthening can relieve pronation and supination contractures.
- Scapula: contralateral rhomboid, trapezius, and latissimus transfer to anchor and support a winged scapula
- Osteotomies (late presentation)
 - External rotational osteotomy of humerus to improve upper extremity function with fixed, internally rotated shoulder
 - Radius rotational osteotomy to address pronation and supination deformities
- Soft tissue (late presentation)
 - Capsulotomies and joint manipulation under anesthesia can facilitate movement in a contracted joint.
 - Local flaps and tissue transfer can augment a contracted flexor or extensor zone.

CODES

ICD10

P14.3 Other brachial plexus birth injuries

FAQ

- Q: My baby was diagnosed with a brachial plexus injury. What are the odds she will recover completely?
- A: Most (roughly 80%) children recover completely. The nerves were stretched and are inflamed, but this should resolve. Babies with more significant injuries causing axonotmesis and neurotmesis may not recover completely or at all.
- Q: My last baby suffered a brachial plexus injury at birth, but since got better. What are the odds my next child will have the same problem?
- A: Your next child has a 14-fold increase in risk for brachial plexus injury compared to the general population.
- Q: My baby is 3 months old and cannot move his left arm? Whom should I call?
- A: A center for brachial plexus injury is ideal. A well-organized team includes physical and occupational therapists, neurologists, and surgeons (neurosurgeon, plastic surgeon, orthopedic surgeon, or combination thereof).
- Q: Could my obstetrician have prevented this?
- A: Likely, not. Although there may be increased risk for shoulder dystocia in some women, it is not a diagnosable problem. Preemptive cesarean section in at-risk women may be unnecessarily risky to mother and fetus.

PERIODIC BREATHING

Richard M. Kravitz

BASICS

DESCRIPTION

- A respiratory pattern consisting of regular oscillations in breathing amplitude
- Typically, a respiratory pattern in which ≥ 3 apneas lasting ≥ 3 seconds occur, separated by < 20 seconds of respiration

ALERT

Don't confuse periodic breathing with obstructive and/or central apnea.

EPIDEMIOLOGY

- Usually absent in the 1st 48 hours of life
- More frequent during rapid eye movement (REM or active) sleep versus non-REM (quiet) sleep
- Less common in prone versus supine position
- In full-term infants
 - Amount of periodic breathing usually $< 4\%$ of total sleep time
 - Amount gradually decreases through the 1st year of life.
 - By 1 year of age, the mean amount of periodic breathing is $< 1\%$ of total sleep time.
- In premature infants
 - Amount of periodic breathing is higher than in full-term infants.
 - Amount correlates inversely with gestational age.

PATHOPHYSIOLOGY

- No common pathologic finding
- Abnormalities, when they exist, are related to the underlying disorder causing the periodic breathing.

ETIOLOGY

- Periodic breathing can be seen in healthy infants, children, and adults.
- Abnormalities, in any component of the breathing control system, may

result in an increased amount of periodic breathing.

- Possible etiologies
 - A delay in detecting changes in blood gas values by the chemoreceptors
 - Increased chemoreceptor gain

COMMONLY ASSOCIATED CONDITIONS

- Periodic breathing in infants is associated with the following:
 - Apnea of prematurity or infancy
 - Familial history of sudden infant death syndrome (SIDS)
 - Anemia of prematurity
 - Hypoxemia
 - Hypochloremic alkalosis
- Periodic breathing with adults is associated with the following:
 - Cardiac abnormalities (especially congestive heart failure [CHF])
 - Neurologic dysfunction (meningitis, encephalitis, brainstem dysfunction)
 - Exposure to high altitudes

DIAGNOSIS

HISTORY

- In most cases, parents notice periodicity in the child's respiratory pattern.
- An apparent life-threatening episode (ALTE) might precipitate an evaluation in which periodic breathing is documented.
- In otherwise healthy premature or term infants, there are no other symptoms.

PHYSICAL EXAM

In otherwise healthy premature or term infants, the physical exam is normal.

DIAGNOSTIC TESTS & INTERPRETATION

Imaging

Chest x-ray: usually normal findings

Diagnostic Procedures/Other

- Polysomnography
 - Assesses the extent of periodic breathing episodes
 - Determines if there is accompanying hypoxemia, hypercarbia, or bradycardia with the events
 - Distinguishes between periodic breathing and obstructive and/or central apnea
 - Useful for following response to treatment (i.e., normalization of polysomnography)
- pH probe done in combination with the polysomnogram (if gastroesophageal reflux is suspected): Record for a minimum of 6 hours.
- 2-channel pneumogram
 - Gives less information than polysomnography
 - Can document periodic breathing, but it may miss episodes of obstructive apnea
 - Monitors heart rate and respiratory effort (If oxygen saturation monitoring is desired, an additional channel is required).

DIFFERENTIAL DIAGNOSIS

- Other forms of apnea:
 - Central apnea
 - Mixed apnea
 - Obstructive apnea (or hypopnea)
- Other forms of periodic breathing:
 - Cheyne-Stokes respirations
 - Biot breathing
 - Kussmaul respirations
- Normal irregular respiration seen in infants

TREATMENT

MEDICATION

- Stimulants
 - Caffeine IV or PO (based on caffeine base; multiply dosage by 2 for

caffeine citrate salt)

- Loading dose: 10 mg/kg
- Maintenance dose: 2.5 mg/kg/24 h
- Therapeutic level: 5–20 mg/L
- Theophylline PO (if using aminophylline IV, divided dosage by 0.79)
 - Loading dose: 4–5 mg/kg
 - Maintenance dose: 3–5 mg/kg/24 h divided t.i.d.
 - Therapeutic level: 6–10 mg/L

ADDITIONAL TREATMENT

General Measures

- Therapy should be directed at treating the underlying primary disease:
 - If periodic breathing is associated with apnea, hypoxemia, and/or other sleep disturbances, appropriate treatment of the underlying etiology should be instituted.
 - In cases secondary to CHF, appropriate cardiac interventions need to be instituted.
 - In cases associated with high altitude, treatment options include the following:
 - Acclimation (if tolerated)
 - Descent to lower altitude, then gradual ascent
 - Medication (acetazolamide most commonly used)
- Duration of therapy
 - Depends on the underlying cause of the periodic breathing
 - Treatment does not change the natural course of periodic breathing in otherwise healthy infants.
 - Therapy should continue until the periodic breathing resolves or is no longer clinically significant.

ADDITIONAL THERAPIES

- Supplemental oxygen: useful if periodic breathing is secondary to hypoxemia
- Nasal continuous positive airway pressure (CPAP): very effective in eliminating periodic breathing
- Home monitoring should be considered (although not absolutely

indicated) in the following cases:

- Significant amount of periodic breathing
- Accompanying apnea
- Associated hypoxia and/or bradycardia
- History of a significant ALTE
- Parental anxiety

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Time to improvement depends on the underlying cause of the periodic breathing.
- Improvement is anticipated as the infant ages.
- When treatment is started, a decrease in the amount of periodic breathing should be seen almost immediately.

PROGNOSIS

- Excellent in otherwise healthy premature or term infants
- Governed by primary process in patients with an underlying cardiac or neurologic disorder

COMPLICATIONS

Relationship between periodic breathing and SIDS is controversial.

R06.3 Periodic breathing

FAQ

- Q: What is the risk of the patient dying of SIDS?
- A: The relationship between periodic breathing and SIDS is not clear, although most studies have not found a higher frequency of SIDS among patients with periodic breathing.

PERIORBITAL CELLULITIS

Aaron E. Kornblith • Christine S. Cho

BASICS

DESCRIPTION

- Periorbital or preseptal cellulitis is an acute infection characterized by pain, erythema, and edema to the anterior eyelid and surrounding tissue.
- The infection lies superficial to orbital septum, a thin fascial layer forming the anterior boundary of the orbital compartment.
- In contrast, orbital cellulitis is an infection involving the deeper structures of the orbit and requires emergent intervention.

EPIDEMIOLOGY

- Often occurs in young children, commonly <5 years of age, but can occur at any age
- Periorbital cellulitis is at least three times more common than orbital cellulitis.

RISK FACTORS

Predisposing factors that may lead to infection include skin trauma and lacrimal/eyelid injury.

PATHOPHYSIOLOGY

Often, extension from an external source including trauma (insect bite, recent surgery, foreign body) or adjacent infection (sinusitis, dacryocystitis, hordeola, dental abscess)

ETIOLOGY

- Variable depending on mechanism
 - Most common pathogens are *Staphylococcus aureus* (increasingly methicillin-resistant) and *Streptococci* species.
 - Anaerobic infections can extend from dental source.
 - *Haemophilus influenza* type B was historically the most common pathogen; consider in unimmunized child younger than 5 years of

age.

COMMONLY ASSOCIATED CONDITIONS

Rarely associated with bacteremia; however, consider this condition in children younger than 3 years of age or in immunocompromised patients.

DIAGNOSIS

HISTORY

- Onset, time course of symptom progression, and any predisposing factors
- A history of trauma is suggestive of periorbital cellulitis.
- The presence of pain supports cellulitis, whereas complaints of pruritus are more suggestive of an allergic etiology.
- Diplopia and visual changes are more suggestive of orbital cellulitis.
- Quantify systemic symptoms such as fever and lethargy.
 - These indicate a more severe, disseminated infection.

PHYSICAL EXAM

- Superficial orbital tissues and lids will be edematous, erythematous, warm to the touch, and typically tender on palpation.
 - Often unilateral, the findings can start in one eyelid, but both the upper and lower eyelids are usually involved.
 - May be signs of previous trauma, cutaneous injury, etc.
- Occasionally, the eyelids are so swollen that it is difficult to examine the globe. To do so, place anesthetic eyedrops on the eye and use ocular speculum or fashion a paperclip into a lid retractor to lift the eyelid.
- The globe should be carefully examined.
 - In periorbital cellulitis, the ocular exam is often normal. The sclera is usually white, although patients can have some conjunctival erythema but rarely chemosis.
 - Any change in vision, pupillary function, or limitations in eye motility suggests orbital involvement.
- The presence of proptosis and/or pain with eye movement suggests deep orbital involvement.

- Neurologic findings, such as cranial nerve deficit, are suggestive of deep space involvement.
- Evaluate for signs of fever, respiratory infection, and sepsis.

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Lab tests are usually not helpful or indicated.
- CBC is warranted only if bacteremia is suspected.
 - Leukocytosis has no value in differentiating periorbital and orbital cellulitis.
- Skin cultures and blood cultures have a low yield.
 - Blood cultures are obtained only when the child is febrile or appears septic.
 - Wound cultures can be obtained if there is an abscess.

Imaging

- Periorbital cellulitis is a clinical diagnosis and radiologic confirmation is only indicated if the diagnosis is unclear. Imaging may be required in the following circumstances:
 - If orbital cellulitis is suspected
 - Cases that do not respond to medical treatment
 - Neurologic symptoms are present.
- Serial CT scanning should be done only if the child is not improving with treatment.

DIFFERENTIAL DIAGNOSIS

- Infectious
 - Early orbital cellulitis, dacryocystitis, stye, severe viral conjunctivitis
 - Orbital cellulitis is an ophthalmologic emergency and requires prompt therapy.
- Allergic
 - Periocular allergic reaction: insect bite, angioedema, contact dermatitis
- Other
 - Periocular trauma
 - Rhabdomyosarcoma

- Idiopathic orbital inflammatory syndrome (IOIS)
- Cavernous venous thrombosis
- Hypoproteinemia

TREATMENT

GENERAL MEASURES

- Simple periorbital cellulitis should be empirically treated based on local prevalence of *Staphylococcus* and *Streptococcus* species.
 - Consider MRSA
 - Examples include second-generation cephalosporins or β -lactamase-resistant penicillins.
- There is no evidence to suggest that intravenous are better than oral antibiotics; however, younger children need close observation and/or follow-up.
- For children <1 year of age, strongly consider hospitalization for IV therapy and very close observation.
- Children between the ages of 1 and 5 years should either be hospitalized or arranged for close follow-up after initiating antibiotics.
- Children >5 years of age can usually be treated with an oral regimen as long as they do not appear toxic or have orbital involvement.
- Any patient with symptoms suggestive of deep space involvement or hematogenous involvement should be hospitalized.

MEDICATION

- In nontoxic children, oral antibiotics: amoxicillin/clavulanate, cefalexin, clindamycin (if MRSA is a concern), etc. are started on an outpatient basis; the child should be seen again within 24–48 hours.
- Consider admission for IV antibiotics (clindamycin, ampicillin/sulbactam, etc.) for those patients younger than 1 year of age, ill appearing, have bacteremia, or symptoms suggestive of orbital involvement.

SURGERY/OTHER PROCEDURES

Surgical intervention is usually required when an abscess or a foreign body is present.

ONGOING CARE

- Patients should have close follow-up 24–48 hours after initiating outpatient treatment.
- Patients who do not improve after close follow-up should be admitted for IV antibiotics and imaging.
- Patients should be seen daily until a definite improvement is noted.

PROGNOSIS

Excellent, with minimal incidence of long-term sequelae, unless a complication is encountered

COMPLICATIONS

- Orbital extension (2.5–17%)
- Skin abscess (8%)
- Eyelid necrosis (1–2%)
- Sepsis
- Intracranial extension (2–3%)

Patient Monitoring

- Watch patients closely for signs of orbital extension, bacteremia, or other forms of disseminated infection.
- Neonates and infants can become septic very quickly, so they need to be closely monitored.

CODES

ICD10

- H05.019 Cellulitis of unspecified orbit
- H00.039 Abscess of eyelid unspecified eye, unspecified eyelid

PERIRECTAL ABSCESS

Naamah Zitomersky

BASICS

DESCRIPTION

- Abscess in the perirectal area
- May be associated with fistula-in-ano
- Classification of the abscess is based on the location in relation to the levator and sphincteric muscles of the pelvic floor.
- Classification by decreasing frequency: perianal, ischioanal, intersphincteric, and supralelevator

EPIDEMIOLOGY

- May occur at any age
 - More common in males 2:1
 - In children, more common in those less than 2 years

PATHOPHYSIOLOGY AND ETIOLOGY

- Most often originates from an occluded anal gland with subsequent bacterial overgrowth and abscess formation
- Infection from within the anal glands, penetrates through the internal sphincter, and ends in the intersphincteric space
- Chronic infection and inflammation may result in the formation of fistula-in-ano. This occurs in up to 50% as a result of persistent anal sepsis or an epithelialized tract.

COMMONLY ASSOCIATED CONDITIONS

- Nonspecific anal gland infection
- Crohn disease
- Immune deficiency (e.g., neutropenia, diabetes mellitus, AIDS)
- Perforation by a foreign body
- External trauma
- Tuberculosis
- Chronic granulomatous disease (CGD)

- Tumor (e.g., carcinoma, rhabdomyosarcoma)

DIAGNOSIS

SIGNS AND SYMPTOMS

- General
 - Constant anal or perianal pain that often precedes local findings
 - Localized swelling, erythema, and fluctuance
 - Painful defecation or ambulation
 - Constitutional symptoms (e.g., fever or malaise)
- Perianal abscess
 - Result of distal vertical spread of the infection to the anal margin
 - Presents as tender, fluctuant mass
 - Most common type of perianal abscess
- Ischiorectal abscess
 - Secondary to horizontal spread of infection across the external anal sphincter into the ischiorectal fossa
 - Infection may track across the internal anal sphincter into the anal canal.
 - Presents as diffuse, tender, indurated, fluctuant area
 - Patients may have pain and fever prior to visible swelling.
- Intersphincteric abscess
 - Limited to the intersphincteric space between the internal and external sphincters; therefore, often does not cause perianal skin changes
 - Associated with painful defecation
 - Accounts for only 2–5% of all anorectal abscesses
- Supralevator abscess
 - May arise from two different sources
 - Proximal vertical spread from the gland through the intersphincteric space to the supralevator space
 - Pelvic inflammation or infection (e.g., Crohn disease)
 - Presents with pelvic or anorectal pain, fever, and, at times, urinary retention
 - Rectal exam usually reveals an indurated swelling above the

anorectal ring.

- Imaging may be necessary to establish the diagnosis.
- Horseshoe abscess
 - Secondary to abscessed anal gland located in the posterior midline of the anal canal
 - Due to presence of anococcygeal ligament, the infection is forced laterally into the ischiorectal fossae and is therefore known as “horseshoe.”
 - May be unilateral or bilateral
 - Presents with pain

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- CBC
- Abscess culture

Imaging

- Magnetic resonance imaging (MRI)
 - Preferred modality, as it provides excellent spatial and contrast resolution
 - Enables comprehensive evaluation of the entire peritoneum and lower pelvis
- Computed tomography (CT) scan
 - Has limited soft tissue contrast resolution which makes distinguishing perineal musculature and fistula tracts difficult, although organized fluid collections larger than 1 cm are generally seen
 - This modality also uses ionizing radiation, which is less desirable in the pediatric population.
- Ultrasound (US)
 - Endoscopic and transperineal US have been used, but do not always show the full extent of inflammation.
 - Deeper structures may not be visualized, owing to the lack of sound wave penetration.
 - Endoscopic US may be used to diagnose, characterize, and monitor rectal abscesses.

DIFFERENTIAL DIAGNOSIS

- Pilonidal infection
- Bartholin abscess
- Presacral epidermal inclusion cyst
- Hidradenitis suppurativa
- Rectal duplication cyst

TREATMENT

GENERAL MEASURES

- Lack of fluctuation should not delay treatment.
- Abscess should be drained with placement of a seton or drainage catheter.
- Abscess should be cultured at time of drainage to direct therapy in the case antibiotics are needed.
- Antibiotics are reserved for situations in which infection does not appropriately respond to drainage or with adjacent cellulitis, an immunocompromised patient, a patient with abnormal cardiac valves, enteric organism on culture, or in Crohn disease.
- Sitz baths may be helpful with drainage.

SURGERY/OTHER PROCEDURES

- Drainage may be performed either with conservative incision and drainage or with judicious probing for fistulae.
- It is a matter of debate as to whether a fistulotomy or fistulectomy should be performed at the time of drainage for an accompanying fistula.

ONGOING CARE

- If abscess recurs, consider other associated conditions (e.g., neutropenia, HIV, diabetes mellitus, Crohn disease, rectal duplication cyst).
- Exploration for fistula-in-ano is recommended to prevent recurrence.

PROGNOSIS

- Prognosis is good if there is early detection and drainage of abscesses.
- Patients typically recover well after surgical drainage without the need for antibiotics.

COMPLICATIONS

- Sepsis
- Fistula formation

SPECIAL CONSIDERATIONS

- Crohn disease should be considered in patients with perirectal abscess with or without fistula-in-ano.
- Signs and symptoms that increase suspicion for Crohn disease include weight loss or poor growth, chronic diarrhea, or abdominal pain.

CODES

ICD10

- K61.1 Rectal abscess
- K60.3 Anal fistula
- K61.3 Ischiorectal abscess

FAQ

- Q: What are complications of this problem?
- A: Fistula formation is seen in up to 50% of patients, with a predilection for males.
- Q: What are the most common organisms of the abscess?
- A: Staphylococcus species
- Q: What other disease may perirectal abscess be associated with?
- A: Crohn disease. If there has been exposure, tuberculosis should also be excluded.
- Q: What treatments can be done other than surgery?
- A: Sitz baths and warm compresses may be able to help with smaller more superficial abscess.

PERITONITIS

Sarah S. Lusman

BASICS

DESCRIPTION

- Inflammation of the peritoneal cavity in reaction to infection or chemical irritation by organic fluids (e.g., intestinal contents, bile, blood, or urine)
- Infectious peritonitis can be classified as follows:
 - Primary or spontaneous bacterial peritonitis (SBP), which occurs without an obvious source or a break in the continuity of the intestinal lumen. Pathogens enter the peritoneum via translocation from the intestine; from the circulation; from vaginal, oropharyngeal, or skin flora; or from foreign bodies inserted into the peritoneal cavity.
 - Secondary peritonitis occurs with visceral disruption from bowel perforation, abscess formation, ischemic necrosis, or penetrating abdominal injury.
 - Tertiary peritonitis is recurrent peritonitis after presumed adequate treatment for secondary peritonitis.
- SBP almost always occurs in patients with cirrhosis and ascites.

RISK FACTORS

- End-stage liver disease
- Serum albumin <1.5 g/dL
- Low serum levels of complement factors C3 and C4
- Nephrotic syndrome (inability to clear organisms, most common is *Streptococcus pneumoniae*)
- Splenectomy (encapsulated organisms: group A streptococci, *Escherichia coli*, *S. pneumoniae*, *Bacteroides* sp.)
- Peritoneal dialysis
- Presence of gastrointestinal hemorrhage
- Prematurity

GENERAL PREVENTION

- Children with chronic liver disease should receive all recommended childhood vaccinations.
- Children with functional asplenia due to portal hypertension should receive the meningococcal and pneumococcal conjugate vaccines as early as possible.
- Oral antibiotic prophylaxis reduces occurrence of SBP and improves short-term survival in adults with cirrhosis.

PATHOPHYSIOLOGY

- When bacteria or chemicals reach the peritoneal cavity, a local peritoneal and systemic host defense response is initiated:
 - Mechanical clearance of bacteria via lymphatics: Entrance of bacteria and bacterial products into the bloodstream contributes to the systemic response.
 - Phagocytosis and destruction of bacteria
 - Sequestration and walling off of bacteria with delayed clearance by phagocytic cells
 - Initial response is characterized by hyperemia, exudate of fluid into peritoneal cavity, and influx of macrophages followed by neutrophils.
 - Mesothelial cells secrete cytokines after stimulation (interleukins [IL-6, IL-8], tumor necrosis factor- α [TNF- α]). IL-6 stimulates T- and B-cell differentiation, and IL-8 is a selective chemoattractant for neutrophils.
 - Cytokines promote local resolution and compartmentalization through fibrin deposition.
- In SBP, pathogenic bacteria are cultured from peritoneal fluid without any apparent intra-abdominal surgical treatable source of infection. Recognized as a complication in patients with ascites as a result of cirrhosis of any etiology
 - Generalized bacteremia and translocation of organisms from the gut (*E. coli*, *Klebsiella* sp.) into the portal veins or lymphatics or, less likely, directly into the ascitic fluid may account for the source of the infection.
 - Clearance of bacteria from the bloodstream may be impaired in

patients with cirrhosis and ascites.

- Poor clearance is due to diminished phagocytic activity of the hepatic reticuloendothelial system secondary to cellular functional defects or shunting of blood away from the liver.
- Complement, necessary for the opsonization of bacteria and ultimately clearance by phagocytes, is decreased in the ascitic fluid.
- Infectious organisms include aerobic gram-negative organisms (*E. coli* and *Klebsiella* species) and aerobic gram-positive organisms (*Streptococcus* and *Enterococcus* species).
- In secondary bacterial peritonitis, the underlying bacterial infection tends to be a complex polymicrobial infection with an average of 3 or 4 different isolates.
 - The most common isolates are combinations of *E. coli* and *Bacteroides fragilis*.
 - The most common gram-positive organisms are nonenterococcal streptococci and enterococci.

ETIOLOGY

- Primary peritonitis: liver cirrhosis or other conditions associated with ascites, such as the following:
 - Budd-Chiari syndrome
 - Congestive heart failure
 - Nephrotic syndrome
 - Systemic lupus erythematosus and other vasculitides
 - Rheumatoid arthritis
- The etiology of secondary peritonitis varies with age.
 - Neonates and infants
 - Meconium peritonitis (begins prenatally)
 - Necrotizing enterocolitis
 - Idiopathic gastrointestinal perforation
 - Perforation due to Hirschsprung disease
 - Spontaneous biliary perforation
 - Omphalitis (common in developing countries due to poor umbilical cord care)
 - Perforation of a urachal cyst
 - Children and adolescents

- Secondary to appendicitis
- Perforation of Meckel diverticulum
- Gastric ulcer perforation
- Pancreatitis
- Cholecystitis
- Traumatic or spontaneous perforation of the intestine
- Intussusception and other bowel obstruction leading to necrosis
- Neutropenic colitis (typhlitis)
- Crohn disease with fistula and abscess formation
- Toxic megacolon
- Tuberculosis
- Salpingitis and pelvic inflammatory disease
- Toxins

DIAGNOSIS

HISTORY

- Dependent on stage, age, and etiology
- Abdominal pain is the most common symptom.
 - Young children may be unable to verbalize pain.
- Fever, chills, vomiting, diarrhea
- ~10% of SBP cases are entirely asymptomatic; presentation may be subtle.
- Infants may present with poor feeding and lethargy.
- Other less common findings include the following:
 - Hypothermia
 - Hypotension
 - Increasing ascites despite diuretics
 - Worsening encephalopathy
 - Unexplained decrease in renal function

PHYSICAL EXAM

- Abdominal distension
- Rebound tenderness
- Decreased bowel sounds

- Evidence of chronic liver disease
- Evidence of ascites

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- Blood
 - Leukocytosis, elevated CRP
 - There may be leukopenia and thrombocytopenia in sepsis.
- Urinalysis to exclude renal diseases which may mimic peritonitis

Imaging

- Abdominal x-ray may show evidence of ileus, obstruction, or perforation.
- Abdominal ultrasound or CT shows ascites, thickening of bowel wall, and abscesses.

Diagnostic Procedures/Other

- Paracentesis is diagnostic and should be performed in all cases of new-onset ascites and when SBP is suspected.
- To improve culture yield, inoculate blood culture bottles with 10 mL of fluid immediately at the bedside. A separate tube is sent for Gram stain.
- Elevated neutrophil count of $\geq 250/\text{mm}^3$ in ascitic fluid is the most important laboratory indicator of SBP.
- Fluid chemistries: albumin, total protein, glucose, LDH, amylase, bilirubin
- Serum-ascites albumin gradient = serum albumin minus fluid albumin. Difference > 1.1 indicates portal hypertension.
- Diagnostic criteria for secondary peritonitis: positive ascitic fluid culture, neutrophil count of $\geq 250/\text{mm}^3$, and surgically treatable source of infection

TREATMENT

MEDICATION

- Empiric antibiotic coverage should be initiated immediately and

directed primarily toward enteric gram-negative aerobes and gram-positive cocci:

- After the organism is identified, the antibiotic coverage may be optimized.
- First line: Cefotaxime is drug of choice for SBP in pediatrics.
- Consider adding metronidazole for secondary SBP.
- Antibiotic resistance is increasing.
 - Quinolones may be used in areas where resistance is low.
 - Second line: carbapenems for severe nosocomially acquired cases

ADDITIONAL TREATMENT

General Measures

- Fluid resuscitation with isotonic saline, 20 mL/kg boluses up to 60 mL/kg, or albumin if large amounts of fluid are required to restore intravascular volume
- Decompression with nasogastric tube
- Patients at significant risk for SBP will benefit from selective intestinal decontamination with fluoroquinolones, trimethoprim-sulfamethoxazole, or rifaximin as an effective preventive measure.

SURGERY/OTHER PROCEDURES

In secondary peritonitis, surgery is the primary management tool:

- Control of the underlying source of infection by closing, diverting, or resecting the affected bowel
- Intraoperative peritoneal lavage and debridement of loculations and abscesses decrease bacterial inoculum and help prevent recurrent sepsis.
- Older studies in adults show benefit of antibiotic peritoneal lavage; controversial, as it may impair the local response and promote adhesions
- Catheters may be placed to drain a well-defined abscess cavity, form a controlled fistula, or provide access for continuous postoperative peritoneal lavage.

ONGOING CARE

PROGNOSIS

- SBP in adults has in-hospital mortality of 10–50%.
 - SBP markedly worsens the prognosis in patients with cirrhosis.
- Recurrence is common: 60% of patients who survive the 1st episode develop 1 or more recurrences.
- Severe secondary peritonitis in adults has a mortality rate of 30–55%.

COMPLICATIONS

- Hypovolemia from reduced fluid intake, vomiting, and third-space fluid extravasation
- Sepsis and multiorgan failure
- Intra-abdominal abscess
- Long-term: adhesions

CODES

ICD10

- K65.9 Peritonitis, unspecified
- K65.2 Spontaneous bacterial peritonitis
- P78.1 Other neonatal peritonitis

FAQ

- Q: Is peritonitis common in children with ascites?
- A: Despite the frequency of ascites from many different causes, peritonitis occurs rarely. In the setting of children with chronic liver disease and ascites, SBP may occur.
- Q: What are the most useful laboratory aids for this diagnosis?
- A: Paracentesis and analysis of the fluid neutrophil count provides the most useful information regarding the diagnosis of peritonitis. Fluid culture is not required for diagnosis but helps to guide therapy.

PERITONSILLAR ABSCESS

Nicholas Tsarouhas

BASICS

DESCRIPTION

Infectious complication of tonsillitis or pharyngitis resulting in an accumulation of purulence in the tonsillar fossa. Also referred to as “quinsy.”

EPIDEMIOLOGY

- Most common deep space infection of head and neck
- Seen most commonly in adolescents but occasionally in younger children

RISK FACTORS

- Tonsillitis
- Pharyngitis

GENERAL PREVENTION

Abscess formation can often be prevented if appropriate antimicrobial therapy is initiated while the infection is still at the cellulitis stage.

PATHOPHYSIOLOGY

- Infectious tonsillopharyngitis progresses from cellulitis to abscess.
- The infection starts in the intratonsillar fossa, which is situated between the upper pole and the body of the tonsil and eventually extends around the tonsil.
- The abscess is a suppuration outside the tonsillar capsule, in proximity to the upper pole of the tonsil, involving the soft palate.
- Purulence usually collects within one tonsillar fossa, but it may be bilateral.
- The pterygoid musculature may become irritated by pus and inflammation, which leads to the clinical finding of trismus.
- Tonsillar and peritonsillar edema may lead to compromise of the upper airway.

ETIOLOGY

- Most of these true abscesses are polymicrobial.
- Group A β -hemolytic streptococci (GABHS)
- α -Hemolytic streptococci
- Staphylococcus aureus: Prevalence of methicillin-resistant S. aureus continues to increase.
- Anaerobic bacteria play an important role:
 - Prevotella
 - Porphyromonas
 - Fusobacterium
 - Peptostreptococcus
- Possible synergy between anaerobes and GABHS
- Gram negatives such as Haemophilus influenzae and, more rarely, Pseudomonas species may be isolated.

COMMONLY ASSOCIATED CONDITIONS

- Tonsillitis or pharyngitis usually precedes its development.
- Peritonsillar cellulitis is often associated with infectious mononucleosis.

DIAGNOSIS

HISTORY

- Fever and sore throat
 - Most common initial complaints
- Trouble swallowing, pain with opening the mouth (trismus), muffled (“hot potato”) voice
 - Classic presenting symptoms
- Unilateral neck or ear pain
 - Other common presenting symptoms

PHYSICAL EXAM

- Unilateral peritonsillar fullness or bulging of the posterior, superior, soft palate
 - Diagnostic finding
- Uvular deviation

- Classic finding, although it may be absent in the more rare bilateral peritonsillar abscess
- Palpable fluctuance of palatal swelling
 - Calls for urgent aspiration
- Erythematous, edematous pharynx, with enlarged and exudative tonsils
 - Coexisting tonsillopharyngitis is common.
- Cervical adenopathy
 - Common
- Drooling
 - Often present
- Torticollis
 - Sometimes seen

DIAGNOSTIC TESTS & INTERPRETATION

Lab

- WBC count
 - Not a mandatory part of the workup
 - Usually elevated with prominent left shift
- Rapid streptococcal throat antigen studies
 - Helpful to diagnose GABHS infection
- Gram stain and culture of aspirate specimen
 - Confirms causative microorganism
- Monospot/EBV antibody titers
 - Not a mandatory part of the workup
 - Infectious mononucleosis is both in the differential diagnosis and may coexist in some cases of peritonsillar abscess.

Imaging

- Radiographic studies are rarely necessary, as this is clinical diagnosis.
- Intraoral ultrasound or CT (with contrast):
 - Sometimes useful if clinical distinction of peritonsillar cellulitis from peritonsillar abscess is difficult
 - CT scan is most useful if patient cannot open mouth secondary to trismus.
 - CT scan is also important if deep neck extension is suspected.
- MRI

- MRI may be more precise than CT in detecting multiple space involvement and, of course, is devoid of radiation exposure.
- Pediatric use is limited by need for longer acquisition time and greater need for patient cooperation.
- In younger children, the need for sedation for MRI introduces additional logistical challenges and potential airway risks.

DIFFERENTIAL DIAGNOSIS

- Peritonsillar cellulitis
 - Most common diagnostic consideration
 - Also referred to as “phlegmon”
 - Can be distinguished by the lack of classic peritonsillar abscess findings: peritonsillar space fullness, uvular deviation, and trismus
- Retropharyngeal abscess
 - Minimal to no peritonsillar findings
 - Widened prevertebral space on lateral neck radiograph
 - This airway-compromising disease usually occurs in preschool children, not adolescents.
- Epiglottitis
 - This life-threatening airway emergency presents abruptly with fever, stridor, increased work of breathing, and drooling.
 - Usually occurs in toxic-appearing children 3–7 years old
 - Rare entity in children since the advent of the *Haemophilus influenzae* type b vaccine
- Other infectious causes of severe tonsillopharyngitis:
 - EBV (infectious mononucleosis), coxsackievirus (herpangina), *Corynebacterium diphtheriae*, and *Neisseria gonorrhoeae*

TREATMENT

MEDICATION

First Line

- Clindamycin or ampicillin/sulbactam are the most commonly used 1st-line antibiotics, owing to their efficacy versus GABHS, *Staphylococcus*, and anaerobes.

- As methicillin-resistant *S. aureus* isolates continue to increase, clindamycin is becoming more popular as drug of choice.
- Some initiate therapy with high-dose IV penicillin—in the presence of a positive strep antigen or throat culture study.

Second Line

- Nafcillin, oxacillin, and cefazolin are acceptable antibiotic alternatives.
- Steroids
 - Some experts recommend steroids to decrease swelling, pain, and trismus.
 - Most evidence from adult rather than pediatric studies
 - Methylprednisolone, dexamethasone, and prednisone all have been used.

ADDITIONAL TREATMENT

General Measures

Treating an abscess without surgical drainage is inadequate and can have airway-threatening implications.

- Abscesses should be urgently/emergently drained via either needle aspiration or surgical incision and drainage.
- Antibiotic therapy as above
- Steroid therapy recommended by some.
- Appropriate analgesia and adequate hydration should be ensured in all cases.

ISSUES FOR REFERRAL

Peritonsillar abscess: Otorhinolaryngology consultation is imperative both for acute and chronic management.

SURGERY/OTHER PROCEDURES

- As mentioned earlier, either needle aspiration or surgical incision and drainage is mandatory in the acute setting for true abscesses.
- Most surgeons currently prefer interval tonsillectomy after the acute infection has been managed with antibiotics and an acute drainage procedure (needle aspiration or I&D).
- Surgical drainage with tonsillectomy is considered in children not responding to parenteral antibiotics within 24–48 hours.

- Acute or “hot” tonsillectomy (also “quinsy tonsillectomy”) is advocated by some.

ONGOING CARE

FOLLOW-UP RECOMMENDATIONS

- Patients may be discharged on oral antibiotics to complete a 10–14-day course when afebrile and peritonsillar swelling has subsided.
- Tonsillectomy should be considered after severe or recurrent peritonsillar abscesses.

PROGNOSIS

- Complete recovery with appropriate therapy.
- Recurrence of the abscess may occur.

COMPLICATIONS

- Upper airway obstruction is the most feared complication.
- Dehydration from decreased oral intake is the most common complication, however.
- Abscesses left untreated can rupture spontaneously into the pharynx, leading to aspiration and pneumonia.
- Other serious complications include parapharyngeal abscess, jugular vein suppurative thrombophlebitis (Lemierre syndrome), cavernous sinus thrombosis, sepsis, brain abscess, meningitis, and dissection into the internal carotid artery.
- Even after appropriate drainage, a small number (10–15%) of peritonsillar abscesses may reform.

J36 Peritonsillar abscess

FAQ

- Q: Are radiographs necessary to make the diagnosis of peritonsillar abscess?
- A: No. The physical examination is diagnostic. A lateral neck radiograph, ultrasound, CT, or MRI are indicated only if the diagnosis is in question or to delineate extent of disease or additional complications.
- Q: Is surgical consultation necessary in cases of peritonsillar abscess?
- A: Yes. Otorhinolaryngology consultation is indicated for both acute as well as chronic management.

PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN

Jessica Howlett • Jenny Yu

BASICS

DESCRIPTION

Clinical syndrome of severe respiratory failure and hypoxia in a neonate characterized by high systemic pulmonary arterial pressures, tricuspid regurgitation, and intracardiac shunting from right to left when pulmonary vascular resistance fails to decrease after birth

EPIDEMIOLOGY

- Incidence of ~2–6 per 1,000 term live newborns, decreasing incidence with the decreased number of deliveries >41 weeks gestation
- Mostly occurs in full-term newborns, owing to the presence of the muscular layer of arterioles, the risk of uteroplacental insufficiency, and the potential for the passage of meconium in utero, but it can complicate the course of an older premature baby with chronic lung disease.
- Meconium aspiration is the number one cause of persistent pulmonary hypertension of the newborn (PPHN).
- PPHN complicates the course of about 10% of newborns with respiratory failure.

RISK FACTORS

Genetics

- Sporadic in occurrence
- Alveolar capillary dysplasia has been documented to be a rare cause of PPHN. The genetic cause is unknown, but it appears to be familial.
- Surfactant B deficiency has also been implicated, but it is a rare, lethal, autosomal recessive disorder.

PATHOPHYSIOLOGY

- At a neonate's first breath after delivery, the pulmonary vascular

resistance normally decreases to redirect ~50% of the cardiac output to the pulmonary circulation. This phenomenon fails to occur in PPHN, hence the previous name of this condition, “persistent fetal circulation.”

- Increased pulmonary vascular resistance increases right ventricular afterload, causing a backflow of blood to the right heart. This leads to increased right heart pressures (and subsequent tricuspid regurgitation), which can lead to right ventricular failure.
